ACKNOWLEDGEMENTS

This report is the result of an effort involving virtually every discipline and department in the Lead Laboratory organization. Its scope is reflected in the approximately 10,000 citations of over 800 separate sources of data and information.

In addition to the indispensable contributions made by the dozens of authors who developed the material presented in this report, significant contributions were made by the many checkers, reviewers, and Quality Compliance Specialists who checked and reviewed the document during its development. Significant contributions were also made by individual members of several other Lead Laboratory departments, among them the Technical Data Management System, the Document Input Reference System, Document Production, Records, and Information Technology.

ACRONYMS AND ABBREVIATIONS

The following is a list of acronyms and abbreviations commonly used in this report. Types of acronyms and abbreviations not listed below would include: (1) acronyms and abbreviations that are defined and used on a limited or a case-by-case basis, (2) widely known acronyms and abbreviations (e.g., "N/A"), or (3) acronyms that appear only in source titles or descriptions, or in organization-specific designations.

Because most users of this document will likely consult individual sections of it according to specific interests or purposes, rather than reading it sequentially, acronyms are not defined in the text upon first use. Instead, they are defined on a case-by-case basis when deemed appropriate or useful. It is therefore recommended that users of this report consult the following list, in conjunction with individual report sections, when seeking the definition of a particular acronym.

Å	angstrom
AICC	adiabatic, constant volume (isochoric) complete combustion (model)
AMR	analysis/model report
ASM	American Society for Metals
ASME	American Society of Mechanical Engineers
ASTM	American Society for Testing and Materials
atm	atmosphere
ATR	advanced test reactor
BDCF	biosphere dose conversion factor
BWR	boiling water reactor
CDF	cumulative distribution function
CDSP	codisposal (waste package)
cm	centimeter
CR	condition report
CSNF	commercial spent nuclear fuel
DHLW	defense high-level waste
DIRS	Document Input Reference System
DLL	dynamic link library
DOE	U.S. Department of Energy
DSNF	DOE spent nuclear fuel
DTN	data tracking number
EBS	Engineered Barrier System
ECRB	Enhanced Characterization of the Repository Block
EDZ	excavation disturbed zone
EPA	U.S. Environmental Protection Agency
ESF	Exploratory Studies Facility
eV	electronvolt

ACRONYMS AND ABBREVIATIONS (Continued)

yr	year

1. PURPOSE

The purpose of this analysis report is to document the screening decisions and technical bases for inclusion or exclusion of each FEP identified as relevant to the TSPA and the Yucca Mountain disposal system, in accordance with the regulatory screening criteria identified for the Yucca Mountain Site. The companion report, *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476]) documents: (1) the origin, and the methods used in the development of a comprehensive list of FEPs that could potentially affect the postclosure performance of the Yucca Mountain disposal system; (2) the methodology and guidance used to screen FEPs for inclusion or exclusion from TSPA; (3) the methodology and guidance used to create scenario classes; and (4) compliance with NUREG-1804 (NRC 2003 [DIRS 163274]) acceptance criteria. The screening decision results presented in this report are reflected in the current performance assessments (or TSPA) described in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]).

Performance assessment is required to demonstrate compliance with the postclosure performance objective for the DOE YMP as stated in proposed 10 CFR 63.2 (70 FR 53313 [DIRS 178394]) and in 10 CFR 63.2 [DIRS 180319]. A performance assessment is an analysis that:

1. Identifies the features, events, processes (except human intrusion), and sequences of events and processes (except human intrusion) that might affect the Yucca Mountain disposal system and their probabilities of occurring;

2. Examines the effects of those features, events, processes, and sequences of events and processes upon the performance of the Yucca Mountain disposal system; and

3. Estimates the dose incurred by the reasonably maximally exposed individual, including the associated uncertainties, as a result of releases caused by all significant features, events, processes, and sequences of events and processes, weighted by their probability of occurrence.

In addition, the performance assessment is required to "provide the technical basis for either inclusion or exclusion of specific features, events, and processes in the performance assessment" as stated in 10 CFR 63.114 [DIRS 180319]. This report describes the required technical basis for the FEPs excluded from the TSPA model, a summary of how the included FEPs are implemented in the TSPA model, and develops an electronic database that is useful to catalog and display the FEP information.

The conclusions drawn from this report include screening decisions and technical bases for each of the FEPs on the TSPA-LA FEP list, and text describing compliance of these activities with the applicable NUREG-1804 (NRC 2003 [DIRS 163274]) acceptance criteria outlined in Section 4.2.

1.1 PLANNING AND DOCUMENTATION

Documentation requirements for this analysis report are described in *Technical Work Plan for the Performance Assessment Features, Events, and Processes* (SNL 2007 [DIRS 184327]).

There is one deviation from the TWP; the title of the report has been changed from that specified in the TWP (SNL 2007 [DIRS 184327], Section 1.1) for consistency with the associated methods report (SNL 2008 [DIRS 179476]).

1.2 SCOPE

This report describes the screening decisions and technical bases for each of the 374 TSPA-LA FEPs identified in *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476], Table 7-1). These screening analyses consider new proposed regulations, new repository design considerations, and new technical information that have been developed since the completion of the previous FEP analysis and screening report, *Development of the Total System Performance Assessment—License Application Features, Events, and Processes* (BSC 2005 [DIRS 173800]). The updated FEP screening analyses in this report supersede the following FEP screening analysis documents:

- *Evaluation of Features, Events, and Processes (FEP) for the Biosphere Model* (BSC 2005 [DIRS 174107])
- *Clad Degradation – FEPs Screening Arguments* (BSC 2004 [DIRS 170019])
- *Features, Events, and Processes: Disruptive Events* (BSC 2005 [DIRS 173981])
- *Engineered Barrier System Features, Events, and Processes* (BSC 2005 [DIRS 175014])
- *Features, Events, and Processes: System Level* (BSC 2004 [DIRS 170021])
- *Features, Events, and Processes in SZ Flow and Transport* (BSC 2005 [DIRS 174190])
- *Features, Events, and Processes in UZ Flow and Transport* (BSC 2005 [DIRS 174191])
- *Waste Form Features, Events, and Processes* (BSC 2004 [DIRS 170020])
- *Screening of Features, Events, and Processes in Drip Shield and Waste Package Degradation* (BSC 2005 [DIRS 174995]).

This report does not supersede *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), but does consolidate information presented in that criticality FEP analysis.

FEP screening is an important process for YMP FEP analysis and scenario development (SNL 2008 [DIRS 179476], Section 1.2). The FEP screening analysis addresses acceptance criterion 2, as outlined in NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.2.1.2.1.3). The methods and approach for FEP screening are outlined in Section 6.1. The screening decisions

and technical bases for each of the 374 FEPs are presented in Section 6.2. The key information provided in Section 6.2 for each FEP is the screening decision (included or excluded) and the associated technical basis. For excluded FEPs, the technical basis is a "screening justification," which documents the rationale for exclusion from the TSPA model. For included FEPs, the technical basis is a "TSPA disposition," which documents how the FEP is implemented in the TSPA model. Section 7 summarizes the screening decisions and describes how the FEP screening addresses the applicable acceptance criterion outlined in NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.2.1.2.1.3).

Additional output from this report includes an update to the FEP electronic database as product output (DTN: MO0706SPAFEPLA.001) that is useful to catalog and display the FEP information. It is acknowledged that the FEP justifications and implementations provided in Section 6.2 may differ from those contained within the output DTN, but only at an editorial level.

The CRs associated with this report are listed below. The actions associated with each CR addressed by this report are summarized below each CR title:

- CR 5600, *Direct Inputs for FEPs AMRs*
  - Appropriate direct inputs are cited, qualified, or justified as necessary, with at least one direct input supporting each FEP excluded from TSPA.
- CR 7452, *Inadequate Justification for Use of Superseded Information in Engineered System AMR*
  - The canceled report identified is no longer used to support excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF) or excluded FEP 2.1.11.03.0A (Exothermic Reactions in the EBS).
- CR 7523, *TSPA Evaluation of Low-Consequence and Low-Probability FEPs*
  - Screening issues were considered and further FEP examination has culminated in this analysis report.
- CR 8408, *Exchanged Information Was Out of Date When Provided for Use*
  - The table indicated by this CR is outdated and no longer used.
- CR 8655, *FEP 2.1.11.09.0C in EBS FEPs Report Needs Discussion of Chemical Aspects*
  - The indicated FEP has been revised to briefly discuss the in-drift chemical effects of convection and references the excluded dust deliquescence FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence).
- CR 9518, *Direct Input Not Included on Information Exchange Drawing*
  - Procedural requirement for design information from the information exchange drawing has since changed, current input usages are compliant.

- CR 10388, *Improper Direct Input Citations to ANL-DSD-MD-000001 for Ti Gr 24 Corrosion Rate*
  - Titanium Grade 24 is not in the current design, so no direct input usages refer to it.
- CR 10755, *EBS FEPs AMR, Section 6.2.64 Contains Citation Error*
  - Usages of "heat treatment" and "annealing" in drip shield FEPs have been clarified.
- CR 10899, *Thermal Alteration of the PTn Unit is Not Explicitly Addressed in FEP Analysis*
  - FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ) justification is expanded to discuss the potential for thermal alteration of the properties within the PTn hydrogeologic unit.
- CR 11323, *Unexpected Literature Results re: Titanium Localized Corrosion*
  - FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields) has been expanded to discuss the information identified by this CR.
- CR 11357, *Pallet Chemical Degradation FEP Status Change*
  - FEP 2.1.06.05.0C (Chemical Degradation of Emplacement Pallet) is now screened as *included*.
- CR 11633, *DTN Submittal Review of FEP Database is Incomplete*
  - The product output DTN of this report is updated and resubmitted with appropriate reviews completed and submitted to records.
- CR 11745, *Exclusion of Hydrothermal Activity FEPs*
  - FEP 1.2.06.00.0A (Hydrothermal Activity) identifies a recently published assessment of DOE's screening approach regarding this process.

Limitations on the use of this report are as follows:

- The screening of TSPA-LA FEPs potentially relevant to the postclosure performance of the Yucca Mountain repository is based on site-specific information, design, and regulations. Therefore, the FEP screening is specific to the regulations, repository design, and processes for the YMP available at this time.

2. QUALITY ASSURANCE

Development of this report and the supporting analyses are subject to the Office of Civilian Radioactive Waste Management quality assurance program as identified in *Technical Work Plan for the Performance Assessment Features, Events, and Processes* (SNL 2007 [DIRS 184327], Section 8.1).

Approved quality assurance procedures were used to conduct and document the activities described in this report as directed by the TWP (SNL 2007 [DIRS 184327], Section 4). Documentation was prepared in accordance with SCI-PRO-005, *Scientific Analyses and Calculations*, and related procedures and guidance documents as outlined in the TWP (SNL 2007 [DIRS 184327], Sections 2 and 4). The TWP (SNL 2007 [DIRS 184327], Section 8.4) also identifies applicable controls for compliance with IM-PRO-002, *Control of the Electronic Management of Information*, during the analysis and documentation activities.

INTENTIONALLY LEFT BLANK

3. USE OF SOFTWARE

Except as noted below, this analysis report does not directly use any qualified software. The analyses and justifications are generally based on results of analyses presented and documented in other analysis reports, and other technical literature. Software and models used in the supporting documentation may be indirectly cited for traceability and transparency purposes in Section 6.2 and in the appendices. Unqualified but controlled software, exempt from software qualification, are used and briefly described here. Only in a single instance is baseline qualified software used, and it is fully described at the end of this section.

The FEPs Viewer (STN: 611664-1.0-00 [DIRS 181089]) is a Visual BASIC for Applications program written within Microsoft Access that was used to produce portions of Sections 6.2, 7, and 8 of this report from the FEP database. This software was used strictly to generate portions of the printed document for visual display and accomplished no calculations or other mathematical processes. This analysis report is subject to check and approval (per SCI-PRO-005, *Scientific Analyses and Calculations*), and therefore in accordance with IM-PRO-003, *Software Management* (Section 2.0), the FEP Viewer software is exempt from qualification requirements.

The software EarthVision V7.5.2 (STN: 607871-7.5.2-00 [DIRS 184835]) is utilized in Appendix D. This software use was only for producing graphical representations of geologic unit depths and thicknesses (Figures D-2 to D-4). As this analysis report is subject to check and approval, it is therefore exempt from qualification requirements in accordance with IM-PRO-003 (Section 2.0).

MathCad Version 13.1 (STN: 611161-13.1-00), running under the Microsoft Windows 2000 Professional operating system, has been used to perform the calculation documented in Appendix E. The standard features of MathCad are sufficient for these calculations. No macros, codes, or software routines are required for or developed during this work. As used here, MathCad Version 13.1 is not required to be qualified or documented in accordance with IM-PRO-003. The formulas, inputs to the formulas, and outputs from the formulas in the MathCad calculation are identified in Appendix E and in the MathCad file itself.

The qualified software EQ3/6 Version 8.1 (STN: 10813-8.1-00 [DIRS 176889]) was used on a Windows 2000 computer to predict the concentration of calcium in Section J21.2. This software is used within its specified limitations of temperature, pressure, and composition range, as determined by the input thermodynamic database.

Much of this report was developed using the common commercial off-the shelf software suite of Microsoft Office. Microsoft Word 2000, Microsoft Word 2003, and Microsoft Word 2007 were used for word processing. Microsoft Excel 2000 and 2003 are used for data organization and simple calculations. Access 2003 is used for creation and manipulation of the FEPs database. All are exempt from qualification in accordance with IM-PRO-003 (Section 2.0).

INTENTIONALLY LEFT BLANK

4. INPUTS

Direct inputs are discussed in Section 4.1. Criteria relevant to FEP screening are described in Section 4.2. Applicable codes, standards, and regulations are identified in Section 4.3.

4.1 DIRECT INPUTS

The bulk of this report consists of Section 6.2, which contains the compilation of 374 FEP screening analyses. Each FEP in Section 6.2 and each appendix have their own table of direct inputs and indirect inputs. Direct inputs are appropriately selected and qualified for use in this report. Direct input from project and external data sources are qualified for their intended use in this report and are provided in Appendix J.

The direct inputs applicable to this report are listed in Table 4-1. The use of the TSPA-LA FEPs list as direct input is appropriate because it identifies the list of FEPS to be used for the screening process performed in this report.

Table 4-1. Direct Inputs

Input	Source	Description
NRC 2003 [DIRS 163274]	Section 2.2.1.2.1.3	Acceptance criteria
SNL 2008. *Features, Events, and Processes for the Total System Performance Assessment: Methods.* [DIRS 179476]	Table 7-1; Section 6.2	List of 374 TSPA-LA FEPs; methodology and criteria for screening FEPs for exclusion from or inclusion in the TSPA model

4.2 CRITERIA

The areas of review, review methods, and acceptance criteria relevant to FEP analysis and scenario development are described in NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.2.1.2.1). These criteria stem from applicable regulations in 10 CFR Part 63 [DIRS 180319] and proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394]). Relevant to this FEP screening analysis report is NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.2.1.2.1.3, Acceptance Criterion 2). Descriptions of other relevant criteria specific to the FEP screening analyses are presented in *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476], Section 4.2.2).

Other NUREG-1804 criteria, related to the process models that represent the FEPs, are addressed within the specific process model reports and are not presented here.

4.3 CODES, STANDARDS, AND REGULATIONS

The following applicable regulatory requirements are most relevant to this report:

- 10 CFR Part 63 [DIRS 180319]
- Proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394])
- NUREG-1804 (NRC 2003 [DIRS 163274])

5. ASSUMPTIONS

There are no assumptions that have broad applicability to FEP screening analyses in this report. Since the FEP documentation in Section 6.2 is presented as a collection of individual FEP analyses, their relevant assumptions are documented in the FEP discussions to which they apply.

Section D1.1 contains the assumption "Zone of Fracturing is Cylindrical with Depth, Rather than Parabolic." Section E.5 contains assumptions from several supporting documents relevant to the calculations in Appendix E.

INTENTIONALLY LEFT BLANK

6. SCIENTIFIC ANALYSIS DISCUSSION

The primary focus of this report is to document the screening analyses for each of the identified 374 TSPA-LA FEPs, and to indicate the screening decision for each of them as being included in or excluded from the TSPA model (SNL 2008 [DIRS 183478]). The methods and approach for FEP screening are outlined in Section 6.1, with the complete FEP process described in detail in the methods report (SNL 2008 [DIRS 179476]). The screening decisions (whether a FEP is included or excluded) and technical bases for each of the 374 FEPs are presented in Section 6.2. For excluded FEPs, the technical basis for that decision is a "screening justification," which documents the rationale for exclusion from the TSPA model. For included FEPs, the technical basis is a "TSPA disposition" which documents how the FEP is implemented within the TSPA model. Section 7 summarizes the results with a listing of the 374 TSPA-LA FEPs and their screening decisions (Table 7-1), and describes how the relevant design criteria are addressed.

6.1 METHODS AND APPROACH

The identification and classification of a comprehensive list of FEPs potentially relevant to repository postclosure performance, based on site-specific information, design, and regulations, is described in *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476], Section 6.1). The methodology and criteria for screening these FEPs for exclusion from or inclusion in the TSPA model were also outlined in that report (SNL 2008 [DIRS 179476], Section 6.2).

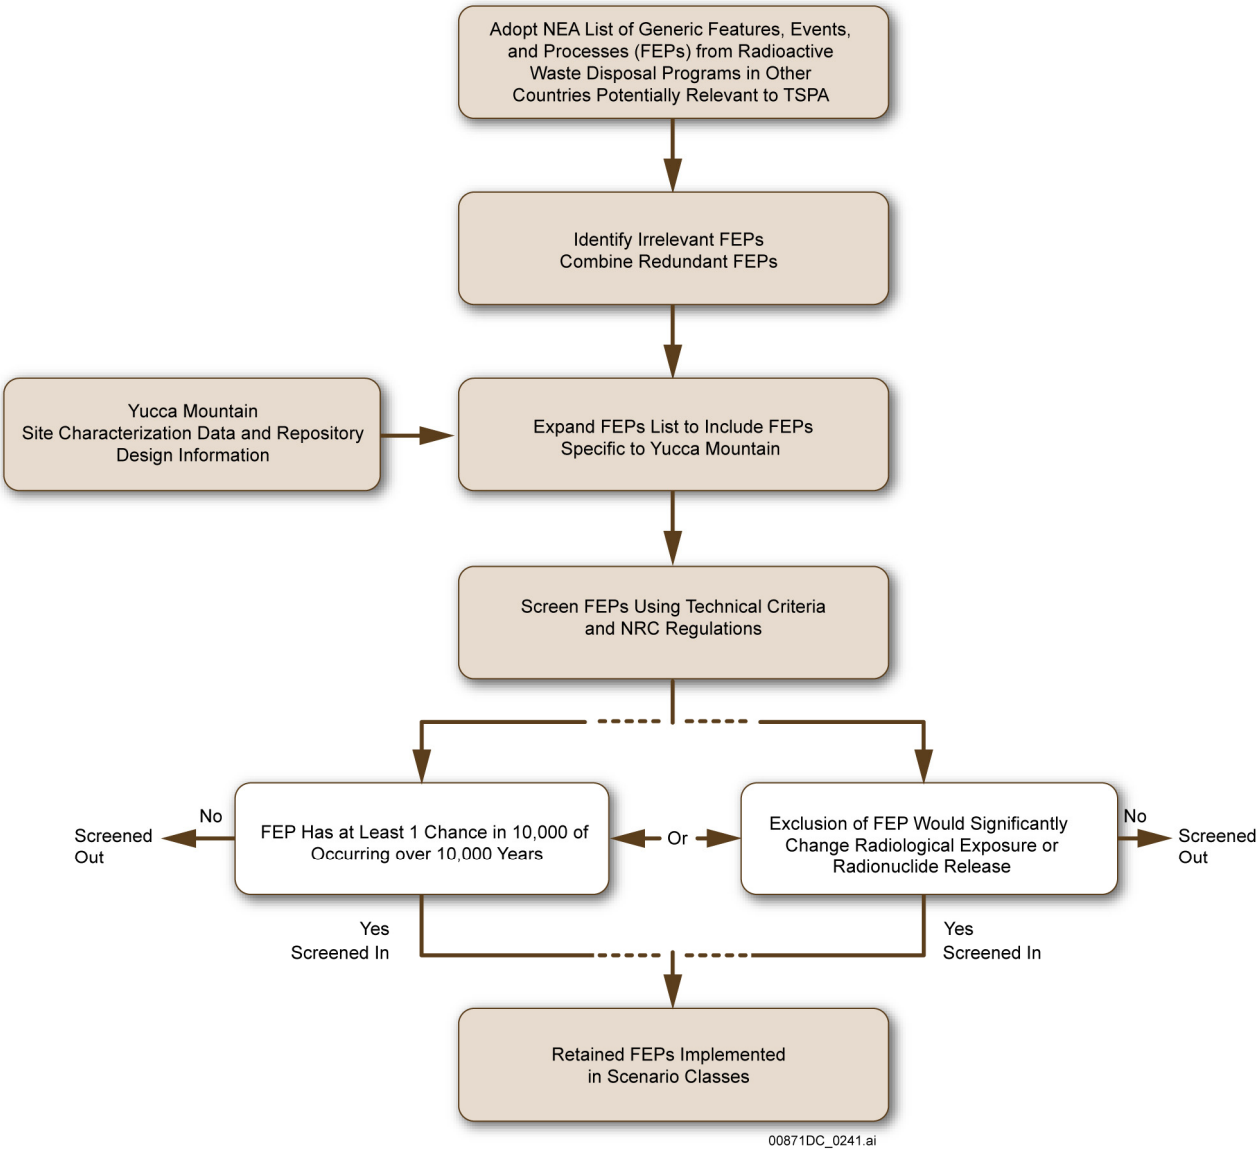
In accordance with the methodology outlined in *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476], Section 6.2), each of the TSPA-LA FEPs is screened to determine whether it should be included or excluded from the TSPA. Criteria for exclusion are by reason of low probability, low consequence, or by regulation. These screening criteria are described elsewhere in detail along with their underlying regulatory basis (SNL 2008 [DIRS 179476], Sections 4.2.2 and 6.2), but can be summarized as follows:

- Low Probability – FEPs having less than one chance in 10,000 of occurring within 10,000 years of disposal.

- Low Consequence – FEPs whose omission would not result in significantly adverse changes in the magnitude or time of the radiological exposures to the reasonably maximally exposed individual (RMEI), or radionuclide releases to the accessible environment.

- By Regulation – FEPs that are inconsistent with the characteristics, concepts, and definitions specified in 10 CFR Part 63 [DIRS 180319] or in proposed changes to that rule (70 FR 53313 [DIRS 178394]).

A FEP need only to satisfy one of these exclusion criteria to be excluded from the TSPA model. A FEP that does not meet any of the exclusion criteria must be included (screened in) in the TSPA model. The steps of this process are illustrated in Figure 6-1.



Source: SNL 2008 [DIRS 183478], Figure 6.1.1-2.

Figure 6-1. Schematic Illustration of the Features, Events, and Processes Analysis Method

Evaluation of the FEPs against the screening criteria may be done in any order. In practice, by-regulation criteria were examined first, and then either low probability or low consequence criteria were examined. FEPs that could not be excluded based on one criterion (e.g., regulatory guidance) were also considered against the other criteria (probability and consequence). Consequently, judgment regarding the order in which to apply the criteria did not affect the final decision. Choosing the most appropriate order to apply the criteria prevented needless work, such as developing quantitative probability arguments for low-consequence events or complex consequence models for low-probability events.

Exclusion of a FEP indicates exclusion with respect to each of the three different postclosure standards: Individual Protection, Individual Protection for Human Intrusion, and Groundwater

Protection (proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and 10 CFR 63.331 [DIRS 180319], respectively). The justification for excluding a FEP may rely on more than one line of reasoning, but the primary basis for exclusion is presented as the overall basis. For example, FEP 1.5.01.01.0A (Meteorite Impact) is excluded on the basis of low probability because large, potentially consequential, impacts are shown to be very unlikely, but as discussed in detail in the screening justification, smaller impact events that may occur with an annual probability above one in 100 million are also shown to have a low consequence. An included FEP is included in the TSPA for one or more of the postclosure standards. If a FEP is included for some but not all of the standards (e.g., inadvertent human intrusion is included for Human Intrusion, excluded for the others), text in the FEP disposition statement will explicitly indicate which standards it is included for and why it is excluded from others. FEPs that are included for performance assessment for all standards are either simply described as included in the screening decision with no exclusion language in the FEP disposition or all three postclosure standards are specifically referenced.

As described in *Features, Events, and Processes for the Total System Performance Assessment: Methods* (SNL 2008 [DIRS 179476], Section 6.1.1), preliminary TSPA-LA FEP analyses were completed in 2005. Those analyses are described in *Development of the Total System Performance Assessment—License Application Features, Events, and Processes* (BSC 2005 [DIRS 173800]) and the results are contained in DTN: MO0508SEPFEPLA.002 [DIRS 175064]. Subsequent to those preliminary FEP analyses, new regulations and changes in the design of the repository and disposal packages occurred, necessitating a "reanalysis" of the FEPs.

This reanalysis involved a general reevaluation of the FEP list, integration of scope between FEPs, and a reanalysis of the FEP screening decisions and technical bases. The reanalysis included contributions from YMP subject matter experts, licensing and performance assessment team members, and external experts. The results of the current FEP screening are presented in Section 6.2 and summarized in Table 7-1.

Indirect inputs are cited to support the direct inputs and to provide background or ancillary information for the analyses. As with direct inputs, indirect inputs used in the individual FEP analyses are identified in a table for each FEP in Section 6.2. Similarly, indirect inputs used in the appendices can be found within those appendices. Indirect inputs applicable to the remainder of the report are provided in Table 6-1.

6.2 FEATURE, EVENT, AND PROCESS SCREENING ANALYSES

This section documents the individual FEP screening analyses for each of the 374 TSPA-LA FEPs. They are ordered numerically by FEP Number.

Each FEP contains the following information:

- **FEP**: The unique identification number assigned to the FEP.
- **FEP Name**: The title of the FEP.
- **FEP Description**: A detailed description of the scope of the FEP.

- **Screening Decision**: Identifies the screening decision for the FEP. Possible screening decisions are:

  - Included
  - Excluded – Low Probability
  - Excluded – Low Consequence
  - Excluded – By Regulation.

- **Screening Justification (Excluded FEPs only)**: Description of the technical basis for excluding the FEP from the TSPA.

- **TSPA Disposition (Included FEPs only)**: Description of how the FEP is included in the TSPA. If the FEP is excluded for one or more of the postclosure standards, a short justification is given for the exclusion relative to that standard.

- **Inputs**: Tables of direct and indirect inputs for the FEP.

This FEP identification and screening information, along with additional FEP source and traceability information, is cataloged in the electronic FEP database. The FEP database content is described in Appendix H. The database itself is in the YMP Technical Data Management System as technical product output (DTN: MO0706SPAFEPLA.001) and is a Microsoft Access database. The FEPs Viewer (STN: 611664-1.0-00 [DIRS 181089]) is useful, but not necessary, to utilize the database; however, it does provide a user-friendly interface for viewing data elements and their relationships.

FEP: 0.1.02.00.0A

FEP NAME:

Timescales of Concern

FEP DESCRIPTION:

This FEP addresses the timescales of concern over which the disposal system may present a significant health or environmental hazard.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The timescales of concern have been set by the NRC in proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394]). Compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) must be demonstrated for the timescale of geologic stability. The period of geologic stability is defined in proposed 10 CFR 63.302 [DIRS 178394] as "the time during which the variability of geologic characteristics and their future behavior in and around the Yucca Mountain site can be bounded, that is, they can be projected within a reasonable range of possibilities. This period is defined to end at 1 million years after disposal." Compliance with the groundwater protection standard (10 CFR 63.331 [DIRS 180319]) must be demonstrated on a timescale of 10,000 years.

Proposed 10 CFR 63.303(a) (70 FR 53313 [DIRS 178394]) states that "Compliance is based upon the arithmetic mean of the projected doses from DOE's performance assessments for the period within 10,000 years after disposal" and proposed 10 CFR 63.303(b) (70 FR 53313 [DIRS 178394]) states that "Compliance is based upon the median of the projected doses from DOE's performance assessments for the period after 10,000 years of disposal and through the period of geologic stability…." This FEP is implemented at the model level in the TSPA model by simulations run for the appropriate time period and outputs were generated at the appropriate times (10,000 and 1,000,000 years, respectively).

FEP: 0.1.03.00.0A

FEP NAME:

Spatial Domain of Concern

FEP DESCRIPTION:

This FEP addresses the spatial domain of concern over which the disposal system may present a significant health or environmental hazard.

SCREENING DECISION:

Included

TSPA DISPOSITION:

From a modeling perspective, the spatial domain of concern is a function of the scale of the analysis being performed. The extent of the spatial domain that is considered in different components of the TSPA model also depends on the phenomenon that is being considered. Individual model domains are described in the documentation of each component of the TSPA model and in individual model or analysis reports.

The spatial domain encompassed by the entire TSPA model extends vertically downwards from the land surface in the vicinity of the repository through the unsaturated zone, through the repository and into the saturated zone, and extends laterally away from the repository to the location of the RMEI.

The potential for environmental impact has been addressed in *Final Environmental Impact Statement for a Geologic Repository for the Disposal of Spent Nuclear Fuel and High-Level Radioactive Waste at Yucca Mountain, Nye County, Nevada* (DOE 2002 [DIRS 155970]) and in *TSPA Information Package for the Draft Supplemental Environmental Impact Statement* (SNL 2007 [DIRS 182846]). In the TSPA, for demonstrations of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), the spatial domain in which there is a potential for a significant health hazard is primarily defined by the location of the RMEI. As specified in 10 CFR 63.312(a) [DIRS 180319], the RMEI:

> (a) Lives in the accessible environment above the highest concentration of radionuclides in the plume of contamination,

and according to 10 CFR 63.302 [DIRS 180319]:

> *Accessible environment* means any point outside of the controlled area,

and the controlled area is defined within 10 CFR 63.302 [DIRS 180319] as:

(1) The surface area, identified by passive institutional controls, that encompasses no more than 300 square kilometers. It must not extend farther:

(i) South than 36° 40′ 13.6661″ North latitude, in the predominant direction of ground-water flow; and

(ii) Than five kilometers from the repository footprint in any other direction; and

(2) The subsurface underlying the surface area.

The compliance location for the groundwater protection standards in 10 CFR 63.331 [DIRS 180319] is the representative volume in the accessible environment, which is defined in 10 CFR 63.332(a) [DIRS 180319].

Therefore, the spatial domain over which the disposal system may present a significant health or environmental hazard extends to approximately 18 km in the direction of groundwater flow (generally to the south) and over the whole of the controlled area (DTN: MO0712DELNPCCA.001 [DIRS 184172]) The postclosure area boundary includes a representative volume of groundwater in the accessible environment as defined in 10 CFR 63.332 (a) [DIRS 180319]. In summary, the spatial domain for the TSPA model is defined by specifying the spatial boundary conditions for the various models used in the performance assessment, and includes the region over which the disposal system may present a significant health or environmental hazard. In practical application, the spatial domain of concern in the TSPA includes the whole of the controlled area and extends to the location of the RMEI approximately 18 km south of the repository, and a representative volume of groundwater in the accessible environment.

FEP: 0.1.09.00.0A

FEP NAME:

Regulatory Requirements and Exclusions

FEP DESCRIPTION:

This FEP addresses regulatory requirements and guidance specific to the Yucca Mountain repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

10 CFR Part 63 [DIRS 180319] and proposed 10 CFR 63 (70 FR 53313 [DIRS 178394]) are the NRC licensing regulations that provide the requirements for Yucca Mountain repository design, construction, operation, and preclosure and postclosure performance. These regulations adopt the three postclosure public health and environmental protection standards promulgated by the EPA in 40 CFR Part 197 [DIRS 155216] and proposed 40 CFR Part 197 [DIRS 105065], respectively. 10 CFR Part 63 [DIRS 180319] and proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394]) require performance assessments to demonstrate compliance with these postclosure radiation protection standards: individual protection standard of proposed 10 CFR Part 63.311 (70 FR 53313 [DIRS 178394]), the human intrusion individual protection standard (although optional in the regulations, the YMP has chosen to use a performance assessment to demonstrate compliance with the human intrusion individual radiation protection standard and groundwater protection standard) of proposed 10 CFR Part 63.321 (70 FR 53313 [DIRS 178394]), and groundwater protection standards of 10 CFR Part 63.331 [DIRS 180319]. The TSPA is the tool used to implement these performance assessments.

Current 10 CFR Part 63 [DIRS 180319] and proposed 10 CFR 63.114 and 63.342 (70 FR 53313 [DIRS 178394]) provide the criteria for the screening of FEPs to determine whether the FEP will be excluded from the TSPA model on the basis of either low probability, low consequence, or by regulation, or included in the TSPA. Included FEPs are used to construct the scenario classes that are evaluated by the TSPA.

NUREG-1804 (NRC 2003 [DIRS 163274]) provides guidance (acceptance criteria) to the NRC staff on how to assess the completeness and adequacy of the information in the DOE license application. The DOE has provided information in the license application to address the acceptance criteria. Therefore, although NUREG-1804 (NRC 2003 [DIRS 163274]) is not a regulatory requirement, the YMP has treated the acceptance criteria as important guidance for development of process models. There are other NUREGs relevant to and adopted by the YMP, including, but not limited to, for example, NUREG-1563, *Branch Technical Position on the Use of Expert Elicitation in the High-Level Radioactive Waste Program* (Kotra et al. 1996 [DIRS 100909]); NUREG-1297, *Peer Review for High-Level Nuclear Waste Repositories: Generic Technical Position* (Altman et al. 1988 [DIRS 103597]); and NUREG-1298,

Qualification of Existing Data for High-Level Nuclear Waste Repositories: Generic Technical Position (Altman et al. 1988 [DIRS 103750]).

The YMP has established regulatory guidance agreements (see BSC 2007 [DIRS 184446] and BSC 2007 [DIRS 184422]).

Management Plan for Development of the Yucca Mountain License Application (LA Management Plan) (ORD 2007 [DIRS 184800]) serves as the implementing document and governs License Application project activities necessary to achieve compliance with regulatory requirements. For example, the results of the performance assessments implemented with the TSPA will be described in the license application pursuant to *Management Plan for Development of the Yucca Mountain License Application* (ORD 2007 [DIRS 184800]).

The OCRWM Lead Laboratory for Repository Systems (Lead Lab) is responsible for postclosure science and performance assessment, including the TSPA. The Lead Lab receives its requirements from a variety of sources, including federal agency orders applicable to Sandia National Laboratories via its Prime Contract; also, via Programmatic Guidance letters from the OCRWM Contracting Officer's Representative. PI-PRO-005, *Requirements Management,* documents the requirements management process for the Lead Lab. Ongoing compliance with requirements is validated through a program of internal and external audits, surveillance, self-assessments, management assessments and/or peer reviews, as appropriate.

The current and proposed 10 CFR Part 63 ([DIRS 180319] and 70 FR 53313 [DIRS 178394]), respectively), as well as NUREG-1804 (NRC 2003 [DIRS 163274]), require a robust quality assurance program. The Lead Lab implements YMP *Quality Assurance Requirements Description* (QARD) (DOE 2007 [DIRS 182051]) and *Augmented Quality Assurance Program (AQAP)* (DOE 2006 [DIRS 177173]) through its procedures (e.g., SCI-PRO-001 *Qualification of Unqualified Data*; SCI-PRO-002, *Planning for Science Activities*; SCI-PRO-003, *Document Review*; SCI-PRO-004, *Managing Technical Product Inputs*; SCI-PRO-005, *Scientific Analyses and Calculations*; and SCI-PRO-006, *Models*).

The technical basis for the license application is based upon reports that have been produced in compliance with these and other requisite quality assurance procedures. These reports discuss the technical basis of specific areas of postclosure science, notably process models. Process models describe the expected future behavior of the repository. Parameters used in the process models reflect relevant FEPs that have been included in the process models and in the TSPA. The process models are abstracted, and the abstractions used, along with other submodels, in the TSPA model to demonstrate compliance with the radiation and groundwater protection standards of current and proposed 10 CFR Part 63 ([DIRS 180319] and 70 FR 53313 [DIRS 178394], respectively).

In conclusion, the TSPA addresses and complies with all applicable postclosure regulatory requirements and guidance.

FEP NAME:

Model and Data Issues

FEP DESCRIPTION:

This FEP addresses issues related to modeling of the disposal system. Model and data issues are general (i.e., methodological) issues affecting the modeling process and data usage. Model issues include the approach and assumptions associated with the selection of conceptual models, the mathematical implementation of conceptual models, model geometry and dimensionality, models of coupled processes, and boundary and initial conditions. Data issues include the derivation of data values, correlations, and dependence of parameter selection on model scale.

Included

TSPA DISPOSITION:

The representation of models and data in the TSPA will be detailed in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]). This document will describe the method, structure, validation or confidence building, and application of a computational model of the performance of the repository system, the TSPA model. The TSPA model draws together data from numerous sources in order to evaluate the ability of the repository to adequately isolate nuclear waste in accordance with NRC regulations set out in proposed 10 CFR 63.114(a)(1)(2) and (3) (70 FR 53313 [DIRS 178394]). These state that any performance assessment used to demonstrate compliance with 10 CFR 63.113 [DIRS 180319] must:

(1) Include data related to the geology, hydrology, and geochemistry (including disruptive processes and events) of the Yucca Mountain site, and the surrounding region to the extent necessary, and information on the design of the engineered barrier system used to define, for 10,000 years after disposal, parameters and conceptual models used in the assessment.

(2) Account for uncertainties and variabilities in parameter values, for 10,000 years after disposal, and provide for the technical basis for parameter ranges, probability distributions, or bounding values used in the performance assessment.

(3) Consider alternative conceptual models of features and processes, for 10,000 years after disposal, that are consistent with available data and current scientific understanding and evaluate the effects that alternative conceptual models have on the performance of the geologic repository.

In addition, proposed 10 CFR 63.114(a)(7) (70 FR 53313 [DIRS 178394]) states that the performance assessment must:

> (7) Provide the technical basis for models used to represent the 10,000 years after disposal in the performance assessment, such as comparisons made with outputs of detailed process-level models and/or empirical observations (e.g., laboratory testing, field investigations, and natural analogs).

The TSPA model will evaluate the performance of engineered and natural components of the Yucca Mountain repository system for the expected natural conditions prevailing at the Yucca Mountain site. The expected natural conditions (referred to as the nominal scenario class) were derived by considering FEPs potentially relevant to the long-term performance of a waste-disposal repository.

METHODOLOGY

The general performance assessment process adopted by the DOE follows the methodology developed by Cranwell et al. (1990 [DIRS 101234], Sections 2 and 3). Over time, the methodology has been enhanced, including input from the NRC, and applied to numerous projects by various international organizations involved in radioactive waste management. Previous performance assessments and related supplemental analyses of the performance of the Yucca Mountain repository were conducted to meet various regulatory milestones, following the publication of the Nuclear Waste Policy Amendments Act of 1987, Public Law No. 100-203 [DIRS 100016]. The Yucca Mountain performance assessments have been iterative, with each succeeding performance assessment building on and extending the scope and results of the previous performance assessments by incorporating both an improved understanding of the processes affecting performance and, through additional field observations and laboratory analyses, better identification and quantification of the parameters used in the TSPA models. The current TSPA model is built on the foundation of those earlier performance assessments and has been enhanced by updated analyses of the processes affecting Yucca Mountain, new proposed regulations, and the design elements of the repository, including a comprehensive consideration of the FEPs that are relevant to repository system performance (SNL 2008 [DIRS 183478]).

The foundation and first stage of the performance assessment consists of a system characterization involving assimilation of the information collected by scientists and engineers involved in site characterization and engineering design. The repository system and site characterization provides information regarding waste properties, facility design, regional geology, regional hydrology, and environmental characteristics of the Yucca Mountain site. Design TSPA data input packages (SNL 2007 [DIRS 179394], SNL 2007 [DIRS 179567], SNL 2007 [DIRS 179354], and SNL 2007 [DIRS 179466]) are used to provide EBS component parameters for conceptual models used in performance assessment. The foundation represents the more than 20-year body of knowledge, collected in the field and in the laboratory, regarding the Yucca Mountain repository system. These data were used to identify the set of possible FEPs that may be part of and affect the performance of the repository system. The second stage of the performance assessment methodology consists of the development and testing of process models that include the retained FEPs, and their outcomes regarding repository performance.

The process models consist of sets of hypotheses, assumptions, simplifications, and idealizations that, together, describe the essential aspects of a system or subsystem of the repository relative to performance. An example of such a process model is one that describes the movement of water and dissolved radionuclides by diffusive flow in rock pores or by advective flow in fracture openings in the unsaturated bedrock surrounding the repository and through the saturated zone below the repository. Because the performance assessment methodology deals with future outcomes and includes uncertainty in both descriptions of processes and parameter values, an essential element of the performance assessment methodology is to capture uncertainty in probabilistic analyses that represent expected outcomes, based on the best available values of process model parameters and the processes involved.

The third stage of the methodology involves the development of abstraction models. These abstractions are progressive representations of the detailed models of physical and chemical processes to more compact, efficient numerical models. Abstractions consist of statistical or mathematical abstractions, including look-up tables, equations representing response surfaces, probability distributions, linear transfer functions, or reductions of model dimensionality. The abstractions used to analyze the projected evolution through time of the various components of the repository system are compact but still capture the salient features of the process models, along with their associated uncertainties.

The outputs of both the process models and their abstractions are subject to confidence-building activities as part of the model development process. These confidence-building activities include comparisons of output with alternative process models or with empirical observations, such as results from laboratory testing, field investigations, and natural analogues. These comparisons strengthen confidence in the technical basis for the models used in the performance assessment.

The last stage of the performance assessment consists of the integrated total system models. The total system model is a numerical model that is used to simulate the integrated behavior of the entire Yucca Mountain repository system. The TSPA model incorporates the abstracted detailed models that describe the TSPA model components, and their submodels, from their development to their implementation, including information from the analysis and model reports. The abstractions and associated process models and submodels describing various repository attributes in a series of analysis and model reports form the technical basis for the TSPA model.

Use of the TSPA model to simulate Yucca Mountain repository behavior and project future outcomes is aided by the development of scenario classes to assist in the analysis of repository performance and provide the framework for the TSPA model analyses. The TSPA model is structured to address a specific set of scenario classes that span the range of possible FEPs for both expected conditions and disruptive events. The TSPA model scenario classes include the nominal scenario class, the early failure scenario class, two disruptive event scenario classes, the igneous scenario class and the seismic scenario class, and a human intrusion scenario.

Features, Events, and Processes Analysis

The development of the TSPA model for the Yucca Mountain repository system includes an analysis and screening of the FEPs that could affect repository performance after closure. The results of the FEPs analyses led to the development of process models and abstractions that

address the attributes necessary to allow the TSPA model to assess repository safety and determine whether or not the repository meets regulatory standards. These process models and their abstractions considered FEPs that could affect the Yucca Mountain repository system and, in turn, FEPs that could be affected by the presence of the repository.

Development of the Scenario Classes

A scenario is a well-defined, connected sequence of FEPs that describes a possible future condition of the repository system. A scenario class is a set of related scenarios that share sufficient similarities that they can usefully be aggregated for the purposes of screening or analysis. The objective of scenario development for the TSPA-LA model is to define a limited set of scenario classes that are representative of the range of future FEPs that are potentially relevant to the licensing of the facility.

The TSPA approach focuses on a set of scenario classes that are distinguished by initiating events. The nominal scenario class includes all possible future outcomes except those initiated by early failure of the drip shields or waste packages, igneous or seismic activity, and inadvertent human intrusion into the repository. The igneous scenario class includes all possible future outcomes initiated by igneous activity. The seismic scenario class includes all possible future outcomes initiated by seismic activity. In addition to the analyses of the scenario classes, the TSPA model also simulates a human intrusion scenario according to the scenario and criteria described in 10 CFR 63.322 [DIRS 180319].

Incorporation of Uncertainty

Uncertainty and variability in the expected behavior of the Yucca Mountain repository system requires that the performance assessment analyses be probabilistic in order to capture the full range of potential outcomes.

Uncertainty in the TSPA model is characterized as either epistemic or aleatory uncertainty where:

- **Epistemic Uncertainty,** also referred to as "reducible" uncertainty, concerns the state of uncertainty in knowledge about a parameter value due to limited data or alternative interpretations of the available data. Epistemic uncertainty can be reduced, in principle, using the results of experimental testing and additional data collection. However, given the complexity of nature and the variability observed over time and space in natural phenomena, there are practical limits below which many uncertainties cannot be reduced. Neither is their reduction necessary once there is a sound technical basis for finding that a proposed system is expected to be sufficiently safe to allow moving forward to the next phase of its development. Scientific work continues at a significant level until the final closure and sealing of the repository, allowing safety evaluations to be informed by new information and repeated in advance of subsequent decision-points in the repository life.

- **Aleatory Uncertainty,** also referred to as "irreducible" uncertainty, concerns whether or not there is a chance occurrence of a FEP. No amount of exploratory work will allow determining whether or not a chance event will or will not occur at any given time, but determining a range of likelihoods of occurrence for a given timeframe is generally supportable through using various formalized means for combining scientific insights from experts in the field.

The TSPA model utilizes multiple realizations to calculate future outcomes using distributions of values for uncertain parameters that may be important to performance, rather than deterministic or single-value calculations for each parameter in the repository system. The model realizations are performed using various combinations of parameter values obtained from the parameter-value distributions in the TSPA input database, where each of the combinations of parameter values is representative of a subset of the full range of potential outcomes. These probabilistic analyses thus reflect an appropriate range of process behaviors or parameter values, or both, of the inherently variable Yucca Mountain repository system, given that complete knowledge of the system is not attainable.

Alternative Conceptual Models

A conceptual model is a set of working hypotheses and assumptions that provide an acceptable description of a system for its intended purpose. Because the performance assessment process deals with future outcomes and includes uncertainty in both process descriptions and parameter values, there may be alternative conceptual models that provide reasonable descriptions of a particular system or subsystem. Considering alternative conceptual models helps build confidence that plausible changes in modeling assumptions or simplifications will not change conclusions regarding subsystem and total-system performance. The model development process includes evaluations of alternative conceptual models, where appropriate. For example, the development of the EBS physical and chemical environment process model included consideration of an alternate initial water chemistry and the potential effect of feldspar equilibrium on seepage water composition, and the potential for carbonate exchange to affect CO_2 composition in the unsaturated zone. These alternative conceptual models were considered but not incorporated in the EBS physical and chemical environment process model.

Because alternative conceptual models must be compatible with known data and established facts, their number is limited. Typically, when two or more models exist for the same phenomena and data, the more conservative one from a total-system perspective has been chosen for implementation. Another approach is to assign probabilities to each alternative conceptual model and probabilistically bring them into the calculations according to their relative frequencies, but this approach places a greater demand on knowledge and adds complexity that is avoided by the more conservative approach.

Data, analysis and model reports, as well as the TSPA, have been developed per procedures which are compliant with *Quality Assurance Requirements and Description* (DOE 2007 [DIRS 182051]). These requirements and the procedures that implement them were developed to ensure adequate treatment of models and data, including the selection of conceptual models, the mathematical implementation of conceptual models, model geometry and dimensionality,

and boundary and initial conditions, as well as data values, correlations, and dependence of parameter selection on model scale.

FEP: 1.1.01.01.0A

FEP NAME:

Open Site Investigation Boreholes

FEP DESCRIPTION:

Site investigation boreholes that have been left open, degraded, improperly sealed, or reopened, could modify flow and transport properties and produce enhanced pathways between the surface and the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The potential impact of site-investigation boreholes on repository performance depends on the location and depth of the boreholes and the properties of the borehole seals. Site investigation boreholes are to be backfilled and plugged according to the Nevada Administrative Code (NAC) at NAC 534.4371 [DIRS 151873]. The hydrologic and transport characteristics of backfilled and plugged boreholes may not be the same as the natural rock formation. However, due to the predominantly vertical flow patterns in the unsaturated zone (BSC 2004 [DIRS 169734], Section 7), only boreholes within or close to the repository block could potentially affect repository performance. Boreholes well outside the footprint of the repository block (more than 300 m) will not influence water movement to the waste emplacement drifts or radionuclide transport from the waste emplacement drifts to the water table. Table 1.1.01.01.0A-1 lists eight deep boreholes in the repository block and seven deep boreholes near the repository block. The locations of these boreholes relative to waste emplacement locations are referenced in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). A deep borehole in the repository block is a borehole that penetrates the TSw (Topopah Spring welded hydrogeologic unit). A deep borehole near the repository block is a borehole that penetrates below the elevation of waste emplacement (DTNs: MO9906GPS98410.000 [DIRS 109059] and MO0004QGFMPICK.000 [DIRS 152554]; SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01).

Boreholes that terminate in or above the PTn (Paintbrush Tuff nonwelded hydrogeologic unit) will have a negligible effect on percolation flux at the repository because flow through these boreholes will be homogenized by matrix flow in the underlying Paintbrush nonwelded hydrogeologic unit relative to spatial variability of infiltration (SNL 2007 [DIRS 184614], Section 6.1.2[a]).

Based on the design layout (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01) and borehole locations in Table 1.1.01.01.0A-1, no waste emplacement drifts are expected to intersect existing boreholes. Water entering these boreholes would continue to flow through the boreholes to the water table, bypassing waste emplacement locations. Therefore, boreholes will not produce significant enhanced pathways for flow and transport between the surface and waste package emplacement locations.

The potential impact of boreholes on radionuclide migration between the repository and the water table may be assessed by considering the range of permeabilities for open boreholes and the fracture network. Fractures and faults represent continuous rapid-transport pathways from the repository to the water table as discussed in included FEP 2.2.07.08.0A (Fracture Flow in the UZ). Lateral flow beneath the repository eventually could encounter one of these high-permeability pathways to the water table. The principal difference between these high-permeability pathways and boreholes is that the cross-sectional area of the boreholes available to intercept lateral flow is much smaller than the area associated with fractures and faults. The 15 boreholes in Table 1.1.01.01.0A-1 with depths greater than 1,000 ft present a total cylindrical area (available to intercept lateral flow) per unit depth equal to πdN, where d is the average borehole diameter, conservatively estimated to be 1 m on the basis that the borehole diameter can exceed the size of the drill bit, and N is the number of boreholes. This gives a total borehole sidewall area of 15π m^2/m. The fractured rock between the repository and the water table has an average fracture area per unit volume of at least 0.1 m^2/m^3 (BSC 2004 [DIRS 170038], Table 6-5). Multiplying this by the 5×10^6 m^2 footprint of the repository (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01) gives a minimum fracture area per unit depth of about 5×10^5 m^2/m. Therefore, the contribution of open boreholes to the flow and transport pathways between the repository and the water table would be negligible compared to that of the fracture network.

Perched water zones, which could also contain radionuclides, may flow through the boreholes. The closure requirements relative to boreholes requires that they are backfilled; however, there are no requirements to make the boreholes impermeable or barriers to flow. Therefore, perched water in contact with the boreholes may be expected to flow along these pathways, which would also carry any dissolved radionuclides contained in the perched water. Although transport may be relatively rapid to the water table through the borehole pathways, an analysis of transport times has been conducted under the assumption that the borehole pathways do not exist (SNL 2008 [DIRS 184748], Section 6.6.2.1 and Appendix D). This analysis demonstrates that transport times for radionuclides released in the northern section of the repository, where large perched water bodies are present, are generally less than 100 years, particularly for the glacial-transition climate that dominates the 10,000 years after repository closure (SNL 2008 [DIRS 184748], Figures D.1-1 through D.1-3). Furthermore, sensitivity analyses for the effects of sorption on neptunium and plutonium radionuclide transport show that changes in sorption for rock units below perched water (mainly the Calico Hills rock units) have little effect on transport, whereas changes in sorption for the Topopah Spring rock units (which comprise the rock between the repository and perched water bodies) have pronounced effects on transport behavior (SNL 2007 [DIRS 177396], Figures 6-37 and 6-44). This result indicates that transport below the perched water bodies has relatively less interaction with the rock matrix as compared with transport through the Topopah Spring rock units, hence transport from perched water levels

to the water table, dominated by transport through faults, is relatively fast compared with transport from the repository to the perched water. Any reduction in travel time associated with radionuclide transport through borehole pathways (rather than fault pathways) would have a negligible effect on performance because travel times through this part of the unsaturated zone are primarily a result of transport between the repository and perched water locations; regardless of the borehole pathways, transport times between perched water zones and the water table are relatively smaller than transport times to those zones.

The borehole closure requirement is to backfill all but the upper 10 ft of a borehole, where a 10-ft cement plug is installed per NAC 534.4371 [DIRS 151873]. If the cement plug is intact, the low permeability of the cement will limit infiltration. If the cement plug should crack, it would not be substantially different than the fractured rock or soil in which it resides, particularly given the very small amount of ground surface area represented by boreholes (on the order of 1 ft in diameter; see Table 1.1.01.01.0A-1). Therefore, boreholes should not play a significant role for infiltration.

Existing test boreholes drilled in the underground facility could provide potential water flow and radionuclide transport pathways. However, these boreholes are all relatively short (they do not penetrate multiple hydrogeologic units) and are only present in access drifts, niches, and alcoves (BSC 2004 [DIRS 170004], Sections 6.1 through 6.12), not in the waste emplacement drifts. Therefore, these boreholes will have no significant effect on radionuclide transport between the repository and the water table. The potential effects of any holes that may be drilled in the waste emplacement drifts are discussed in excluded FEP 1.1.01.01.0B (Influx through Holes Drilled in Drift Wall or Crown).

In summary, site investigation boreholes are expected to be backfilled and plugged but will not prevent water movement into or through the boreholes. However, the boreholes are not expected to produce significant enhanced pathways for flow between the ground surface and the repository or for flow and radionuclide transport between the repository and the water table. Based on the previous discussion, omission of FEP 1.1.01.01.0A (Open Site Investigation Boreholes) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.01.01.0B

FEP NAME:

Influx Through Holes Drilled in Drift Wall or Crown

FEP DESCRIPTION:

Holes may be drilled through the drift walls or crown for a variety of reasons including, but not limited to, rock bolt and ground support, monitoring and testing, or construction related activities. These openings may promote flow or seepage into the drifts and onto the waste packages.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The boreholes drilled through the walls of emplacement drifts are designed for rock bolts and ground support (SNL 2007 [DIRS 179354], Table 4-1, Parameter 01-15). Other activities such as monitoring, testing, or construction, will not require drilling through drift walls. Detailed simulations have been made using the predictive seepage model for performance assessment (BSC 2004 [DIRS 167652], Sections 6.5 and 6.6.4) to study the effect of rock bolt boreholes extending vertically upward from the drift crown. In a sensitivity analysis, several combinations of capillarity and permeability were examined, including cases representing both grouted and ungrouted boreholes. According to the simulation results (BSC 2004 [DIRS 167652], Section 6.6.4 and Table 6-4), these features were found to have only a minor effect on seepage, increasing the predicted seepage rates by less than 2% compared to seepage simulations without rock bolts. This result is understandable considering that: (1) an open borehole without grout acts as a capillary barrier to unsaturated flow, (2) the cross-sectional area of the rock bolt borehole, onto which flow may be incident, is small, and (3) water that may have seeped into the borehole can imbibe back into the rock along its length. Note that only ungrouted boreholes will be used in emplacement drifts (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-15 and 01-16). From these results, the presence of boreholes drilled in drift wall or crown is not considered to have significant impact on seepage into drifts.

Based on the above discussion, omission of FEP 1.1.01.01.0B (Influx through Holes Drilled in Drift Wall or Crown) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.02.00.0A

FEP NAME:

Chemical Effects of Excavation and Construction in EBS

FEP DESCRIPTION:

Chemical effects associated with excavation and construction of the underground regions of the repository may affect the long-term behavior of the engineered and natural barriers. Excavation-related effects include chemical changes to the rock and incoming groundwater due to explosives residue. Excavation and other construction activities could also directly cause groundwater chemistry changes within the tunnel due to contaminants such as diesel exhaust or other organic contaminants. Finally, oxidizing water introduced into the repository during excavation and construction could impact repository conditions and performance.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Use of explosives for repository excavation could introduce small amounts of chemical components to the repository. Related excavation and operational activities could also introduce other organic and inorganic substances in residual amounts, such as diesel exhaust, lubricants, coolants, battery acid, cleaning solvents, and/or oil mist from compressed air systems. These materials could conceivably have an impact on groundwater chemistry within the EBS by impacting corrosion processes and/or facilitating radionuclide transport. Other potential impacts of excavation and construction are considered in excluded FEP 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near Field) and excluded FEP 1.1.02.00.0B (Mechanical Effects of Excavation and Construction in EBS). Excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) considers the effects of cement dust that may blow into emplacement drifts. Potential effects from residual organics are considered in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS).

To limit undesired effects from excavation and construction (e.g., corrosion and radionuclide transport impacts), requirements have been established to identify, analyze, and control the use of any materials (including water) that will be present in the repository at closure and could adversely impact postclosure performance. The application of these controls is described in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03). Prior to construction of the emplacement drifts and operation and closure of the repository, administrative controls will be developed and imposed to prevent impact on waste isolation from materials used, lost, or left in the repository. These controls will be supported by technical evaluation.

The following constraints will be imposed on the administrative control of tracers, fluids, and materials, construction materials, and committed materials (SNL 2007 [DIRS 179354],

Table 4-1, Parameter Number 02-03): (1) all material not technically evaluated and determined acceptable prior to the permanent closure of the repository will be removed from subsurface facilities prior to permanent closure; (2) committed materials that are proposed to remain in the underground repository following the permanent closure period will be technically evaluated and determined acceptable prior to use; and (3) administrative controls will include accounting and inspection, as appropriate, to confirm that controls on the approved quantities and compositions of tracers, fluids, and materials are met.

The emplacement drifts will be excavated using tunnel boring machines (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-09). Water will be introduced by tunnel boring machines, and any such water remaining in the emplacement areas after construction will be removed by ventilation, which will operate during waste emplacement and for a minimum of 50 years after waste emplacement (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-01). Dryout of the repository during ventilation is discussed in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.1.3).

Salt-bearing dust generated by construction activities could cause localized corrosion of EBS components as a result of deliquescence and subsequent formation of highly concentrated brine droplets. Screening justifications for this process are presented in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence) and excluded FEP 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces Due to Deliquescence).

Evaluation of effects from degradation of construction materials used for ground support (principally Stainless Steel Type 316L rock bolts and steel sheets (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-15)) and for construction of the invert (crushed tuff and carbon steel; SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08) is described for excluded FEP 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near Field). Sensitivity analyses of the effects of ground support and invert steels on aqueous chemistry are documented in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.8). When relatively large quantities of degrading Stainless Steel Type 316L (up to 1.3×10^{-1} moles per kilogram H_2O) were added to representative seepage water only slight differences were calculated in the ionic strength and dissolved inorganic carbon total molality (SNL 2007 [DIRS 177412], Section 6.8.4.1, Tables 6.8-5 and 6.8-6). Similar analysis to characterize the impact of invert steel corrosion also produced only negligible changes in water chemistry (SNL 2007 [DIRS 177412], Section 6.8.4.1, Tables 6.8-3 and 6.8-4). A bounding approach was used, so the conclusions of this analysis are not tied directly to a particular design or set of degradation rate data. Under oxidizing conditions (SNL 2007 [DIRS 177412], Section 6.7), additional steel leads to greater accumulations of corrosion-product precipitates and effectively no change in fluid chemistry (SNL 2007 [DIRS 177412], Section 6.8.4.2).

Based on the above discussion, omission of FEP 1.1.02.00.0A (Chemical Effects of Excavation and Construction in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.02.00.0B

FEP NAME:

Mechanical Effects of Excavation and Construction in EBS

FEP DESCRIPTION:

Mechanical effects associated with excavation and construction of the underground regions of the repository may affect the long-term behavior of the engineered and natural barriers. Excavation-related effects include changes to rock properties due to boring and blasting.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Emplacement drifts, access mains, and exhaust mains will be excavated using tunnel boring machines (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-09). Tunnel boring machines use a series of rolling disc cutters mounted on a rotating face to gradually cut the rock by forming rock chips under the shearing action of the cutters, and produce the least excavation damage among available excavation methods. This is because energy is focused on the rock to be removed, so that excess energy is not dispersed into the surrounding rock, as from blasting (Craig 2001 [DIRS 171411], pp. 1, 3, and 8).

The potential effects of excavation on the mechanical response of the rock mass fall into three categories: (1) a compromised ability to excavate nominally circular tunnel profiles consistent with modeled geometry; (2) altered or degraded mechanical properties in an excavation disturbed zone (EDZ) around the periphery of the opening; and (3) altered transport properties in the EDZ that could affect the quantity or chemistry of seepage water entering the drift, or radionuclide transport processes. Changes in rock properties that could affect water flow and radionuclide transport are addressed by included FEP 2.2.01.01.0A (Mechanical Effects of Excavation and Construction in the Near Field). Accordingly, the following analysis addresses only categories (1) and (2), the geometry and rock mechanical properties resulting from excavation and construction.

The ESF and ECRB Cross-Drift tunnels were driven with tunnel boring machines, to diameters comparable to the repository emplacement drifts (Craig 2001 [DIRS 171411], p. 1; SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-10) and provide data on the effects of excavation and construction activities in the repository host rock units. Examination of exposed rock through full-periphery geologic mapping and borehole logging has been used to define the character and extent of mechanical damage induced by tunnel boring (Craig 2001 [DIRS 171411], pp. 3 to 11, 16; BSC 2004 [DIRS 166107], Section 7.6.5.2). The observations are summarized as follows:

Circular Cross Section: Where the rock mass has relatively few natural fractures, the roughness of the tunnel walls (resulting from the action of the disc cutters) is on the order of 1 to 10 mm.

Where the rock is heavily fractured with natural jointing, the tunnel wall surface roughness is controlled by plucking of rock blocks bounded by natural fractures from the tunnel wall, resulting in a "blocky" surface appearance. Areas with abundant large (>60 cm) lithophysae produce a similar surface due to plucking along both abundant natural fractures connecting the lithophysae and along excavation-induced fractures. In all cases, the circular cross-section of the tunnel is maintained, and the variability of this cross-section introduced by surface roughness is small in comparison to the tunnel radius, and therefore the initial circular geometry used in modeling studies is reasonable.

Excavation-Induced Damage to Rock Mass: In rock with few fractures, the tunnel boring machine-induced fracturing of the tunnel periphery is confined to a depth of influence of less than 5 cm (Craig 2001 [DIRS 171411], p. 16). The depth of mechanically induced damage is therefore less than 1% of the tunnel diameter (5.5 m). In the poorest quality rock, rock containing abundant large lithophysae and/or an abundance of natural fractures, damage effects can penetrate to depths of approximately 50 cm, along the springline of the tunnel where the effects are greatest (Craig 2001 [DIRS 171411], p. 16; corroborated by BSC 2004 [DIRS 166107], Section 7.6.5.2). In either case, no significant impacts on the probability or amount of rockfall are expected to result from mechanical damage associated with tunnel boring activities.

In summary, excavation using tunnel boring machines will maintain circular tunnel geometry, and the resulting changes in the mechanical properties of the rock around the drift are insignificant for drift stability analyses. Hence, the effects of excavation damage do not need to be included in mechanical modeling studies.

Consistent with the above discussion, omission of FEP 1.1.02.00.0B (Mechanical Effects of Excavation and Construction in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP 1.1.02.00.0B is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.02.01.0A

FEP NAME:

Site Flooding (During Construction and Operation)

FEP DESCRIPTION:

Flooding of the site during construction and operation could introduce water into the underground tunnels, which could affect the long-term performance of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Flooding during storm events is not unusual and leads to infiltration and runoff. Areas that would be inundated in the probable maximum flood in the vicinity of the North Portal pad were calculated in *Preliminary Hydrologic Engineering Studies for the North Portal Pad and Vicinity* (BSC 2002 [DIRS 157928], Figures 17 through 19), and presented in DTN: MO0209EBSPMFSD.029 [DIRS 161845]. The maps contained therein show that flooding is not expected to reach the main portals of the Exploratory Studies Facility or the intake and exhaust shafts. To preclude repository flooding during construction and operation, the current design requires that portal and shaft locations are outside of the probable maximum flood areas (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-19).

Areas that would be inundated in the maximum potential flood for the Yucca Mountain area have also been calculated in *Flood Inundation Areas in the Vicinity of Yucca Mountain* (DTN: MO0004YMP98132.004 [DIRS 149806]). Percolation flux in the UZ is predominantly vertical (BSC 2004 [DIRS 169734], Section 7), so flooding over waste emplacement areas is expected to impact long-term performance of the repository. However, very little of the flood zone overlies waste emplacement zones. A small region of the maximum potential flood zone overlies the repository footprint in the upper part of Drill Hole Wash. Boreholes USW NRG-7a, USW G-1, and USW H-1 lie near the potential flood zone within Drill Hole Wash, which overlies the repository footprint (DTN: MO0011YMP00114.000 [DIRS 171565]). To minimize the introduction of surface runoff into these boreholes prior to the final borehole plugging, each borehole casing, which is cemented into the hole, extends above the ground surface (DTN: MO9906GPS98410.000 [DIRS 109059]). This FEP is intended to address the effects of site flooding during the preclosure period only, and the casings are not relied upon for long-term performance. All boreholes within the repository area have casings that extend above the ground surface (DTNs: MO9906GPS98410.000 [DIRS 109059]; MO9912GSC99492.000 [DIRS 165922]; MO0011YMP00114.000 [DIRS 171565]). As discussed for excluded FEP 1.1.01.01.0A (Open Site Investigation Boreholes), it is not expected that open boreholes will significantly increase the amount of water that enters the waste emplacement locations. Any flooding of the subsurface repository during construction or operations will be addressed as a non-conforming condition, as consistent with excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design) and remediated prior to repository closure.

The effects of flooding for the postclosure time period are addressed in excluded FEPs 1.1.04.01.0A (Incomplete Closure) and 2.1.05.01.0A (Flow Through Seals (Access Ramps and Ventilation Shafts)) and included FEP 2.3.11.02.0A (Surface Runoff and Evapotranspiration).

Based on the preceding discussion, omission of FEP 1.1.02.01.0A (Site Flooding (During Construction and Operation)) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP NAME:

Preclosure Ventilation

FEP DESCRIPTION:

The duration of preclosure ventilation acts together with waste package spacing (as per design) to control the extent of the boiling front (zone of reduced water content).

SCREENING DECISION:

Included

TSPA DISPOSITION:

As discussed in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862], Section 1), there are two distinct phases considered in repository operation. The first phase, or preclosure phase, which includes emplacement of the waste, is a period when heat generated from the decay of radionuclides contained in waste packages is actively removed from the repository by forced ventilation of the emplacement drifts. In the second phase, or postclosure phase, forced ventilation of the drifts is stopped and the repository is closed; natural ventilation and convective air movement through the drift continues to occur. The analysis described in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862]) calculates the preclosure thermal conditions in the host rock and characterizes the postclosure host rock response in terms of ventilation efficiency. The ventilation efficiency is computed as a percentage of total decay heat that is removed from the repository by the exhaust ventilation; the method of calculation is shown in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862], Section 6.4). The ventilation efficiency is determined through simulation of temporally and spatially dependent heat transfer processes (thermal radiation, convection, and conduction), which occur simultaneously in the drift and the surrounding rock mass during the ventilated preclosure period. The analytical ventilation model developed in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862], Section 6.4) was further developed in *Thermal Management Flexibility Analysis* (SNL 2007 [DIRS 179196], Section 6.3). Modifications to the original ventilation model included implementing alternative thermal loading schemes and host rock properties, expanding the ventilation duration analysis options, and correcting/updating several inputs to the calculation. The ventilation duration used for performance assessment is 50 years following final emplacement (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-01).

The ventilation efficiency is a direct input to *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2.15[a]), where it is used to calculate the reduction in the heat generation rate during preclosure ventilation (the heat generation rate is multiplied by a specified fraction). The MSTHM (SNL 2008 [DIRS 184433], Section 8.3[a]) in turn provides postclosure thermal and relative humidity conditions to the TSPA. The ventilation model (BSC 2004 [DIRS 169862]) and the MSTHM (SNL 2008 [DIRS 184433]), therefore, address the effect of ventilation on the removal of waste package heat during the preclosure period.

The condensation model described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.3.5.2.5) accounts for preclosure ventilation when calculating in-drift thermal conditions for use in determining condensation rates within the drift. That model uses the average annual ventilation efficiency based on a 600-m drift for the 50-year postemplacement ventilation period (SNL 2007 [DIRS 181648], Section 6.1.1[a]). The condensation model provides correlations of drift wall condensation rates and probabilities, as functions of percolation rate, to TSPA.

The impact of preclosure ventilation on the thermal load provided to the rock is explicitly simulated in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Sections 4.1.1.3 and 6.2.1.3.3). Those results are incorporated into the seepage abstraction by using time-dependent boundary conditions for the thermal load (SNL 2007 [DIRS 181244], Section 6.4.3.1). Thus, the thermal-hydrologic (TH) modeling results from the TH seepage model directly account for the impact of preclosure ventilation and waste package spacing on two-phase flow and the TH conditions in the near-drift rock. As discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2), the abstraction of thermal seepage utilizes these modeling results to develop an appropriate thermal seepage abstraction methodology.

For each of the three models discussed above, a single value for ventilation efficiency is used in simulations providing inputs to TSPA. In each case, the impact of uncertainty in the ventilation efficiency is evaluated using sensitivity analyses (SNL 2008 [DIRS 184433], Section 6.3.12[a]; SNL 2007 [DIRS 181648], Section 6.1.3[a]; SNL 2007 [DIRS 172232], Section 6.2.2.1.3), and is shown to be small relative to other model uncertainties that are propagated to the TSPA.

Preclosure ventilation also causes initial rock drying in the drift vicinity because of evaporation effects. The reduced relative humidity in the emplacement drifts leads to evaporation of water at the drift surfaces and development of a small zone of reduced saturation in the drift vicinity. This early dryout due to evaporation is not credited in the MSTHM (SNL 2008 [DIRS 184433], Section 7.5.2) and the TH seepage model (SNL 2007 [DIRS 181244], Section 6.5.2) because the effects are small, and seepage into ventilated drifts is not expected. The effects of preclosure ventilation on dryout of the rock are treated similarly in the thermal-hydrologic-chemical (THC) model (SNL 2007 [DIRS 177404], Section 6.5.5.2).

Ventilation efficiencies are used in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.2.4.3) to model evolution of the thermal field through time. Results from that report (SNL 2007 [DIRS 177412], Section 8.2) are implemented in TSPA in the form of the lookup tables for the determination of seepage water chemistries.

To summarize, the dominant effect of preclosure ventilation is to reduce the thermal load provided to the drift walls, limiting the temperature rise in the rock during this period. This effect is incorporated into models supporting performance assessment. Ventilation also results in dryout of the rock proximal to the drift. This effect is not credited because it has no impact on postclosure modeling of the repository; once ventilation ceases, a dryout zone rapidly develops around the drift in any case.

FEP: 1.1.02.03.0A

FEP NAME:

Undesirable Materials Left

FEP DESCRIPTION:

During construction and preclosure operation of the repository, unwanted materials might be left in the vicinity of the radioactive waste. These materials could, to some extent, affect many long-term processes in the repository from waste package corrosion to radionuclide transport mechanisms.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Inherent in the approach to FEP evaluation is the expectation that the repository will be constructed, operated, and closed according to the design used as the basis for FEP screening and in accordance with NRC license requirements. Repository construction, operation, and closure will be subject to a quality assurance program and quality control procedures that will evaluate and disposition any deviations from the design. Of particular relevance, controls on activities and materials used during the excavation, construction, and preclosure operation phases of the repository will aim to prevent unwanted materials from being left in the repository after repository closure.

Requirements have been established to identify, analyze, and control the use of any materials that will be present in the repository at closure and could adversely impact postclosure performance. Controls on activities and materials used during the excavation, construction, and preclosure operation phases of the repository will aim to prevent unwanted materials from being left in the vicinity of radioactive waste. The application of controls on materials is described in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03). The following constraints will be imposed on the administrative control of tracers, fluids, and materials, construction materials, and committed materials: (1) all material technically evaluated and determined not to be acceptable prior to the permanent closure of the repository will be removed from subsurface facilities prior to permanent closure; (2) committed materials that are proposed to remain in the underground repository following the permanent closure period will be technically evaluated and determined acceptable prior to use; and (3) administrative controls will include accounting and inspection, as appropriate, to confirm that controls on the approved tracers, fluids, and materials quantities and compositions are met.

The controls on materials will be sufficient to ensure that if any materials are left in the repository, they would not significantly affect radionuclide transport pathways or radiological dose to the RMEI. These controls will be supported by technical evaluation. Therefore, the effects of undesirable materials left in the repository after closure are excluded from the

performance assessments on the basis of low consequence. The potential impacts of chemical components left in the repository as a result of excavation and construction are considered in excluded FEP 1.1.02.00.0A (Chemical Effects of Excavation and Construction in EBS) and are also excluded on the basis of low consequence. Significant quantities of unwanted materials could only be left in the repository in the event that controls on activities and the materials used during the excavation, construction, and preclosure operation phases were inadequate. Inadequate controls are discussed in excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design).

Based on the previous discussion, omission of FEP 1.1.02.03.0A (Undesirable Materials Left) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.03.01.0A

FEP NAME:

Error in Waste Emplacement

FEP DESCRIPTION:

Deviations from the design and/or errors in waste emplacement could affect long-term performance of the repository. A specific example of such an error would be erroneously emplacing the waste packages in a saturated or wet zone of the repository. Errors of this type would impact repository performance by affecting waste package corrosion and radionuclide transport.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Possible types of waste emplacement errors are emplacement of packages closer to each other than in the design specification, and emplacement of a package so that it straddles a known Quaternary fault with potential for significant displacement. The emplacement of waste packages in a wet zone (i.e., zones of potential seepage) is not an erroneous emplacement, and is expected, and is included in the TSPA (see included FEP 2.1.08.01.0A (Water Influx at the Repository)). Saturated conditions are not expected in the repository (see excluded FEP 2.1.08.09.0A (Saturated Flow in the EBS)).

Inherent in the approach to FEP evaluation is the expectation that the repository be constructed, operated, and closed according to the design used as the basis for FEP screening and in accordance with NRC license requirements. Repository construction, operation, and closure will be subject to a quality assurance program and quality control procedures that will evaluate and disposition any deviations from the design. Of particular relevance, control procedures imposed during the repository operation phase will aim to ensure that any errors in waste emplacement are rectified before repository closure.

Inadequate quality controls on operational issues such as these are discussed in detail in excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design), and are excluded from the performance assessments. As a result of the rigorous quality assurance/quality control requirements governing emplacement of waste packages and inspection and approval of such emplacement, errors in emplacement location resulting in waste packages being placed substantially closer to each other than specified by design, or being placed on a known fault, are not expected. The regulatory requirements for performance confirmation and quality assurance require that any deviation from design be evaluated for potential impact, and that significant deviations which are detected during the operational period be corrected. Erroneous emplacement of waste packages is not expected because of quality controls.

In summary, FEP 1.1.03.01.0A (Error in Waste Emplacement) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of regulation.

FEP: 1.1.03.01.0B

FEP NAME:

Error in Backfill Emplacement

FEP DESCRIPTION:

Deviations from the design and/or errors in the backfill emplacement could affect long-term performance of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Backfill is not part of the design for the waste emplacement regions of the repository. Specifically, engineered backfill shall not be present in the space between the drip shield and the drift wall, and there is no design requirement for backfill in access mains or exhausts (SNL 2007 [DIRS 179354], Parameter Number 05-04). Closure of shafts and ramps shall include backfill of the opening (SNL 2007 [DIRS 179466], Parameter Number 09-01); however, as discussed in excluded FEP 2.1.05.01.0A (Flow through Seals (Access Ramps and Ventilation Shafts)), long-term performance of the repository is not adversely affected by flow in the shafts and ramps. Hypothetical deviations from backfill design and/or errors in backfill emplacement in shafts and ramps are not relevant to the emplacement area and would have no impact on overall performance of the repository if they occurred. Omission of FEP 1.1.03.01.0B (Error in Backfill Emplacement) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.04.01.0A

FEP NAME:

Incomplete Closure

FEP DESCRIPTION:

Disintegration of society could result in incomplete closure, sealing, and decommissioning of the disposal vault.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

10 CFR 63.305(a),(b), and (c) [DIRS 180319] specifies that:

(a) Features, events, and processes that describe the reference biosphere must be consistent with present knowledge of the conditions in the region surrounding the Yucca Mountain site.

(b) DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application.

(c) DOE must vary factors related to the geology, hydrology, and climate based upon cautious, but reasonable assumptions consistent with present knowledge of factors that could affect the Yucca Mountain disposal system over the next 10,000 years.

Incomplete closure due to inadequate quality control is covered by excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design). Included FEP 0.1.09.00.0A (Regulatory Requirements and Exclusions) addresses regulatory requirements and guidance specific to the Yucca Mountain repository including postclosure activities.

Because FEP 1.1.04.01.0A (Incomplete Closure) is, by definition, predicated on an assumption of a disintegration of society (i.e., an increase or decrease of human knowledge or technology), it is therefore excluded by regulation. Incomplete closure is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of regulation.

INPUTS:

	10 CFR 63.311	Individual protection standard after permanent closure

FEP: 1.1.05.00.0A

FEP NAME:

Records and Markers for the Repository

FEP DESCRIPTION:

This FEP addresses the retention of records of the contents of the repository and markers constructed to inform future humans of the location and contents of the repository. Performance assessments must consider the potential effects of human activities that might take place within the controlled area at a future time when institutional controls and/or knowledge of the presence of a repository cannot be assumed.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The requirements for constructing monuments as repository markers, preserving and archiving records, and a program of continued oversight are listed in 10 CFR 63.51(a)(3)(i-iii), 10 CFR 63.72(a), and 10 CFR 63.72(b)(1-11) [DIRS 180319]. 10 CFR 63.72(a) states:

> DOE shall maintain records of construction of the geologic repository operations area at the Yucca Mountain site in a manner that ensures their usability for future generations.

10 CFR 63.102(k) [DIRS 180319] addresses the use of institutional controls that are expected to reduce significantly, but not eliminate, the potential for human activity that could inadvertently cause or accelerate the release of radioactive materials. The regulation requires that both passive and active institutional controls be maintained. Specifically, 10 CFR 63.302 [DIRS 180319] defines passive institutional controls as:

(1) Markers, as permanent as practicable, placed on the Earth's surface;

(2) Public records and archives;

(3) Government ownership and regulations regarding land or resource use; and

(4) Other reasonable methods of preserving knowledge about the location, design, and contents of the Yucca Mountain disposal system.

Proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) requires an analysis of the consequences of a stylized human intrusion taking no credit for the efficacy of records and markers. Accordingly, FEP 1.1.05.00.0A (Records and Markers for the Repository) is excluded from consideration in the TSPA by regulation. Further discussion of institutional controls is provided in excluded FEP 1.1.10.00.0A (Administrative Control of the Repository Site).

FEP: 1.1.07.00.0A

FEP NAME:

Repository Design

FEP DESCRIPTION:

This FEP addresses the consideration of the design of the repository and the ways in which the design contributes to long-term performance. The performance assessment must account for design features, material characteristics, and the ways in which the design influences the evolution of the in-drift environment.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Repository design is one of the bases for the models used for the performance assessments. Particularly relevant to this FEP are the model components for waste package and drip shield degradation, waste form degradation and mobilization, and EBS flow and transport. These model components take into account the physical dimensions, material characteristics, and evolution of the in-drift environment, all of which stem directly from design considerations. The design elements are included in the TSPA as parameters that define the physical dimensions, characteristics, and long-term behavior of the waste form, waste packages, emplacement drift, drip shields and other components of the EBS. A mapping of these parameters to FEPs evaluations and their use in performance assessment is contained in Appendix A.

Proposed 10 CFR 63.114(a) (70 FR 53313 [DIRS 178394]) states that any performance assessment prepared to demonstrate compliance with 10 CFR 63.113 [DIRS 180319] must:

> (1) Include data related to the geology, hydrology, and geochemistry (including disruptive processes and events) of the Yucca Mountain site, and the surrounding region to the extent necessary, and information on the design of the engineered barrier system used to define, for 10,000 years after disposal, parameters and conceptual models used in the assessment.

The following is a summary description of the design of the repository subsurface facility and EBS considered in the FEPs evaluation and included in the performance assessments. Descriptions of the repository subsurface facility are found in *Postclosure Modeling and Analyses Design Parameters* (BSC 2008 [DIRS 183627]); *Total System Performance Assessment Data Input Package for Requirements Analysis for Transportation Aging and Disposal Canister and Related Waste Package Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179394]); *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354]); and *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466]).

Repository Layout

The layout of the subsurface facility analyzed is generally defined by *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02). The emplacement drifts will be excavated using a tunnel boring machine to a diameter of 5.5 m, with a nominal length of 600 m (available drift lengths will range from 324 to 777 m). Emplacement drifts will be excavated in a sequence of panels, which will contain 70,000 metric tons of heavy metal waste. Emplacement drifts will be arranged with a uniform spacing of 81 m between their centerlines (SNL 2007 [DIRS 179466],Table 4-1, Parameter Number 01-13). The repository design used in the postclosure performance analyses (BSC 2005 [DIRS 174101], Section 4.1.12) calls for approximately 100 waste packages to be placed in a single emplacement drift with a nominal length of 600 m (SNL 2008 [DIRS 183478], Section ES 5.1). There is an area in the southern section of the repository that will be constructed to allow for contingencies during waste emplacement. The repository host-rock units contain lithophysal and nonlithophysal units (SNL 2007 [DIRS 179466], Table 4-1, Parameter 01-03). The lithophysal rock units are characterized by numerous cavities (lithophysae), which result in high porosities. The lithophysal rock units are highly fractured and the fractures have short trace lengths. In contrast, the nonlithophysal rock units are characterized by few cavities, lower porosities, and fractures with generally longer trace lengths. Approximately 80% to 85% of the emplacement drift area will be excavated in lithophysal units, and 15% to 20% will be excavated in nonlithophysal units of the repository host horizon (BSC 2007 [DIRS 182926], Table 1).

Features of the Engineered Barrier System

The subsurface facility system includes ground support, such as rock bolts, steel liner, cement, and wire mesh. The EBS design includes a drip shield, a two-layer waste package, a corrosion-resistant emplacement pallet (made of Alloy 22 and stainless steel) on which the waste packages will be placed, and an invert, consisting of a steel support structure and crushed, welded tuff, at the base of the emplacement drifts. The following provides a description of each of the EBS components and repository thermal loading.

Drip Shield

The drip shields will be composed of two corrosion-resistant titanium alloys. The function of the drip shields is to reduce the effect of rockfall and dripping on the waste packages. The drip shields are designed to link together, forming a single continuous barrier for the entire length of the emplacement drifts (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-02). The drip shields will be fabricated from Titanium Grade 7 plates, with Titanium Grade 29 for structural support (SNL 2007 [DIRS 179354], Section 4.1.2). The base plates will be composed of Alloy 22 to prevent direct contact between titanium and the steel members of the invert horizon (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-07).

Waste Package

Waste packages will consist of an outer corrosion barrier and an inner vessel. The outer corrosion barrier is 25-mm-thick corrosion-resistant Alloy 22. The waste packages will be

treated to minimize the possibility of SCC, and the outer closure weld will be stress mitigated. The inner vessel is 50-mm-thick stainless steel and serves three functions. First, the inner vessel provides structural strength to resist rockfall, to support the internal waste form components, to allow the waste packages to be supported by the emplacement pallets, and to facilitate handling. Second, the inner layer provides radiation shielding to reduce the exterior surface contact dose rate (SNL 2007 [DIRS 179394], Table 4-1, Parameter Numbers 03-09 and 03-10; Table 4-3). Third, because of sorption of radionuclides on corrosion products from the degradation of the inner vessel, it acts as a limited containment part of the EBS barrier for the radioactive waste inside the waste packages. The inner vessel is not considered to be a barrier to flow. To calculate radionuclide transport through the waste packages, the TSPA uses the TAD canister with 21-PWR fuel assemblies as the representative commercial SNF waste package, and the 5-DHLW/DOE Long waste package as the representative configuration for the codisposal waste packages. These commercial SNF and codisposal waste packages are planned to be the most common two types of waste packages in the repository (SNL 2007 [DIRS 177407], Section 6.3.3.1).

Emplacement Pallet

An emplacement pallet will support each waste package (SNL 2007 [DIRS 179394], Table 4-3, Parameter Numbers 03-03 and 03-04). The emplacement pallets are designed to prevent the waste packages from coming in contact with the invert of the emplacement drifts and, therefore, prevent direct exposure to invert moisture or materials that may induce accelerated corrosion of the waste packages. The material supporting the waste packages will consist of Alloy 22, providing long-term corrosion resistance and an identical material in contact with the outer surfaces of the waste packages. To reduce the possibility of SCC, the emplacement pallets will also be annealed to remove stresses from welding and fabrication.

Invert

The invert will provide support for the waste package emplacement pallets and the drip shields. The invert consists of two components: a steel invert structure and a crushed tuff fill. The granular crushed tuff will be composed of crushed welded tuff produced from the excavation of the repository underground openings with the tunnel boring machines, and will be placed in and around the steel invert structure to an elevation just below the top of the longitudinal and transverse support beams. The crushed tuff will be compacted (BSC 2007 [DIRS 182746], Report Summary) to prevent long-term settlement (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08).

Waste Form

Spent nuclear fuel consists of fuel removed from nuclear reactors after its useful heat-generating capacity has been spent. The performance assessments analyze the disposal of waste packages containing commercial SNF and codisposal waste packages, containing DOE SNF (BSC 2004 [DIRS 169766]; BSC 2008 [DIRS 185102]) and HLW (BSC 2004 [DIRS 169988]). Commercial SNF consists primarily of uranium oxide, some of which has been enriched with surplus plutonium to create a MOX fuel. DOE SNF is fuel associated with DOE defense programs and research and development programs. The majority of DOE SNF consists of a

uranium-metal compound SNF with zirconium cladding, which accounts for approximately 86% of the mass of the DOE SNF inventory. However, there are 11 categories of DOE SNF representing a variety of uranium-based waste forms. Naval SNF, a category of DOE SNF, is classified material and, as such, cannot be included in the unclassified postclosure performance assessments. Naval fuel is represented as commercial SNF for modeling purposes. HLW consists of by-products of nuclear reactions, material generated during fuel preparation and reprocessing, and sludges and residues recovered from nuclear-waste storage tanks. HLW will be mixed and solidified in a high-temperature, borosilicate glass for storage in stainless-steel canisters. Codisposal waste packages typically contain five HLW canisters surrounding one DOE SNF canister.

Waste Form Cladding

Nuclear fuel generally consists of stacked pellets of uranium-based fuel encased in a metallic protective cladding. However, for the performance assessments, it is assumed that commercial SNF cladding is failed at the time the waste packages are breached. In addition, DOE SNF cladding is in poor condition and is considered to be failed upon emplacement.

Emplacement Drift

The nuclear waste will be placed in 5.5-m diameter, circular emplacement drifts excavated with tunnel boring machines (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-10). The drifts will serve to enhance the role of the natural barriers and the EBS due to two processes: (1) the formation of a capillary barrier at drift walls that will be active during the thermal and ambient postclosure periods, and (2) the formation of a dryout zone helping to prevent percolation from reaching the repository during the thermal period (SNL 2008 [DIRS 184433], Section 6.1.3). The effectiveness of these processes depends on the strength of the capillary pressure in the fractures close to the drift, the host rock permeability close to the drifts, the local percolation flux above the drifts, the temperature of the rock near the drift walls, and the shape of the drift openings.

Internal Waste Package Components

There are two general waste package types evaluated in the performance assessment: the CSNF waste package and the codisposal waste package. For commercial SNF waste packages, the waste package internal component is the TAD canister. Codisposed waste packages will have internal steel components consisting primarily of carbon-steel basket guides and basket tubes, and stainless steel canisters for HLW and DOE SNF (SNL 2007 [DIRS 179394], Tables A-1, A-2, and 4-2). Additionally, TAD canisters and DOE SNF canisters will contain neutron absorbers for criticality control (SNL 2007 [DIRS 179394], Table A-4). The internal steel components are expected to degrade to iron oxyhydroxides upon exposure to water and repository atmospheric conditions following waste package failure. These degradation products could potentially sorb radionuclides released from the degradation of the waste forms.

Waste Emplacement Approach

Waste packages will be placed in the emplacement drifts in a line-load configuration with a waste package-to-waste package spacing of approximately 10 cm, and a line-averaged heat load of 2.0 kW/m. No waste package will exceed 18 kW (SNL 2007 [DIRS 179354], Table 4-4, Parameter Numbers 05-02 and 05-03). Preclosure ventilation will be active for at least 50 years after final waste emplacement (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-01).

The performance assessment modeling of engineered systems recognizes that degradation can lead to deterioration and alteration of engineered features that are included in models of EBS performance and, therefore, can affect system performance. Related included FEPs 2.1.03.08.0A (Early Failure of Waste Packages) and 2.1.03.08.0B (Early Failure of Drip Shields) specifically include the consideration of manufacturing and welding defects within the waste package and drip shield degradation analyses. Deficiencies beyond those specifically included in these FEPs are addressed in excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design). The incorporation of repository design elements for waste retrievability is discussed in included FEP 1.1.13.00.0A (Retrievability). In conclusion, FEP 1.1.07.00.0A (Repository Design) is included in the TSPA.

FEP: 1.1.08.00.0A

FEP NAME:

Inadequate Quality Control and Deviations from Design

FEP DESCRIPTION:

This FEP addresses issues related to inadequate quality assurance and control procedures and inadequate testing during the design, construction, and operation of the repository. It also includes inadequacy in the manufacture of the waste forms, waste packages, and engineered features. Lack of quality control could result in a poorly designed repository, unmodeled design features, deviations from design, material defects, faulty waste package fabrication, and faulty or non-design standard construction. All of these may lead to reduction in the effectiveness of the engineered barriers.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

As described below, this FEP is excluded from the performance assessments on the basis of low consequence. Implementation of sound administrative and safety controls including a quality assurance program that meets the regulatory requirements of 10 CFR 63.142 [DIRS 180319] provides the foundation for demonstrating that unanalyzed defects in quality control or deviations from design will not have a significant adverse impact on postclosure performance of the repository.

Inherent in the FEPs evaluation approach is the expectation that the repository will be constructed, operated, and closed according to the design used as the basis for the FEP screening and in accordance with NRC license requirements. The postclosure-relevant aspects of the repository design are consistent with included FEP 1.1.07.00.0A (Repository Design). The inclusion of the repository design is accomplished through analyses of individual FEPs that are either excluded or included based on that design. The structures, systems, and components of the repository design that are relevant to the features of the natural barriers and the EBS used in performance assessment are identified in *Postclosure Modeling and Analyses Design Parameters* (BSC 2008 [DIRS 183627]); *Total System Performance Assessment Data Input Package for Requirements Analysis for Transportation Aging and Disposal Canister and Related Waste Package Overpack Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179394]); *Total System Performance Assessment Data Input Package for Requirements Analysis for DOE SNF/HLW and Naval SNF Waste Package Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179567]); *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354]); and *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466]).

If there are significant deviations from the design that result from inadequate quality control, it is possible to affect the analyzed conditions. In recognition of this, regulations establish requirements for the management systems for the construction and operation of the repository to include administrative and procedural safety controls as well as design verification, testing, and performance confirmation. The establishment of adequate administrative and procedural safety controls ensure construction and operations are within analyzed conditions of the postclosure safety analysis and TSPA or that any deviations are analyzed for significance. This is consistent with the approach used to establish bounds for the performance evaluation of any engineering project. It is also necessary because the determination of the degree of the deviation (due to the potential inadequacy of the quality assurance, quality control, or testing) cannot always be evaluated a priori and must ultimately be based on specific deviations on a case-by-case basis.

Adequate Quality Assurance and Quality Control Procedures

The DOE Quality Assurance Program is established by regulation. As specified by 10 CFR 63.142 [DIRS 180319], "Quality assurance criteria:"

> *(a) Introduction and Applicability*.
>
> DOE is required by § 63.21(c)(20) to include in its safety analysis report a description of the quality assurance program to be applied to all structures, systems, and components important to safety, to design and characterization of barriers important to waste isolation, and to related activities. These activities include: site characterization; acquisition, control, and analyses of samples and data; tests and experiments; scientific studies; facility and equipment design and construction; facility operation; performance confirmation; permanent closure; and decontamination and dismantling of surface facilities.

Of particular relevance is the fact that 10 CFR Part 63 [DIRS 180319] requires the DOE to implement a layered quality assurance program for DOE, major contractor, and vendor activities similar to those for the 10 CFR Part 50 [DIRS 181964] power reactor and utilization facility environment. These programs provide a layered, defense-in-depth approach to activities (control of design, materials, shipping, handling, storage, fabrication, construction, installation, inspection, testing, operations, maintenance, oversight, identification and correction of nonconformances and conditions adverse to quality, etc.) for the applicant/licensee; engineering, procurement, and construction contractors; and vendors of equipment, materials, and services. In regulating other activities and facilities, the NRC has found that these programs are sufficiently self critical and self correcting to permit a conclusion that their implementation provides a reasonable assurance of safety. Since the 10 CFR Part 63 [DIRS 180319] quality assurance requirements are drawn from those established for reactors in 10 CFR Part 50 [DIRS 181964], repository safety analyses place the same reliance on the effectiveness of the quality assurance program as is done in the case of reactors.

In addition, provisions exist to evaluate the acceptability of and uncertainty in data that were not produced in accordance with the quality assurance program. These provisions require DOE to evaluate data required to support its license application. If data related to structures, systems, and components important to safety, to design and characterization of barriers important to waste isolation, and to activities related, thereto, have not been collected in accordance with a quality

assurance program that meets these requirements, the DOE is required to show that such data have been qualified for their intended use. The NRC recognizes that some data supporting a license application for a high-level waste repository may not have been initially collected under the quality assurance program. NUREG–1298 (Altman et al. 1988 [DIRS 103750], *Qualification of Existing Data for High-Level Nuclear Waste Repositories*, provides guidance on the use and qualification of data not initially collected in accordance with the quality assurance program. This guidance has been incorporated into the quality assurance program.

Adequate Testing During Design, Construction, and Operation of the Repository

Adequate testing requirements are also established by regulation. 10 CFR 63.74 establishes testing requirements during design, construction, and operation of the repository. In particular:

> (a) DOE shall perform, or permit the Commission to perform, those tests the Commission considers appropriate or necessary for the administration of the regulations in this part. This may include tests of—
>
> (1) Radioactive waste,
> (2) The geologic repository, including portions of the geologic setting and the structures, systems, and components constructed or placed therein,
> (3) Radiation detection and monitoring instruments, and
> (4) Other equipment and devices used in connection with the receipt, handling, or storage of radioactive waste.
>
> (b) The tests required under this section must include a performance confirmation program carried out in accordance with subpart F of this part.

The performance confirmation program is being conducted to evaluate the adequacy of assumptions, data, and analyses that form the bases of the postclosure performance assessment. Key geotechnical and design parameters, including any interactions between natural and engineered systems and components, will be monitored throughout site characterization, construction, emplacement, and operation to identify any significant changes in the conditions assumed in the license application that may affect compliance with the performance objectives specified in 10 CFR 63.113(b) and (c) [DIRS 180319].

Adequacy in the manufacture and testing of waste forms, waste packages, and engineered features.

As noted, the quality assurance program is required to be applied to design and characterization of barriers important to waste isolation, and to related activities; this includes the manufacture and testing of waste forms, waste packages, and engineered features. The performance confirmation program specifies requirements for the testing and monitoring waste forms, waste packages, and engineered features in 10 CFR 63.133 and 10 CFR 63.134 [DIRS 180319]. These requirements include:

> 10 CFR 63.133, Design testing.
>
> (a) During the early or developmental stages of construction, a program for testing of engineered systems and components used in the design, such as, for

> example, borehole and shaft seals, backfill, and drip shields, as well as the thermal interaction effects of the waste packages, backfill, drip shields, rock, and unsaturated zone and saturated zone water, must be conducted.

and

> 10 CFR 63.134, Monitoring and testing waste packages.
>
> (a) A program must be established at the geologic repository operations area for monitoring the condition of the waste packages. Waste packages chosen for the program must be representative of those to be emplaced in the underground facility.
>
> (b) Consistent with safe operation at the geologic repository operations area, the environment of the waste packages selected for the waste package monitoring program must be representative of the environment in which the wastes are to be emplaced.
>
> (c) The waste package monitoring program must include laboratory experiments that focus on the internal condition of the waste packages. To the extent practical, the environment experienced by the emplaced waste packages within the underground facility during the waste package monitoring program must be duplicated in the laboratory experiments.

Errors in the manufacture and fabrication of waste packages.

The treatment of waste-package failure as a result of errors (which remain undetected) due to inadequacy in their manufacture and fabrication are addressed in included FEP 2.1.03.08.0A (Early Failure of Waste Packages). Several general types of manufacturing defects are considered as mechanisms that could possibly adversely affect waste package performance, and include weld flaws, improper weld material, improper base metal, improper heat treatment, improper low plasticity burnishing, improper weld-flux material, poor weld-joint design, surface contamination, mislocated welds, missing welds, handling or installation damage, and administrative or operational error (SNL 2007 [DIRS 178765]). These defects are considered in the development of the early waste package failure event probabilities.

The closure lid welding process could also induce stresses in the waste package outer barrier lid, which could contribute to stress corrosion cracking of the waste packages. Induced stresses from the final closure weld process are addressed in included FEP 2.1.03.02.0A (Stress Corrosion Cracking of Waste Packages). This FEP accounts not only for stresses induced by welding the lid, but also lid weld flaws. Therefore, lid weld stresses and lid weld flaws that contributed to stress corrosion cracking of the waste packages are directly accounted for in the performance assessments.

Errors in the manufacture and fabrication of waste forms and waste package internals.

The radionuclides in the waste form are generally of a form that are highly insoluble to water and are not expected to mobilize, except for a limited number of radionuclides, thus significantly

reducing the radionuclide release rate. Control parameters related to the waste form capabilities are waste form moisture removal and inerting, loading of waste forms, and handling of waste forms. Deviations from design with respect to loading waste packages is addressed in excluded FEP 2.1.14.15.0A (In-Package Criticality (Intact Configuration)) Waste form manufacture and fabrication errors related to the use of improper absorber materials or waste form misloads are addressed in the excluded criticality FEPs (see for example FEP 2.1.14.15.0A (In-Package Criticality (Intact configuration))). Excluded FEP 2.1.13.01.0A (Radiolysis) evaluates the effects of a design-specified quantity of water being left inside a waste package.

As indicated in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal), cladding degradation prior to receipt at the repository can occur during reactor operation, spent fuel pool storage, dry storage, transport, and handling. The representation of all defense SNF cladding (with the exception of naval SNF cladding) and commercial SNF cladding in performance assessments assumes the cladding will be breached on emplacement in the repository and will inhibit neither groundwater contacting the fuel matrix nor the release of radionuclides after groundwater contact (SNL 2008 [DIRS 183478], Section 6.3.7.3.1). This representation bounds any errors that may have occurred during the manufacture, fabrication, and handling of cladding.

Errors in the manufacture and fabrication of engineered features (drip shields)

Evaluation of undetected errors during manufacture and installation of drip shields is addressed in included FEP 2.1.03.08.0B (Early Failure of Drip Shields). Such errors could lead to early failure of the drip shields. Several general types of manufacturing defects are considered as possible mechanisms that could adversely affect drip shield performance, including weld flaws, base metal flaws, improper weld material, improper base metal, improper heat treatment, improper low plasticity burnishing, improper weld-flux material, poor weld-joint design, surface contamination, mislocated welds, missing welds, handling or installation damage (including gaps between drip shields), and administrative or operational error.

Deviations from design and non-standard construction.

Deviations from design and non-standard construction are also addressed by regulatory requirements linked to testing and quality assurance. For example, 10 CFR 63.132 [DIRS 180319], "Confirmation of geotechnical and design parameters" requires:

> (a) During repository construction and operation, a continuing program of surveillance, measurement, testing, and geologic mapping must be conducted to ensure that geotechnical and design parameters are confirmed and to ensure that appropriate action is taken to inform the Commission of design changes needed to accommodate actual field conditions encountered.
>
> (b) Subsurface conditions must be monitored and evaluated against design assumptions.
>
> (c) Specific geotechnical and design parameters to be measured or observed, including any interactions between natural and engineered systems and components, must be identified in the performance confirmation plan.

> (d) These measurements and observations must be compared with the original design bases and assumptions. If significant differences exist between the measurements and observations and the original design bases and assumptions, the need for modifications to the design or in construction methods must be determined and these differences, their significance to repository performance, and the recommended changes reported to the Commission.
>
> (e) In situ monitoring of the thermomechanical response of the underground facility must be conducted until permanent closure, to ensure that the performance of the geologic and engineering features is within design limits.

In 10 CFR 63.73(a) [DIRS 180319], the NRC requires prompt notification if there is a significant deficiency found in: (1) the characteristics of the Yucca Mountain site, or (2) the design and construction of the geologic repository area, including significant deviations from the design criteria and design bases stated in the application. Significant deviations that are detected during the operational period will be evaluated and, as needed, corrected. Any residual defects or fabrication or construction deficiencies, therefore, will be of a minor nature and will not lead to significant effects on repository performance. Compliance with the requirements described will ensure that significant effects from undetected deviations in design are not expected.

Modifications and deviations from the design are subject to regulatory requirements and review that address deliberate changes and modifications. The manner in which the DOE must address changes, and by which the NRC is informed of the changes, is codified in 10 CFR 63.44 [DIRS 180319]. After the NRC authorizes construction of the repository, changes to the repository design or procedures as described in the SAR will be subject to the requirements of 10 CFR 63.44 [DIRS 180319], "Changes, tests, and experiments," as well as any specific license conditions imposed in accordance with 10 CFR 63.32 [DIRS 180319], "Conditions of construction authorization;" 10 CFR 63.42 [DIRS 180319], "Conditions of license;" or 10 CFR 63.43 [DIRS 180319], "License specification."

The DOE process for controlling changes under 10 CFR 63.44 [DIRS 180319] is subject to the DOE Quality Assurance Program, in accordance with the guidance in NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.5.1.3, Acceptance Criteria 2(7), 2(10), and 3(21)).

The DOE Quality Assurance Program includes the following provisions for controlling design changes (DOE 2007 [DIRS 182051], Section 3.2.6):

A. Changes to final designs, field changes, and nonconforming items dispositioned "use-as-is" or "repair" shall be justified and shall be subject to design control measures commensurate with those applied to the original design.

B. Changes shall be approved by the same affected groups or organizations that approved the original design documents.

    1. If an organization that originally was responsible for approving a particular design document is no longer responsible, a new responsible organization shall be designated by the OCRWM.

2. The designated approving organization shall have demonstrated competence in the specific design area of interest and have an adequate understanding of the requirements and intent of the original design.

C. The design process and design verification methods and implementing documents shall be reviewed and modified, as necessary, when a significant design change is necessary because of an incorrect design.

D. Errors and deficiencies in approved design documents, including design methods (i.e., computer software supporting a safety or waste isolation function), that could adversely affect [structures, systems, and components] important to safety or waste isolation shall be documented and action taken to ensure all errors and deficiencies are corrected.

E. Deviations from specified quality standards shall be identified and formally documented. Procedures shall be established to ensure control of these deviations.

F. Measures shall be provided to ensure personnel are notified of design changes/modifications that may affect the performance of their duties.

G. Prior to the issuance of a design change initiated after the construction authorization, the design changes shall be evaluated pursuant to applicable regulatory requirements.

The potential impacts of excavation and construction are considered in excluded FEPs 1.1.02.03.0A (Undesirable Materials Left), 1.1.03.01.0A (Error in Waste Emplacement), 1.1.12.01.0A (Accidents and Unplanned Events during Construction and Operation), 1.1.02.00.0A (Chemical Effects of Excavation and Construction in EBS), 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near Field), and 1.1.02.00.0B (Mechanical Effects of Excavation and Construction in EBS). Excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) considers the effects of cement dust that may blow into emplacement drifts. Improper placement of drip shields is addressed in included FEP 2.1.03.08.0B (Early Failure of Drip Shields). Potential effects from residual organics are considered in excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS). To limit undesired effects from excavation and construction (e.g., corrosion and radionuclide transport impacts), requirements have been established to identify, analyze, and control the use of any materials (including water) that will be present in the repository at closure and could adversely impact postclosure performance. The application of these controls is described in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03).

The provided examples are not exhaustive because the deviation and the degree of deviation (due to the potential inadequacy of the quality assurance, quality control, or testing) cannot always be evaluated a priori and must be evaluated on a case-by-case basis. The DOE approach to demonstrating waste isolation includes a repository system that relies on multiple barriers, the use of multiple lines of evidence related to system performance, and a continuous learning approach to repository design and construction. The subsurface facilities are planned to be

constructed in phases. The development of the subsurface facility will proceed while emplacement operations are conducted in the completed drifts and will be done in a manner that safely accommodates waste package emplacement. Phased construction and operation provides an opportunity for orderly implementation of lessons learned and incorporation of new information that would improve the safety of construction and operations. The repository will implement a management system that includes the evaluation of changes, tests, and experiments. Lessons learned and new information will be evaluated against the criteria in 10 CFR 63.44 [DIRS 180319], and the lessons learned or new information will be implemented following construction authorization or license amendment if any of the criteria are met; otherwise, the proposed changes will be implemented and documented in updates to the SAR. This is consistent with the National Research Council's description of staged development that allows for proposed adaptation without unacceptable impacts on safety or waste isolation (National Research Council 1995 [DIRS 100018], Chapter 3), incorporation of new knowledge on features and processes that determine repository performance, and accommodation of significant changes in repository requirements.

Finally, 10 CFR 63.51 [DIRS 180319] requires the DOE to submit an application to amend the license before permanent closure of a geologic repository. The submission must include an update of the assessment of the performance of the geologic repository for the period after permanent closure. The updated assessment must include any performance confirmation data collected under the program required by Subpart F, and pertinent to compliance with 10 CFR 63.113 [DIRS 180319]. This ensures that effectiveness of the engineered barriers are evaluated with respect to any significant deviations from design during construction and operation of the repository.

In summary, FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence. In addition, the regulatory requirements for performance confirmation and quality assurance require that any deviation from design during the operational period be evaluated for potential impact, and that deviations with a significant adverse impact on postclosure performance be corrected.

FEP: 1.1.09.00.0A

FEP NAME:

Schedule and Planning

FEP DESCRIPTION:

This FEP addresses the sequences of events and activities occurring during construction, operation, and closure of the repository. Deviations from the design construction or waste emplacement schedule may affect the long-term performance of the disposal system.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Scheduling and planning are components of the process implemented to achieve the expected repository postclosure conditions. The subsurface facilities are planned to be constructed in phases and the development of the subsurface facilities will proceed while emplacement operations are conducted in the completed drifts. The schedule for waste emplacement and planned subsurface ventilation will affect the radionuclide inventories and thermal-hydrological conditions at the time of repository closure. In particular, conditions at closure will depend on the implementation of design requirements for subsurface facilities and their ventilation, sealing, and closure (SNL 2007 [DIRS 179466]), and for waste emplacement (SNL 2007 [DIRS 179354]).

Modifications and deviations from the design for construction, operation, and closure of the repository are subject to regulatory requirements and review that address deliberate changes and modifications. The manner in which the DOE must address changes, and by which the NRC is informed of the changes, is codified in 10 CFR 63.44 [DIRS 180319]. After the NRC authorizes construction of the repository, changes to the repository design or procedures as described in the SAR will be subject to the requirements of 10 CFR 63.44 [DIRS 180319], "Changes, tests, and experiments," as well as any specific license conditions imposed in accordance with 10 CFR 63.32, "Conditions of construction authorization," 10 CFR 63.42 [DIRS 180319], "Conditions of license," or 10 CFR 63.43 [DIRS 180319], "License specification." Deviations from design as a result of inadequate quality control during repository construction, operation, and closure is addressed in excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design), which is excluded from the TSPA by regulation.

Phased construction and operation provides an opportunity for orderly implementation of lessons learned and incorporation of new information that would improve the safety of construction and operations. The repository will implement a management system that includes the evaluation of changes, tests and experiments. Lessons learned and new information will be evaluated against the criteria in 10 CFR 63.44 [DIRS 180319], and the lessons learned or new information will be implemented following construction authorization or license amendment if any of the criteria are met; otherwise, the proposed changes will be implemented and documented in updates to the

SAR. This is consistent with the National Research Council description of staged development (National Research Council 1995 [DIRS 100018], Chapter 3) that allows for proposed adaptation without unacceptable impacts on safety or waste isolation, incorporation of new knowledge on features and processes that determine repository performance, and accommodation of significant changes in repository requirements.

In summary, scheduling and planning are included in the TSPA model because they influence the conditions at repository closure and are components of the process implemented to achieve the expected repository postclosure conditions, both of which are inputs to the TSPA model.

FEP: 1.1.10.00.0A

FEP NAME:

Administrative Control of the Repository Site

FEP DESCRIPTION:

Administrative control can reduce the potential for detrimental or unplanned human activities within the controlled area that could inadvertently cause or accelerate the release of radioactive material.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Administrative controls are defined in 10 CFR 63.43(6) [DIRS 180319] as "provisions relating to organization and management, procedures, recordkeeping, review and audit, and reporting necessary to assure that activities at the facility are conducted in a safe manner and in conformity with the other license specification." This definition of administrative controls addresses preclosure operational activities that are addressed in included FEPs 0.1.09.00.0A (Regulatory Requirements and Exclusions) and 1.1.09.00.0A (Schedule and Planning), and excluded FEPs 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design) and 1.1.12.01.0A (Accidents and Unplanned Events during Construction and Operation).

Administrative controls may also include the use of policies, procedures, markers, training or supervision of records to control risk. Markers and repository archives are discussed in excluded FEP 1.1.05.00.0A (Records and Markers for the Repository). The NRC recognizes that such institutional controls are expected to significantly reduce, but not eliminate, the potential for human activity that causes or accelerates the release of radioactive material. In 10 CFR 63.102(k) [DIRS 180319], the regulations address the use of institutional controls; they require that both passive and active institutional controls be maintained, but not relied upon for TSPA. The regulation states:

> Active and passive institutional controls will be maintained over the Yucca Mountain site, and are expected to reduce significantly, but not eliminate, the potential for human activity that could inadvertently cause or accelerate the release of radioactive material. However, because it is not possible to make scientifically sound forecasts of the long-term reliability of institutional controls, it is not appropriate to include consideration of human intrusion into a fully risk-based performance assessment for purposes of evaluating the ability of the geologic repository to achieve the performance objective at §63.113(b). Hence, human intrusion is addressed in a stylized manner as described in paragraph (I) of this section.

The requirements for constructing monuments, preserving and archiving records, and oversight are also of relevance to administrative controls and are listed in 10 CFR 63.51(a)(3)(i-iii), 10 CFR 63.72(a), and 10 CFR 63.72(b)(1-11) [DIRS 180319]. Land ownership and control requirements are specified in 10 CFR 63.121 [DIRS 180319]. On the basis of the quoted regulation, and the aforementioned FEPs, this FEP is excluded by regulation from consideration in performance assessments.

FEP: 1.1.11.00.0A

FEP NAME:

Monitoring of the Repository

FEP DESCRIPTION:

Monitoring that is carried out during or after operations, for either operational safety or verification of long-term performance, has the potential to detrimentally affect long-term performance. For example, monitoring boreholes could provide enhanced pathways between the surface and the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Appropriate planning of repository activities and the effective implementation of quality control procedures will ensure that monitoring activities have an insignificant effect on long-term repository performance. The extent and, correspondingly, the impact of invasive activities for the purpose of monitoring will be insignificant compared to the scale of construction of the repository itself and will therefore be of low consequence to the long-term performance of the repository. As for all repository activities, these activities will be performed in accordance with NRC regulatory requirements during the preclosure period. Modifications to, and deviations from, the design are subject to regulatory requirements that address deliberate changes and modifications (10 CFR 63.44 [DIRS 180319]). Furthermore, 10 CFR 63.73(a) [DIRS 180319] requires that DOE "promptly notify the [NRC] of each deficiency found in the characteristics of the Yucca Mountain site, and design, and construction of the geologic repository operations area that, were it to remain uncorrected, could: (1) adversely affect safety at any future time; (2) represent a significant deviation from the design criteria and design basis stated in the design application; or (3) represent a deviation from the conditions stated in the terms of a construction authorization or the license, including license specification." As discussed below, deviations in the design, conditions of construction authorization, or license related to monitoring activities, or findings that the monitoring activities may adversely affect safety at any future time, will be evaluated and corrected, as needed.

Regulation 10 CFR Part 63, Subpart F [DIRS 180319] provides a list of requirements for a performance confirmation program to confirm design parameters and to ensure that the NRC is informed of changes needed in the design to accommodate field conditions. 10 CFR 63.131(c) [DIRS 180319] requires that "The program must include in situ monitoring, laboratory and field testing, and in situ experiments, as may be appropriate to provide the data required by paragraph (a) of this section," where paragraph (a) establishes the performance confirmation program. Consequently, the use of in situ monitoring and experimentation is anticipated. However, the regulation also states that any monitoring program must be implemented so that "It does not adversely affect the ability of the geologic and engineered elements of the geologic repository to meet the performance objectives" (10 CFR 63.131(d)(1) [DIRS 180319]). The repository

performance confirmation program for a repository at Yucca Mountain is described in *Performance Confirmation Plan* (BSC 2004 [DIRS 172452]). Appropriate planning of repository activities and the effective implementation of quality control procedures will ensure that monitoring activities have an insignificant effect on long-term repository performance as described in *Perfomance Confirmation Plan* (BSC 2004 [DIRS 172452], Section 3.3; note that the procedure governing the evaluation of site activites has been superseded by SCI-PRO-007, *Determination of Importance and Site Performance Protection Evaluations*). These topics are discussed further in excluded FEPs 1.1.09.00.0A (Schedule and Planning) and 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design), although not with specific reference to monitoring.

The strategy for collection, evaluation, and presentation of monitoring data throughout site characterization, construction, and operation is an integral component of the performance confirmation plan. Preclosure monitoring activities will be diverse and will be modified as appropriate to current and ongoing repository activities. The performance confirmation activities that could have the greatest impact on repository performance are those that are, in some way, intrusive to the repository, through the use of boreholes, wells, drilling, construction of monitoring alcoves, or equipment emplacement in the drifts. These activities include seepage monitoring, subsurface water and rock testing, unsaturated zone testing, saturated zone monitoring, saturated zone alluvium testing, construction effects monitoring, seal testing, monitoring in or near thermally accelerated drifts, and saturated zone fault hydrology testing (BSC 2004 [DIRS 172452], Section 3.3).

Planned monitoring activities in the unsaturated zone, including seepage monitoring, rock and water sampling, and testing of transport properties and field sorptive properties of the host rock, are described in *Performance Confirmation Plan* (BSC 2004 [DIRS 172452], Sections 3.3.1.2, 3.3.1.3, and 3.3.1.4). Seepage monitoring is expected to have low impact because the amount of seepage that could be sampled is insignificant so as to not impact water reaching the drifts. In thermally accelerated drifts, the monitoring and testing period will be followed by closure of the test bed, which may include removing waste packages and instrumentation and sealing, as appropriate (BSC 2004 [DIRS 172452], Sections 3.3.1.2 and 3.3.1.9). Rock and water sampling is expected to have low impact because the drilling to obtain samples is very limited and occurs in a very small portion of the drift and main cross section. Since the amount of rock that may be sampled is an insignificant amount, impact to the pathway of water reaching the drifts is negligible, especially during the periods after closure (BSC 2004 [DIRS 172452], Section 3.3.1.3). Testing of transport properties and field sorptive properties of the host rock are expected to have low impact because the alcoves and drilling to obtain samples is very limited and occurs in a very small portion of the repository. The amount of rock anticipated to contain residual concentrations of tracers is negligible with respect to performance (BSC 2004 [DIRS 172452], Section 3.3.1.4). In general, further evaluations of waste isolation, test-to-test interference, and operations will be conducted during the detailed test planning. Any boreholes or alcoves used may be sealed prior to closure if modeling results indicated that they would increase seepage potential or alter the chemistry of potential water leaving the drifts. Any monitoring boreholes that unexpectedly intercept waste emplacement drifts have addtional sealing requirements (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 09-03).

Planned monitoring activities in the saturated zone, including monitoring, sampling, and analyzing saturated zone water from Nye County and site wells, hydraulic and tracer testing of fault zone hydrologic characteristics, and evaluation of transport properties of the alluvium are described in *Performance Confirmation Plan* (BSC 2004 [DIRS 172452], Sections 3.3.1.5, 3.3.1.6, and 3.3.1.7). Monitoring and sampling from Nye County and site wells are not expected to have an impact because the monitoring of existing wells, including the obtaining of samples, will remove only a very small amount of water from the groundwater reservoir. The amount of water that may be sampled is of such an insignificant amount as to not impact the saturated zone (BSC 2004 [DIRS 172452], Section 3.3.1.5). Hydraulic and tracer testing of faults is not expected to have an impact because the new wells that may be tested, including obtaining samples, remove only a very small amount of water from the fractured and nonwelded tuffs of the groundwater reservoir. The amount of water that may be sampled is of such an insignificant amount as to not impact the saturated zone. The amount of rock that could contain residual concentrations of tracers is of such an insignificant amount as to not impact the chemical environment of groundwater in the flow path (BSC 2004 [DIRS 172452], Section 3.3.1.6). The evaluation of transport properties of the alluvium is not expected to have an impact because the existing wells that will be tested, including obtaining samples, remove only a very small amount of water from the alluvial deposits of groundwater reservoir. The amount of water that may be sampled is of such an insignificant amount as to not impact the saturated zone. The amount of alluvium that will contain residual concentrations of tracers is of such an insignificant amount as to not impact the chemical environment of groundwater in the flow path (BSC 2004 [DIRS 172452], Section 3.3.1.7). In general, further evaluations of waste isolation, test-to-test interference, and operations will be conducted during the detailed test planning. Any boreholes or wells used for performance confirmation may be sealed prior to closure if modeling results indicated that they would increase the probability of vertical migration or alter the chemistry of potential water traveling through the saturated zone along radionuclide transport pathways.

Testing of borehole seals is a regulatory requirement in 10 CFR 63.133(d) [DIRS 180319], which states that "[t]ests must be conducted to evaluate the effectiveness of borehole, shaft, and ramp seals before full scale operation proceeds to seal boreholes, shafts, and ramps." Excluded FEP 2.1.05.03.0A (Degradation of Seals) evaluates the impacts of seal degradation on performance. The impacts of boreholes and monitoring wells are discussed in excluded FEP 1.1.01.01.0A (Open Site Investigation Boreholes) and excluded FEP 1.1.01.01.0B (Influx Through Holes Drilled in Drift Wall or Crown). The effects of boreholes on the transport of radionuclides were shown to be negligible in comparison to the transport pathways associated with fractures and faults. The effects of rock-bolt boreholes drilled in the drift wall or crown were analyzed (BSC 2004 [DIRS 167652], Section 6.5), and the holes were found to increase seepage by less than 2% (DTN: LB0304SMDCREV2.001 [DIRS 173235]; BSC 2004 [DIRS 167652], Table 6-4).

All other performance confirmation activities (including precipitation monitoring, subsurface mapping, seismicity monitoring, corrosion testing, waste-form/waste package testing, drift inspection, and dust buildup monitoring) involve remote monitoring, minimal instrumentation and/or analysis off-site (BSC 2004 [DIRS 172452], Section 3.3). These activities are not expected to adversely affect the ability of the repository to meet performance objectives because the instrumentation is very small and covers an insignificant portion of the rock in the repository (BSC 2004 [DIRS 172452], Section 3.3).

In general, further evaluations of waste isolation, test-to-test interference, and operations will be conducted during the detailed test planning. Any boreholes or alcoves used may be sealed prior to closure if modeling results indicated that they would increase seepage potential or alter the chemistry of potential water leaving the drifts. Any boreholes or wells used for performance confirmation may be sealed prior to closure if modeling results indicated that they would increase the probability of vertical migration or alter the chemistry of potential water traveling through the saturated zone along radionuclide transport pathways.

In summary, monitoring is required to provide data for the assessment of repository performance confirmation (10 CFR 63.131(c) [DIRS 180319]). However, monitoring must not adversely affect the ability of the geologic and engineered elements of the repository to meet the repository performance objectives (10 CFR 63.131(d)(1) [DIRS 180319]). Appropriate planning of repository activities and the effective implementation of quality control procedures will ensure that monitoring activities have an insignificant effect on long-term repository performance.

Based on the preceding discussion, omission of FEP 1.1.11.00.0A (Monitoring of the Repository) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.1.12.01.0A

FEP NAME:

Accidents and Unplanned Events During Construction and Operation

FEP DESCRIPTION:

The long-term performance of the disposal system might be seriously affected by unplanned or improper activities that take place during construction, operation, and closure of the repository.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Inherent in the FEP evaluation approach used as the basis for the FEP screening is the expectation that the repository will be constructed, operated, and closed in accordance with DOE design control, DOE QA process, and NRC license requirements. In 10 CFR 63.73 [DIRS 180319], the NRC requires prompt notification if there is a significant deficiency found in the characteristics, design, and construction of the geologic repository operations area that, were it to remain uncorrected, could adversely affect safety in the future. This includes significant deviations from the design criteria and design basis stated in the application, construction authorization, or the license. Quality control procedures are designed to detect operational events, such as accidents and unplanned events, resulting in deviations from the repository design that might affect long-term performance. It is expected that significant deviations would be detected during regular audits and inspections, pursuant to 10 CFR Part 63, Subpart D [DIRS 180319], and corrected before further work in the repository would be allowed to continue.

In 10 CFR 63.73(a) [DIRS 180319], the NRC requires the DOE to "promptly notify the commission of each deficiency found in the characteristics of the Yucca Mountain site, and design, and construction of the geologic repository operations area that, were it to remain uncorrected, could: (1) adversely affect safety at any future time." Significant deviations that are detected during the operational period will be evaluated and, as needed, corrected. Undetected accidents or undetected unplanned events are expected to be inconsequential, because detected accidents and events will be analyzed and remediated (as necessary). Compliance with the requirements described will ensure that significant effects from accidents or unplanned events on design are not expected.

Further discussion of quality control procedures and regulations covering deviations from design is provided in excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design).

In summary, regulation of accidents and unplanned events during construction and operation will prevent any effects on long-term performance of the repository and will not cause a significant adverse effect on the magnitude or timing of calculated radiological exposures to the RMEI or

radionuclide releases to the accessible environment. Therefore, FEP 1.1.12.01.0A (Accidents and Unplanned Events During Construction and Operation) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 (10 CFR 63 [DIRS 180319]), on the basis of regulation.

INPUTS:

FEP: 1.1.13.00.0A

FEP NAME:

Retrievability

FEP DESCRIPTION:

This FEP addresses design, emplacement, operational, or administrative measures that might be applied or considered to enable or ease retrieval of waste. There may be a requirement to retrieve all or part of the waste stored in the repository, for example, to recover valuable fissile materials or to replace defective waste packages.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Retrievability is a performance objective of the repository as specified in 10 CFR 63.111(e)(1, 2, and 3) [DIRS 180319], and features are included in the design to allow for retrievability for any reason including resource recovery. The regulation specifies that the repository be designed in such a way that it preserves "the option of waste retrieval throughout the period during which wastes are being emplaced … so that any or all of the emplaced waste could be retrieved on a reasonable schedule starting at any time up to 50 years after waste emplacement operations are initiated" (10 CFR 63.111(e)(1) [DIRS 180319]). This precludes further FEP consideration for retrieval past 50 years after the start of waste emplacement. Postclosure retrieval of wastes or other repository system components for resource recovery was addressed by the NRC in the supplementary information for 10 CFR Part 63 (66 FR 55732 [DIRS 156671], p. 55743) as follows:

> As for longer retrieval periods [>50 years]…the Commission has previously noted that its retrieval provision is not intended to facilitate recovery. Waste retrieval is intended to be an unusual event only to be undertaken to protect public health and safety.

Regardless, the repository design is part of the basis of the postclosure evaluation, and aspects of the repository design related to waste retrievability are therefore considered as part of the basis for the TSPA modeling and are included, as noted in included FEP 1.1.07.00.0A (Repository Design). The incorporation of repository design information into the framework of the various TSPA model components has been accomplished using TSPA data input packages (SNL 2007 [DIRS 179394], SNL 2007 [DIRS 179567], SNL 2007 [DIRS 179354], and SNL 2007 ([DIRS 179466]) which are cited, as needed, in the individual model or analysis reports. The drawings contain information regarding material characteristics and properties, component dimensions, and component performance properties under various specified test conditions (e.g., corrosion rates, and seismic response damage areas).

The approach to support successful retrieval operations is to develop the subsurface facility in such a manner that access to the waste is maintained throughout the preclosure period. *Concepts for Waste Retrieval and Alternate Storage of Radioactive Waste* (BSC 2007 ([DIRS 183416], Section 6.2) discusses the details of waste retrieval operations using an electrically powered rail-based vehicle. The design requirements established for the subsurface facility incorporate aspects and parameters that enable retrieval of waste. For example, a design life of 100 years (including maintenance) has been established for the ground support system in the access mains, ventilation mains, and emplacement drifts, to assure access to the emplaced waste packages (BSC 2007 [DIRS 183416], Section 4). A maintenance plan to test, inspect, and repair ground support as necessary in the future has also been planned to support this design strategy. Similarly, the subsurface communication and transportation infrastructure is designed for the preclosure operating life and supports access for maintenance or equipment replacement as needed. The repository design as described in included FEP 1.1.07.00.0A (Repository Design) is based on this approach.

FEP: 1.2.01.01.0A

FEP NAME:

Tectonic Activity - Large Scale

FEP DESCRIPTION:

Large-scale tectonic activity, such as regional uplift, subsidence, folding, mountain building, or other processes related to plate movements, could affect repository performance by altering the physical and thermohydrologic properties of the geosphere.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Large-scale tectonic activity results from interactions between the lithospheric plates covering the surface of the earth. These interactions produce effects that are expressed at a regional scale such as broad uplift, subsidence, folding, faulting, and related changes in geothermal characteristics. These regional-scale effects, if they were to occur at a sufficient rate, could potentially impact flow in the unsaturated and saturated zones and transport properties, thereby affecting dose and radionuclide release to the accessible environment. However, as described below, because rates of tectonic activity in the vicinity of Yucca Mountain are low, the magnitude of any related effects would be small with consequent low impact on flow and transport of radionuclides. Thus, this FEP is excluded based on low consequence.

Site-scale effects of seismic and igneous activity at Yucca Mountain are explicitly addressed in FEPs separate from this one for large-scale tectonic activity. Site-scale effects are expressed locally and include effects such as fault displacement within the waste emplacement area and igneous intrusion of a waste emplacement drift. Seismic-related FEPs addressing local, site-scale effects are:

- 1.2.02.03.0A Fault Displacement Damages EBS Components (Included)
- 1.2.03.02.0A Seismic Ground Motion Damages EBS Components (Included)
- 1.2.03.02.0B Seismic-Induced Rockfall Damages EBS Components (Excluded)
- 1.2.03.02.0C Seismic-Induced Drift Collapse Damages EBS Components (Included)
- 1.2.03.02.0D Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology (Included)

- 1.2.03.02.0E Seismic-Induced Drift Collapse Alters In-Drift Chemistry (Excluded)
- 1.2.03.03.0A Seismicity Associated With Igneous Activity (Included)
- 1.2.10.01.0A Hydrologic Response to Seismic Activity (Excluded)
- 2.2.06.01.0A Seismic Activity Changes Porosity and Permeability of Rock (Excluded)
- 2.2.06.02.0A Seismic Activity Changes Porosity and Permeability of Faults (Excluded)
- 2.2.06.02.0B Seismic Activity Changes Porosity and Permeability of Fractures (Excluded)
- 2.2.06.03.0A Seismic Activity Alters Perched Water Zones (Excluded)

Igneous-related FEPs addressing site-scale effects are:

- 1.2.04.02.0A Igneous Activity Changes Rock Properties (Excluded)
- 1.2.04.03.0A Igneous Intrusion Into Repository (Included)
- 1.2.04.04.0A Igneous Intrusion Interacts With EBS Components (Included)
- 1.2.04.04.0B Chemical Effects of Magma and Magmatic Volatiles (Included)
- 1.2.04.05.0A Magma or Pyroclastic Base Surge Transports Waste (Excluded)
- 1.2.04.06.0A Eruptive Conduit to Surface Intersects Repository (Included)
- 1.2.04.07.0A Ash Fall (Included)
- 1.2.04.07.0B Ash Redistribution in Groundwater (Excluded)
- 1.2.04.07.0C Ash Redistribution Via Soil and Sediment Transport (Included)
- 1.2.06.00.0A Hydrothermal Activity (Excluded)
- 1.2.10.02.0A Hydrologic Response to Igneous Activity (Excluded)

This approach of separately considering regional-scale and site-scale effects ensures that all aspects of tectonic activity are appropriately addressed.

Low Rates of Tectonic Activity—Yucca Mountain lies within the southern Great Basin of the Basin and Range physiographic province (BSC 2004 [DIRS 169734], Figure 2-1a) and is located on the south flank of a large Miocene caldera complex (BSC 2004 [DIRS 168030], Section 6.3.1). Yucca Mountain is also within the Walker Lane domain, an approximately 100-km-wide structural belt along the western edge of the Basin and Range province. Walker Lane is characterized by northwest- and north-to-northeast-striking strike-slip faults that accommodated much of the early extension in this region (BSC 2004 [DIRS 169734], Section 2.2.1).

On a more local scale, Yucca Mountain is within the Crater Flat structural domain as defined by Fridrich (1999 [DIRS 118942], pp. 170 through 178). The Crater Flat structural domain (also referred to as the Crater Flat structural basin) includes the Crater Flat topographic basin on the west, and Yucca Mountain, near the center of the structural basin, where Miocene ash-flow tuffs crop out. These exposed tuff units comprise Yucca Mountain and adjacent mesas. Structurally, Yucca Mountain is dominated by subparallel fault blocks that trend to the north and tilt to the east. The blocks of ash-flow tuff are bounded by typical Basin and Range style, high-angle, generally west-dipping, normal and oblique faults that formed by rapid east-west extension during the waning phases of Miocene volcanism. Secondary intrablock faults are common (BSC 2004 [DIRS 168030], Section 6.3.1; BSC 2004 [DIRS 169734], Section 3.5).

Extensional tectonics has characterized the Yucca Mountain region since Oligocene time (BSC 2004 [DIRS 169734], Section 2.4.2). During the period of peak tectonism (approximately 11.6 Ma to 12.7 Ma), the western part of Crater Flat basin subsided due to the basin extending from 18% to 40% in 1.1 million years or less (Fridrich et al. 1998 [DIRS 164051], p. 1). After 11.6 Ma, the rate of extension in the basin declined in a roughly exponential manner. The late Quaternary rate of extension is less than 1% of the initial rate (Fridrich et al. 1998 [DIRS 164051], pp. 1 and 13) and may be as low as 0.1% to 0.2% per million years (Fridrich et al. 1998 [DIRS 164051], pp. 19 and 20). The pattern of Quaternary deformation mimics the pattern of middle Miocene activity, but at substantially lower rates (Fridrich et al. 1998 [DIRS 164051], pp. 1 and 2). Even during the Quaternary, the rate of subsidence appears to have diminished consistently over the last several million years and the locus of subsidence due to extension has migrated west of Yucca Mountain (inferred from Fridrich 1999 [DIRS 118942], p. 189; Dixon et al. 1995 [DIRS 102793], p. 765).

Fridrich (1999 [DIRS 118942], p. 190) also notes that recent extension across the Crater Flat structural domain diminishes from south to north. Across the southern part of the Crater Flat basin, the northwest-southeast lengthening is approximately 0.1 m per thousand years. Across central Yucca Mountain the late Quaternary extension rate is approximately one-half as great, and across northern Yucca Mountain it is an order of magnitude lower.

Average slip rates over the past tens to hundreds of thousands of years for block bounding faults in the Crater Flat structural domain provide additional evidence of the low rate of tectonic activity (BSC 2004 [DIRS 168030], Table 6). As part of the probabilistic seismic hazard analysis for Yucca Mountain, six teams of experts assessed fault slip rates. Their interpretations of the data indicate that slip rates for active faults in the Yucca Mountain vicinity range from 0.001 to 0.05 mm/yr. Even given uncertainties in slip-rate estimation, the slip rates at Yucca Mountain are low to very low. For example, faults with slip rates of 0.01 mm/yr or less are

associated with extremely low rates of activity in a classification of active faulting developed by Slemmons and dePolo (1986 [DIRS 106815]). The slip rates observed at Yucca Mountain also fall within the moderately low to low activity fault classification in a regional scheme developed by dePolo (1994 [DIRS 104855], p. 49). This scheme uses slip rates to categorize the activity of normal faults in the Basin and Range province. The slip rates on faults at Yucca Mountain are equal to, or less than, the lowest values in a regional compilation of slip rates developed by McCalpin (1995 [DIRS 104770]) from fault studies in the entire Basin and Range province. It should be noted that paleoseismic investigations capable of providing slip rates are rarely conducted on faults with these low rates of activity.

In addition to the information on the rate of tectonism over the past tens to hundreds of thousands of years from average fault slip rates, data are also available on shorter-term deformation rates from geodetic studies. Savage et al. (1999 [DIRS 118952]; 2001 [DIRS 183366]) evaluated strain accumulation in the vicinity of Yucca Mountain for the periods 1983 to 1998 and 1993 to 1998 using Geodolite and Global Positioning System data. The measurement networks had apertures of about 35 and 50 km. They found principal strain accumulation rates of 22.8±8.8 nanostrain/year N77.6±13.5°W and −8.8±11.9 nanostrain/yr N12.5±13.5°E for the 1993 to 1998 period and 2±12 nanostrain/year N87±12°W and −22±12 nanostrain/year N03±12°E for the 1983 to 1998 period. Wernicke et al. (1998 [DIRS 103485]) interpreted Global Positioning System data for the period 1991 to 1998 to indicate a N65°W extension rate of 50±9 nanostrain/year. However, the factor of 2 greater extension rate may result from not explicitly taking into account transient post-seismic effects of the Little Skull Mountain earthquake that occurred in 1992 (Savage et al. 1999 [DIRS 118952], p. 17,627; Wernicke et al. 2004 [DIRS 175199], Section 1). For the Savage et al. (2001 [DIRS 183366]) results, only the west-northwest extension rate differs significantly from zero.

A network of continuously recording Global Positioning System stations was established in the Yucca Mountain region in 1999. Data from the first 3.75 years of operation indicate 20±2 nanostrain/year N20°W right-lateral shear (Wernicke et al. 2004 [DIRS 175199], Section 5). The source of this contemporary strain accumulation is not well resolved. Models of strain accumulation associated with regional faults suggest that the effect of just the Death Valley fault is insufficient to explain the data, implying that other faults may be contributing to the strain field (Wernicke et al. 2004 [DIRS 175199], Section 4). While questions remain as to the source and significance of contemporary strain accumulation, if any, in the Yucca Mountain region, the data suggest that strain rates are low, although perhaps currently higher than the long-term average determined from geologic observations of fault slip over the past tens to hundreds of thousands of years.

Volcanism in the Yucca Mountain vicinity also provides information on the rate of large-scale tectonic activity. The earliest volcanism in the Yucca Mountain region was dominated by a major episode of caldera-forming, silicic volcanism that occurred primarily between about 15 and 11 million years ago, forming the southwestern Nevada volcanic field (Sawyer et al. 1994 [DIRS 100075]). Silicic volcanism was approximately synchronous with a major period of extension, which occurred primarily between 13 and 9 million years ago (Sawyer et al. 1994 [DIRS 100075], Figure 4). Silicic volcanism has not occurred in the Yucca Mountain region in the last 7 or 8 million years. The commencement of basaltic volcanism occurred during the latter part of the silicic caldera-forming phase as extension rates waned. Small-volume basaltic

volcanism has continued into the Quaternary as part of a general decline in eruption volume over the past 11 million years (Perry et al. 1998 [DIRS 144335], Chapter 2).

Post-Miocene volcanism (younger than 5 million years) has occurred in six episodes in the Yucca Mountain region, at approximately 4.8, 3.7, 3.1, 1.0, 0.4, and 0.08 million years ago (Perry et al. 1998 [DIRS 144335], Table 2.B; Heizler et al. 1999 [DIRS 107255]). The total eruption volume of the post-Miocene basalts is about 6 km^3. The volume of individual episodes has decreased progressively through time, with the three Pliocene episodes having volumes of approximately 1 to 3 km^3 each and the three Quaternary episodes having a total volume of only about 0.5 km^3 (Perry et al. 1998 [DIRS 144335], Table 3.1; DTN: LA0004FP831811.002 [DIRS 149593], Table S00235_001). The Quaternary volcanoes are of small volume (about 0.1 km3 or less) and typically consist of a single main scoria cone surrounded by a small field of aa basalt flows, which commonly extend about 1 km from the scoria cone.

The decreased eruptive volume through time, together with geochemical evidence (Perry et al. 1998 [DIRS 144335], p. 4-8), indicates that the intensity of mantle melting processes that produce basaltic magma beneath the Yucca Mountain region has waned over the past 5 million years (Perry and Crowe 1992 [DIRS 106488], p. 2,359). Considered in terms of total eruption volume, frequency of eruptions, and duration of volcanism, basaltic volcanic activity in the Yucca Mountain region in the past 5 million years defines one of the least active basaltic volcanic fields in the western United States (CRWMS M&O 1998 [DIRS 105347], Figure 4-2).

Thus, geologic, geodetic, and volcanic evidence indicate that the rate of large-scale tectonic activity in the Yucca Mountain region is currently low and has been low during the recent geologic past (i.e., tens to hundreds of thousands of years). Because the rate of large-scale tectonic activity changes slowly, in response to changes in the plate tectonic setting, rates similar to those observed now and in the recent geologic past are expected to persist for the coming tens to hundreds of thousands of years. Effects related to large-scale tectonic activity (such as uplift, subsidence, folding, and mountain building) during the postclosure period, therefore, are expected to be on the order of meters. For example, if subsidence related to faulting occurred at a rate of 0.01 mm/yr, the net subsidence over ten thousand years would be 0.1 m. Even for a rate of 1 mm/yr, the total subsidence over ten thousand years would be only 10 m. Such a change is negligible relative to the current distance between the base of the repository and the saturated zone (about 300 m) and to maximum increases in water table elevation (about 115 m) during Plio-Pleistocene time when different climates were in effect at Yucca Mountain (Stuckless 1996 [DIRS 119051], pp. 98 to 99). Thus, the low rate of large-scale tectonic activity leads to small magnitude effects that have low consequence to overall repository performance. Therefore, large scale tectonic activity has been excluded from the TSPA on the basis of low consequence.

Based on the previous discussion, omission of FEP 1.2.01.01.0A (Large-Scale Tectonic Activity) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.02.01.0A

FEP NAME:

Fractures

FEP DESCRIPTION:

Groundwater flow in the Yucca Mountain region and transport of any released radionuclides may take place along fractures. The rate of flow and the extent of transport in fractures are influenced by characteristics such as orientation, aperture, asperity, fracture length, connectivity, and the nature of any linings or infills.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Fractures are included in process models for flow and transport in the UZ and the SZ flow and transport models. The UZ flow model is based on a dual-permeability concept with fractures and matrix each represented by a continuum in the dual permeability mesh (SNL 2007 [DIRS 184614]). The fracture continuum represents the spatially averaged flow through discrete fractures and interacts with the matrix continuum, which comprises matrix blocks separated by fractures. The SZ flow model is based on a single, effective continuum with the effects of fractures intrinsically incorporated into unit permeabilities.

Unsaturated Zone Flow Model

Fracture continuum properties include permeability, porosity, interface area per unit volume, van Genuchten α and m parameters (the saturation-capillary pressure and relative permeability factors), residual saturation, and an active fracture parameter (which accounts for preferential flow in a subset of the total fracture population). These parameters and the associated ranges of values are obtained as described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.1.5) and adjusted as described in Section 6.2.3 of that report (SNL 2007 [DIRS 184614]) for each unsaturated zone model layer (DTN: LB0205REVUZPRP.001 [DIRS 159525]).

Fracture permeability is based on field measurements that integrate discrete fracture characteristics such as orientation, aperture, asperity, fracture length, connectivity, and the nature of any linings or infills. Permeabilities and other properties are further calibrated as described in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3) and *Analysis of Hydrologic Properties Data* (BSC 2004 [DIRS 170038]). The fracture continuum properties are used as inputs to the UZ flow model and their effects are incorporated into the output flow fields developed for use in the TSPA (output flow fields are in DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507], where each DTN represents a different climate).

The permeability of bedrock (either unfractured PTn or fractured TCw depending on location) significantly impacts rates and distributions of net infiltration (SNL 2008 [DIRS 182145], Section 6.1.2). *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5.2.6) discusses conceptual treatment of fractures in the infiltration model and numerical values and parameters used (SNL 2008 [DIRS 182145], Sections 6.5.2.5[a] and 6.5.2.6).

The influence of fractures on radionuclide transport through the unsaturated zone is implicitly investigated using a dual-permeability model (SNL 2008 [DIRS 184748], Section 6.4.3). The influences of fracture characteristics on unsaturated zone flow are evident in the output flow fields (SNL 2008 [DIRS 184748], Section 6.5.1; DTNs: LB0612PDFEHMFF.001 [DIRS 179296]; LB0701MOFEHMFF.001 [DIRS 179297]; LB0701GTFEHMFF.001 [DIRS 179160]; LB0702PAFEM10K.002 [DIRS 179507]). Fracture aperture, porosity, and frequency (DTNs: LB0205REVUZPRP.001 [DIRS 159525] and LB0207REVUZPRP.001 [DIRS 159526]) affecting unsaturated zone radionuclide transport are summarized in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.7). Fracture porosity and frequency data are statistically sampled during TSPA multirealization simulations using the distributions provided in DTN: LA0701PANS02BR.003 [DIRS 180497].

Flow processes in fractures or other channels are important for seepage because the amount of seepage is controlled by the fracture diversion capacity in the drift vicinity. This process is modeled in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.3). Seepage-relevant parameters are determined in *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.3 and 6.5) and are based upon data related to fracture–matrix interactions developed in *In Situ Field Testing of Processes* (BSC 2004 [DIRS 170004], Sections 6.1 and 6.2). The seepage simulation results developed in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652]) are abstracted for use in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.3.1). These flow processes are influenced by fracture characteristics such as orientation, aperture, asperity, length, connectivity, and fillings. All seepage process models that feed into the seepage abstraction explicitly simulate the flow processes in fractures using appropriate continuum properties (SNL 2007 [DIRS 181244], Section 6.4).

For ambient seepage, the relevant continuum properties are the continuum permeability and the effective fracture capillary strength in the vicinity of the drift. For the seepage abstraction, probability distributions describing the spatial variability and uncertainty of these parameters have been developed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.6) based on air-permeability measurements and liquid-release tests combined with inverse modeling (SNL 2007 [DIRS 181244], Sections 6.6 and 6.4). Ambient seepage calculations will be conducted within the TSPA by sampling from these probability distributions and interpolating seepage rates from the lookup tables given in DTNs: LB0702PASEEP01.001 [DIRS 179511] and LB0702PASEEP02.001 [DIRS 181635]. During the thermal period, the ambient seepage rates will be adjusted based on the TH modeling results from *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]), which explicitly simulate thermally perturbed fracture flow conditions. Results are given in DTN: LB0301DSCPTHSM.002 [DIRS 163689]. Thermal-hydrologic-mechanical (THM) and thermal-hydrologic-chemical

(THC) effects on fracture characteristics are evaluated with process models that explicitly account for fracture flow affected by THM and THC parameter alterations (SNL 2007 [DIRS 181244], Section 6.4.4; excluded FEPs 2.1.09.12.0A (Rind (Chemically Altered Zone) Forms in the Near-Field) and 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository)). It has been demonstrated that these potential alterations need not be addressed in TSPA because the effects on seepage quantities are expected to be small and any anticipated changes are expected to lead to less seepage (SNL 2007 [DIRS 181244], Section 6.5.1.4[a]).

Flow processes in fractures or other channels affect modeled THC coupled processes because of their strong effect on thermal-hydrologic behavior (SNL 2007 [DIRS 181244], Sections 6.4.4.1 and 6.4.4.2) and their strong effect on water and gas chemistry (SNL 2007 [DIRS 177404], Section 6.2.1). The latter effect is primarily due to volatilization of steam and CO_2 from the rock-matrix water and subsequent transport and condensation in fractures. The amount of CO_2 mobilized by steam directly affects the pH of the condensate, which in turn affects the degree of water–rock interaction and water chemistry. These THC processes are influenced by fracture characteristics such as orientation, aperture, asperity, length, connectivity, and fillings. The THC seepage model explicitly simulates the flow processes in fractures using appropriate continuum properties (SNL 2007 [DIRS 177404], Sections 6.4.3, 6.4.4, and 6.4.7).

Summary tables of concentrations through time are presented in DTNs LB0302DSCPTHCS.002 [DIRS 161976], which is output from *Drift-Scale THC Seepage Model* (SNL 2007 [DIRS 177404]), and in DTN: LB0307DSTTHCR2.002 [DIRS 165541], which is output from *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]), and summary statistics through time are presented in DTN: LB0311ABSTHCR2.001 [DIRS 166714], which is output from *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244]). These data are used to feed and/or provide the technical basis for *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412]), which generates the lookup tables used in the TSPA model.

Saturated Zone Flow Model

Groundwater flow through fractures in the volcanic units is included in the SZ flow and transport model described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]). Groundwater flow through the fractured volcanic units is modeled in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Sections 6.3.1.2, 6.3.1.9, and 6.3.1.10) using an effective continuum approach (SNL 2007 [DIRS 177391], Section 6.4.1). Observations at Yucca Mountain indicate that in the fractured volcanic units delineated in the hydrogeologic framework model (SNL 2007 [DIRS 174109]), flow is primarily through the fracture network instead of the matrix. Furthermore, at the scales of interest (hundreds of meters to kilometers), the fracture networks appear to be well-connected over large distances. The drawdown response to pumping at wells surrounding the C-wells complex in multiwell pump tests indicates a well-connected fracture network in the Miocene tuffaceous rocks in this area (Geldon et al. 1997 [DIRS 100397]; Geldon et al. 1998 [DIRS 129721], p. 31; SNL 2007 [DIRS 177394], Section 6.2). In addition, Finsterle (2000 [DIRS 151875]) demonstrated through a comparison of continuum and discrete-fracture models that the continuum approach is valid for predicting long-term average seepage rates. These findings support the use of a continuum approach for

simulating groundwater flow in fractured rocks in the saturated zone, which is a larger scale process than drift seepage and, thus, more accurately represented as a continuum.

Groundwater flow through the fractured rock in the saturated zone was simulated using a continuum representation of the media. Several continuum approaches are available, including single continuum, dual porosity, and dual permeability–dual porosity. Often, the single continuum approach is used to model relatively homogeneous media while the dual-permeability approach is used for heterogeneous media that contain distinct and variable permeability zones lying in the same representative elemenatary volume (e.g., a fractured porous medium). In such heterogeneous media, advective flow demonstrates distinctively different flow rates and a dual-permeability model may be better suited to predict flow and transport through this type of system.

The dual-porosity approach simulates the flow of water in a heterogeneous system where local interzonal permeabilities differ by several orders of magnitude. This method is useful for simulating flow and transport in fractured media where the permeability of the matrix is much less than fractures, as is the case for fractured tuff units in the saturated zone. Fast flow occurs in fractures, but solute transport is tempered by diffusion into the matrix. In this case, the matrix acts as a large storage reservoir for water and solutes. Steady-state flow in fractured media can be successfully simulated with a single-continuum approach; however, accurate representation of transport processes, including matrix diffusion, requires a dual-porosity, effective-continuum approach for fractured tuff in the saturated zone (SNL 2008 [DIRS 184806], Section 6.3).

As discussed in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014], Section 6.3), only a subset of existing fractures is observed to transmit flow in the saturated zone. The hydrogeologic characteristics of these "flowing interval" zones vary spatially. In the SZ transport abstraction and the one-dimensional transport models (SNL 2008 [DIRS 183750], Sections 6.3.1 and 6.3.2]), variability in the groundwater specific discharge due to variability in fracture permeability and orientation is modeled by scaling the horizontal anisotropy in permeabilities (SNL 2007 [DIRS 177391], Section 6.5.2.10) with stochastically sampled scaling parameters for groundwater specific discharge and horizontal anisotropy in the volcanic units. Additionally, the characteristics of the fracture properties, such as fracture orientation, aperture size, degree of infilling, and tortuosity are modeled through probabilistically modeled parameters. The parameters are described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2.1, 6.5.2.4, 6.5.2.5, 6.5.2.8, 6.5.2.9, 6.5.2.10, 6.5.2.11, 6.5.2.12, and 6.5.2.15, Tables 6-8, and 6-7[a]).

FEP: 1.2.02.02.0A

FEP NAME:

Faults

FEP DESCRIPTION:

Numerous faults of various sizes have been noted in the Yucca Mountain region, and specifically in the repository area. Faults may represent an alteration of the rock permeability and continuity of the rock mass, an alteration or short-circuiting of the flow paths and flow distributions close to the repository, and/or unexpected pathways through the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Stratigraphic units or layers and fault geometries in the Yucca Mountain vicinity are defined in *Geological Framework Model (GFM2000)* (BSC 2004 [DIRS 170029]) and in DTN: MO0012MWDGFM02.002 [DIRS 153777]. These sources provide the basis for the UZ model grid as outlined in *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855]). Major displacement, dip-slip, strike-slip, and detachment faults within the model domain are discretized in the mountain-scale UZ flow and transport models described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Sections 6.1.5, 6.2.2, 6.6.2.3, and 6.7.3) and *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855], Section 6.6.1). These faults are represented in the UZ model grid developed in *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855]) as 30-m-wide vertical or inclined discrete zones that include existing displacements affecting the relative geometry of the hydrogeologic model units. Specific hydrogeologic properties are assigned to fault zones. Fault properties (matrix and fracture parameters) are found in DTN: LB0612MTSCHPFT.001 [DIRS 180296]. Calibration of these properties is described in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3.4) and *Analysis of Hydrologic Properties Data* (BSC 2004 [DIRS 170038]). The fault properties are used as inputs to the UZ flow model and their effects are incorporated into the output flow fields developed for use in TSPA (output flow fields are in DTNs: LB0612PDFEHMFF.001 [DIRS 179296]; LB0701MOFEHMFF.001 [DIRS 179297]; LB0701GTFEHMFF.001 [DIRS 179160]; and LB0702PAFEM10K.002 [DIRS 179507], where each DTN represents a different climate).

The influence of faults on TSPA dose predictions is based on the effects of faults on radionuclide transport and drift seepage abstractions. The influence of faults on radionuclide transport is included through the use of pregenerated flow fields from the UZ flow model (as described above) that include the faults in the three-dimensional model in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.1; DTNs: LB0612PDFEHMFF.001 [DIRS 179296]; LB0701MOFEHMFF.001 [DIRS 179297]; LB0701GTFEHMFF.001 [DIRS 179160]; and LB0702PAFEM10K.002 [DIRS 179507]), and

through the assignment of specific transport propeties of fractures within the faults (SNL 2008 [DIRS 184748], Section 6.5.7). The UZ flow model and UZ transport model compute processes on the same numerical grid, therefore, the direct representation of major faults in the UZ flow model grid is also contained in the UZ transport model abstraction (SNL 2008 [DIRS 184748], Section 6.5.1). The effects of faults on the percolation flux arriving at the waste emplacement drifts are included through the UZ flow model output of percolation flux at the PTn/TSw interface (DTNs: LB0612PDPTNTSW.001 [DIRS 179150]; LB0701MOPTNTSW.001 [DIRS 179156]; LB0701GTPTNTSW.001 [DIRS 179153]; and LB0702UZPTN10K.002 [DIRS 179332]). This flux is the boundary condition used by the seepage abstraction in TSPA (SNL 2007 [DIRS 181244], Section 6.6.5.1).

Geologic features and hydrostratigraphic units are included in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]), Section 6.3.1) in a configuration that accounts for the effects of existing faults based on the hydrogeologic framework model (SNL 2007 [DIRS 174109], Section 6) and mapped faults identified in DTNs: GS010608312332.001 [DIRS 155307] and GS010908314221.001 [DIRS 162874]. Important faults were represented as calibration parameters in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.3.1.10). As discussed in that report (SNL 2007 [DIRS 177391], Section 6.4.3.1), and in *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Sections 6.1, 6.3.1.1, 6.3.1.2, 6.4.2, and 6.4.4), the hydrogeologic framework model presents a simplified representation of faults and other hydrogeologic features (such as zones of hydrothermal alteration) that affect saturated zone flow and provide the basis upon which the saturated zone site scale flow model is developed.

The hydrogeologic properties of discrete features are developed through calibration of the saturated zone site-scale flow model (SNL 2007 [DIRS 177391], Section 6.5.1.3). Faults in the model area can dip at almost any angle, but most are high-angle faults. Given numerical flow model resolution (250 × 250 m^2 horizontal cells) and uncertainties in fault orientation, they are treated as vertical features. Hydraulic testing in the volcanic units of the saturated zone has investigated portions of the aquifer and has yielded sufficient data to estimate horizontal permeability anisotropy, which may be influenced by faults (SNL 2007 [DIRS 177394], Section 6.2.6). Faults in the saturated zone site-scale flow model domain that were considered important to groundwater flow (some of which are critical to achieve calibration like the Solitario Canyon Fault) were included in the model. Although numerous faults exist near Yucca Mountain, only some affect groundwater flow patterns by acting as either conduits or barriers (SNL 2007 [DIRS 177391], Sections 6.3.1.10 and 6.4.3.7). Additionally, faults can enhance dispersion by increasing permeability heterogeneities along saturated zone flowpaths (SNL 2008 [DIRS 184806], Sections 6.3.1.0 and 6.4.3.7, and Table 6-7).

The offsets of hydrostratigraphic units across major faults are incorporated into the model and some key faults (e.g., the Solitario Canyon, U.S. Highway 95, and Fortymile Wash Faults) are included as low- or high-permeability features (SNL 2007 [DIRS 177391], Table 6-7).

Abstraction model parameters, including the ratio of horizontal anisotropy in permeability (SNL 2008 [DIRS 183750], Section 6.5.2.10), and the groundwater specific discharge multiplier (SNL 2008 [DIRS 183750], Section 6.5.2.1[a]), include the potential impacts of faults on

groundwater flow and are modeled probabilistically to account for the uncertainty in hydrologic properties associated with faults and fractures in the volcanic units (SNL 2008 [DIRS 183750], Sections 6.5.2.1[a] and 6.5.2.10). For a more detailed description of specific faults, see *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Table 6-7).

FEP: 1.2.02.03.0A

FEP NAME:

Fault Displacement Damages EBS Components

FEP DESCRIPTION:

Movement of a fault that intersects drifts within the repository may cause the EBS components to experience related movement or displacement. Repository performance may be degraded by such occurrences as tilting of components, component-to-component contact, or drip shield separation. Fault displacement could cause a failure as significant as shearing of drip shields and waste packages by virtue of the relative offset across the fault, or as extreme as exhumation of the waste to the surface.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Fault displacement is considered to be a potentially disruptive process with sudden relative rock/soil displacements across a fault surface. The effects of fault displacement are potentially relevant to the integrity of the waste packages, drip shields, and cladding, and are included in the performance assessment to demonstrate compliance with the individual protection requirements of the proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]). The effects of fault displacement are excluded from the performance assessments to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) and with the groundwater protection standard (10 CFR 63.331 [DIRS 180319]). This is appropriate because damage from fault displacement occurs for seismic events with exceedance frequencies less than 2.5×10^{-7} per year (SNL 2007 [DIRS 176828], Table 6-67), which is substantially below the requirement to consider events with 1 chance in 10 over 10,000 years (10^{-5} per year) for the individual protection and groundwater protection standards, in accordance with the proposed rule in 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394])).

Once a waste package has failed from fault displacement, it is conservatively assumed that its associated drip shield cannot deflect seepage away from the waste package and that the waste form within the failed waste package is directly exposed to the water or air of the repository environment. The impacts of seismically induced ground motion, rockfall, and drift collapse on EBS components are addressed under separate FEPs: included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components), and included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components), respectively. Floor buckling damage to the emplacement pallet and the invert in the absence of seismic events is discussed in excluded FEP 2.1.07.06.0A (Floor Buckling).

This FEP description mentions extreme conditions of fault displacements leading to waste exhumation. The depth of the repository below the surface is approximately 200 m or greater (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06). The potential for exhumation due to fault movement is not considered credible given the low fault slip rates on the block-bounding faults (i.e., Solitario Canyon and Bow Ridge). Anticipated fault slip rates for these faults are at most 0.03 mm/yr, equivalent to 30 cm or less in 10,000 years (BSC 2004 [DIRS 168030], Table 6). The potential for waste exhumation from fault displacement is not considered further.

Technical Approach for Inclusion—The potential for fault displacement damage from block-bounding faults, such as the Solitario Canyon Fault, is not considered in the TSPA model, as discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.11.3). The Solitario Canyon Fault lies outside the emplacement area of the repository and repository design requires a minimum stand-off of 60 m between this type of fault and the emplacement drifts (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-05). A second named fault, the Ghost Dance Fault, runs parallel to the Solitario Canyon Fault and between the waste emplacement areas of the repository (SNL 2007 [DIRS 176828], Figure D-1). The main Ghost Dance Fault is not considered in the TSPA model because no waste packages will lie on it, although the western splay off the main Ghost Dance Fault is considered in the TSPA model (SNL 2007 [DIRS 176828], Section 6.11.3).

The potential for fault displacement damage from intra-block faults and other generic faulting features that may exist within the repository footprint is included in the TSPA model for the individual protection requirement. For a fault displacement that occurs across an emplacement drift, a sudden discontinuity in the floor and roof of the tunnel may occur. Fault displacement is assumed to be on a discrete plane, and to occur perpendicular to the tunnel axis with the displacement being purely vertical (SNL 2007 [DIRS 176828], Section 6.11.1.1). Such a displacement would result in a vertical offset of the tunnel relative to the adjacent section across the fault. The vertical offset could cause shearing of the waste package and drip shield and cladding at that location. The vertical offset could also cause separation between adjacent drip shields.

The technical basis for inclusion of this FEP involves a comparison of the potential fault displacements to the clearances between various elements of the repository design (i.e., waste package-to-drip shield spacing, waste package-to-drift wall spacing, and set-back requirements). The clearances have been analyzed for two conditions: (1) with an intact drip shield, and (2) with a failed drip shield, when the waste package is surrounded by rubble (SNL 2007 [DIRS 176828], Section 6.11.1). For the intact drip shield, the approximation is made that the emplacement pallet collapses into the invert on the elevated side of the fault. No credit is taken for the potential increase in clearances due to further shifting of the ballast in the invert or for the potential upward movement of the drip shield during the fault displacement. For a failed drip shield, the waste package is surrounded by rubble and the available clearance around the waste package during a fault displacement is estimated to be one-quarter of the waste package outer diameter. The fault displacement damage abstraction for TSPA is based on the minimum predicted clearances, which correspond to the clearances for the case with the failed drip shield.

If a waste package is damaged by fault displacement, the damaged area is sampled from a uniform distribution of 0% to 100% of the lid area of the waste package (SNL 2007 [DIRS 176828], Section 6.11.5). The uniform distribution is a simple approximation to the upper and lower damage bounds in lieu of detailed structural response calculations. The upper bound is a reasonable estimate for a severely crimped waste package that loses its lid because of cracking in the welds that hold the lid in place. The lower bound is a reasonable estimate for a waste package that is minimally damaged, either because the fault displacement slightly exceeds the available clearance or because the vertical displacement occurs toward the center of the waste package, resulting in a crimp that is far from the waste package lids.

Crimping and shear from vertical displacement are the main damage mechanisms for the waste package because the package is a robust structure that will not be damaged by tilting or minor displacements. In addition, because of the ability of the waste package to move on the pallet, it is not anticipated that a large enough bending moment or torsion can be applied to cause failure while the drip shield is intact. After the drip shield fails, the rubble surrounding the waste package acts to distribute loads over the surface of the waste package, reducing concentrated bending moments or torsion on the waste package.

The lid welds have the potential to fracture, separating the lid from the waste package and potentially exposing the entire waste form to water seepage and consequent release (SNL 2007 [DIRS 176828], Section 6.11.5). Once radionuclides are released from the EBS, flow and transport in the unsaturated zone and the saturated zone are based on the same models and algorithms as are used for nominal conditions. An exception is that changes can occur in the in-drift environment, due to seismic-induced drift collapse, as discussed in included FEP 1.2.03.02.0D (Seismic-induced Drift Collapse Alters In-drift Thermohydrology).

Damage to a drip shield from fault displacement is assumed to be 100% if it surrounds a damaged waste package or 0% if it does not. A sheared drip shield will allow all seepage to pass through it; that is, there is no flux splitting (diversion of seepage) on the drip shield. Drip shield separation is not relevant here because a sheared drip shield already allows seepage to pass through it. For example, the relative vertical displacement required to separate two adjacent drip shields is on the order of one meter (BSC 2004 [DIRS 169753], Section 5.2.1). A one meter displacement corresponds to an exceedance frequency less that 10^{-7} per year for the intrablock faults that can intersect the emplacement drifts (SNL 2007 [DIRS 176828], Table 6-61). The ground motions associated with exceedance frequencies less than 10^{-7} per year will generally result in sheared drip shields on the intrablock faults, so drip shield separation is not relevant.

The output of the fault displacement damage abstraction is the number of waste packages failed by fault displacement and the combined surface area from the waste packages that fail from fault displacement. The number of waste packages failed is based on lookup tables that relate exceedance frequencies between 2.5×10^{-7} and 10^{-8} per year with the expected number of waste package failures for two representative waste package groups (SNL 2007 [DIRS 176828], Sections 6.11.4 and 6.11.5, particularly Table 6-67). The two representative waste package groups abstracted into the TSPA model are a TAD canister group, with naval waste packages and TAD canister-bearing waste packages, and a codisposal group with all types of codisposal waste packages.

Seismic Consequence Abstraction (SNL 2007 [DIRS 176828]) provides an algorithmic description for the fault displacement damage abstraction for the EBS components (SNL 2007 [DIRS 176828], Section 6.12.2, step 21), as well as a definition of parameters for the TSPA model that specifically relate to breach of the waste packages and drip shields from fault displacement (SNL 2007 [DIRS 176828], Table 6-93).

FEP: 1.2.03.02.0A

FEP NAME:

Seismic Ground Motion Damages EBS Components

FEP DESCRIPTION:

Seismic activity that causes repeated vibration of the EBS components (drip shield, waste package, pallet, and invert) could result in severe disruption of the drip shields and waste packages, through vibration damage or through contact between EBS components. Such damage mechanisms could lead to degraded performance.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Ground motion associated with seismic activity has the potential to disrupt the integrity of the waste package and other EBS components, which could lead to breaching of the waste packages and radionuclide release. The EBS components are the waste package, the waste package internals, the waste form/cladding, the emplacement pallet, the drip shield, the drift invert, and the emplacement drift. Damage to the waste package and its internals from vibratory ground motion is included in TSPA. Damage to the cladding is not considered here because all fuel cladding (stainless steel and Zircaloy) for commercial SNF is considered to be breached upon emplacement in the repository, as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Table 7-2[a]). Damage to the drip shield is excluded because: (1) the presence of stress corrosion cracks on the drip shield does not compromise its ability to divert seepage away from the waste package (see excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield)), (2) drip shield separation is not predicted to occur (SNL 2007 [DIRS 176828], Section 6.7.3), and (3) failure of the drip shield from waste package impacts is not predicted to occur (SNL 2007 [DIRS 176828], Section 6.8.5). The drift invert and the emplacement pallet could also be damaged as a result of ground motion, but these components do not contribute to the capability of the EBS barrier to prevent the release of radionuclides and, in this respect, such effects do not require further consideration.

The rockfall induced by vibratory ground motion can have a significant impact on the emplacement drifts and other EBS components. The response of EBS components to rockfall induced by vibratory ground motion is considered by several other FEPs. The response of waste packages and drip shields in a partly or completely collapsed drift in the lithophysal units of the repository is discussed in included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). The response of the drip shield plates and waste packages to rock block impacts in nonlithophysal units is discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components).

The effects of seismic events with exceedance frequencies as low as 10^{-8} per year are included in the performance assessments to demonstrate compliance with the individual protection stardard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). These performance assessments are represented by the seismic scenario class (SNL 2007 [DIRS 178765], Section 6.6). The seismic scenario class is represented by two modeling cases. The first modeling case includes the response of EBS components to the vibratory ground motion associated with a seismic event. This first modeling case includes the effects of general corrosion on EBS components during the period of geologic stability, as required by proposed 10 CFR 63.342(c)(i) (70 FR 53313 [DIRS 178394]). The second modeling case includes the response of EBS components to fault displacement, and is discussed further in included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components).

The effects of unlikely seismic events (events having less than one chance in 10 of occurring in 10,000 years) are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), consistent with the requirements of the proposed rule in 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

The effects of likely seismic events, with exceedance frequencies greater than or equal to 10^{-5} per year, have been considered for inclusion in the performance assessments to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321; proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394])). Inclusion of the effects of likely seismic events on EBS components in the assessment of the stylized human intrusion scenario would not increase the calculated annual dose to the RMEI, as discussed in excluded FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion). The effects of vibratory ground motion are therefore excluded from the performance assessment to demonstrate compliance with the individual protection standard for human intrusion on the basis of low consequence.

The effects of vibratory ground motion from likely seismic events are included in the performance assessments to demonstrate compliance with the groundwater protection standards, consistent with the requirements in 10 CFR 63.331 [DIRS 180319] and proposed 10 CFR 63.342(b) (70 FR 53313 [DIRS 178394]).

Failure Mechanisms in Response to Vibratory Ground Motion—Seismic-induced deformation of EBS components may result in plastic yielding or failure of EBS components. If the residual stress on a plastically deformed EBS component exceeds a threshold value, then stress corrosion cracks may initiate and propagate through-wall, resulting in transport pathways into and out of the waste packages. The area in which the residual stress threshold is exceeded is referred to as a "damaged area," and is conceptualized to result in the immediate formation of a tightly spaced network of stress corrosion cracks. Stress corrosion cracking of waste packages and drip shields is discussed further in included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages) and in excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields). The combined mechanical-corrosion failure mechanism of deformation caused by vibratory ground motion followed by potential SCC is expected to be a primary cause of damage to the waste packages and drip shields (SNL 2007 [DIRS 176828], Section 6.1.4 and 6.1.5).

Damaged areas are distinct from structural failures, which corresponding to the tearing, rupture, or buckling of an EBS component. A rupture or tear may occur if the local strain exceeds the ultimate tensile strain, and may partly or completely negate the effectiveness of the EBS component in preventing the inflow of seepage water or the outward transport of radionuclides. Buckling of an EBS component may change its structural configuration, possibly changing a component's effectiveness as part of the EBS barrier to seepage or rockfall. Rupture or puncture of the OCB of the waste package and buckling of the sidewalls of the drip shield are important failure mechanisms in the seismic damage abstractions (SNL 2007 [DIRS 176828], Section 6.1.4).

The effects of vibratory ground motion depend on the condition of the components and the in-drift environment. The thicknesses of EBS components will be continually reduced by general corrosion during the time scale of geologic stability. The in-drift environment will change as emplacement drifts fill with rubble and as drip shields fail under the combined loading of rockfall and vibratory ground motion. Damage from multiple seismic events may accumulate, leading to failure of EBS components. These responses have been incorporated into the seismic damage abstractions for the TSPA model (SNL 2007 [DIRS 176828], Section 6.1.2).

Abrasion between the waste package and pallet could also potentially reduce the thickness of the OCB. However, abrasion is not included in the seismic damage abstractions because abrasion is anticipated to be a secondary or tertiary effect on waste package response that will have low consequence for seismic response. Any effect from abrasion is encompassed by the existing seismic damage abstractions:

- The kinematic damage abstractions are based on structural response calculations with an OCB thickness of 23 mm, and the results for the 23-mm-thick OCB determine the response of the waste package for OCB thicknesses between 23 mm and 25.4 mm (SNL 2007 [DIRS 176828], Equation 6.5-1 in Section 6.5.2.2 and Equation 6.5-4 in Section 6.5.2.5). That is, the probability of damage and the damaged area are set to their values for a 23-mm-thick OCB if the OCB thickness is greater than 23 mm. As it requires several hundred thousand years after repository closure for the spatially averaged thickness of the OCB to thin from 25.4 mm to 23 mm (SNL 2007 [DIRS 176828], Section 6.5.1.2), the kinematic damage abstractions encompass any potential thickness loss from abrasion during this time period.

- The seismic damage abstractions for a waste package surrounded by rubble are based on two-dimensional structural response calculations that ignore the bending moment from the waste package lids at both ends of the package, thereby underestimating the load-bearing capacity of the waste package (SNL 2007 [DIRS 178851], Section 6.5.1.1). The two-dimensional representation is thought to encompass any potential strength reduction from abrasion of the rubble on the OCB.

Drip Shield Damage due to Vibratory Ground Motion−Vibratory ground motion associated with a seismic event may cause impacts between waste packages and drip shields that could compromise the structural stability of the drip shields or tear the interior support bulkhead beneath the crown of the drip shields (SNL 2007 [DIRS 176828], Section 6.8.5). The structural stability of the drip shields when surrounded by rubble and subjected to lateral impacts by the

waste packages has been investigated with three-dimensional finite-element calculations (BSC 2005 [DIRS 173172], Section 5.6.2 and Attachment VI). The results from these calculations demonstrate that lateral impacts would not cause catastrophic failure of the drip shields, as discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.8.5). Three-dimensional finite-element calculations were also performed for a waste package that "clips" a bulkhead support beam on the underside of the crown of the drip shield (SNL 2007 [DIRS 178851], Section 6.4.5). Such impacts were determined to have a low probability of occurrence in comparison to the buckling of the sidewalls of the drip shield under dynamic load (SNL 2007 [DIRS 176828], Section 6.8.5). Therefore, waste package-to-drip shield impacts are not represented in the TSPA model.

Vibratory ground motion may cause adjacent drip shields to separate if there is a large vertical displacement between adjacent drip shields or if the welds holding the drip shield connector guides tear loose from the drip shield plates during the dynamic response. However, the frictional forces between EBS components and the loads from rockfall provide a restraint on the movement of the drip shields, preventing the differential motion that could lead to separation (SNL 2007 [DIRS 176828], Section 6.7.3). Therefore, drip shield separation as a result of vibratory ground motion is excluded from the TSPA model.

Waste Package Damage due to Vibratory Ground Motion−The mechanical response of a waste package to a seismic event will depend on the configuration and structural integrity of the EBS components at the time of the seismic event (SNL 2007 [DIRS 176828], Section 6.1.2). The mechanical response of the waste packages to seismic events is defined for three configurations or states of the system: (1) an initial state in which the drip shield is intact, (2) an intermediate state in which the sidewalls of the drip shield have buckled, but the drip shield plates remain intact, and (3) a final state in which the waste packages are surrounded by rubble after the drip shield plates have failed.

These three states lead to three distinct damage "modes" for the waste packages (SNL 2007 [DIRS 176828], Section 6.1.3). In the first state, the waste packages are free to move beneath the drip shield and the "kinematic" response can cause impact-related damage. The kinematic response can also cause severe deformation of the waste package, potentially causing rupture of the OCB from multiple impacts. These impact-related mechanisms are the subject of this FEP and are discussed below. The damage that can occur in the second and third states is discussed in included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components).

In the initial state, when the drip shield is intact, waste packages can move freely beneath the drip shield and there is minimal accumulation of rockfall. The predominant mechanism for damage is seismic-induced impact between EBS components. The potential for damage from impacts between adjacent waste packages and between a waste package and its emplacement pallet are discussed below. The potential for damage to the waste package from impacts with the invert is not included in the seismic damage abstractions because the damaged areas from the side-on impact of a waste package on a flat elastic surface is zero or very small (SNL 2007 [DIRS 176828], Section 6.5.6). The potential for damage to the waste package from lateral impacts between the waste package and drip shield is not included in the seismic damage abstractions based on a similar rationale (SNL 2007 [DIRS 176828], Section 6.8.5).

Rigid body kinematic calculations have been performed for an emplacement drift containing a combination of TAD canister-bearing waste packages and codisposal waste packages. The responses of waste packages with Alloy 22 OCB thicknesses of 23 mm or 17 mm and with intact or degraded internals have been analyzed (SNL 2007 [DIRS 178851], Section 6.3.1). The 23-mm-thick OCB represents a reduction from the initial OCB thickness of 25.4 mm and provides a representation for an intact or almost intact waste package. The 17-mm-thick OCB represents a waste package that has undergone substantial corrosion at late times after repository closure. The waste package internals are assumed to degrade as a structural component after the first breach of the OCB and before the next seismic event occurs. Structural response calculations were performed for seventeen ground motion time histories (i.e., 17 three-component accelerograms) for four levels of horizontal PGV: 0.4, 1.05, 2.44, and 4.07 m/s (SNL 2007 [DIRS 178851], Section 6.3.2.1.2). Damaged areas were determined for three values of the residual stress threshold (RST): 90%, 100%, and 105% of the yield strength of Alloy 22 (SNL 2007 [DIRS 176828], Section 6.1.4). The output from the structural response calculations provide the basis for the kinematic damage abstractions for the TAD canister and codisposal waste packages in response to a seismic event (SNL 2007 [DIRS 176828], Sections 6.5 and 6.6).

Summary−As documented in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]), the potential for damage to a TAD canister or codisposal waste package from end-to-end impacts between adjacent waste packages and from waste package-to-pallet impacts is included in the performance assessments to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394)) in the seismic scenario class. Damage from waste package-to-drip shield impacts and drip shield separation as a result of vibratory ground motion are not included in these performance assessments.

FEP: 1.2.03.02.0B

FEP NAME:

Seismic-Induced Rockfall Damages EBS Components

FEP DESCRIPTION:

Seismic activity could produce jointed-rock motion and/or changes in rock stress leading to enhanced rockfall that could impact drip shields, waste packages, or other EBS components.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Introduction—Vibratory ground motion from seismic activity could cause failure of the host rock around emplacement drifts. The potential for the resulting rockfall to damage the drip shields, waste packages, and waste package internals is evaluated in this excluded FEP. The screening justification for this FEP is structured into ten sections: (1) Introduction, (2) Rock Failure Mechanisms, (3) Mechanical Failure Mechanisms, (4) Drip Shield Damage Due to Rock Block Impacts, (5) Exclusion of Damaged Areas on the Drip Shield Plates, (6) Exclusion of Tearing of the Drip Shield Plates, (7) Exclusion of Tearing of the Axial Stiffeners, (8) Exclusion of Waste Package Damage Due to Rock Block Impacts, (9) Response During the Period of Geologic Stability, and (10) Summary. Each of these sections describes an important aspect of the response of the drip shields or waste packages to rockfall generated by jointed-rock motion in the nonlithophysal units of the repository.

At Yucca Mountain, the emplacement drifts will transect both nonlithophysal and lithophysal rock types. In the nonlithophysal units, vibratory ground motion could cause jointed-rock motion that dislodges large rock blocks from the sides or crown of drifts in the nonlithophysal units. Damage to EBS components from rockfall generated by jointed-rock motion is excluded from the TSPA model based on the screening justification in this FEP. In the lithophysal units, vibratory ground motion could fracture the host rock into smaller fragments that partly or completely collapse a drift. The damage to EBS components from seismic-induced drift collapse of the lithophysal units is included in the TSPA model (see included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components)), and the resulting seismic damage abstractions (SNL 2007 [DIRS 176828], Sections 6.7.1 and 6.10.1) are applied to all the drip shields and waste packages in the repository. In other words, the damage to the drip shields and waste packages from the seismic-induced response of the host rock is based on the rockfall process in the lithophysal units (included FEP 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components)), rather than on rockfall generated by jointed-rock motion in nonlithophysal units. This is a reasonable approach because of the screening justifications in this FEP and because the rockfall volume and loads from drift collapse in the lithophysal units are much greater than those from rockfall induced by jointed-rock motion in the nonlithophysal units (SNL 2007 [DIRS 176828], Section 6.7.2.1).

The emplacement pallet and invert are also features of the EBS, but do not need detailed evaluation as part of this FEP. The emplacement pallet could be damaged as a result of host rock failure induced by vibratory ground motion, but the TSPA does not take credit for the pallet's contribution to delaying or preventing the transport of radionuclides, so it does not require further consideration. The invert is filled with compacted ballast that will not be damaged by host rock failure because the ballast is made from run-of-mine rock tailings, so the invert does not require further consideration. Finally, the emplacement drift is also a feature of the EBS, and the response of the emplacement drift to rockfall is represented in the TSPA model through included FEP 1.2.03.02.0D (Seismic-induced Drift Collapse Alters In-Drift Thermohydology).

Vibratory ground motion can cause direct damage to the EBS components through rigid body motions and impacts between adjacent EBS components. These effects are addressed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components). The direct effects of fault displacement on the EBS components are discussed in included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components).

Rock Failure Mechanisms—The type of rock failure that could occur in an emplacement drift as a result of seismic activity depends on the local strata that the drift transects. At Yucca Mountain, the nonlithophysal units encompass 15% to 20% of the repository emplacement area (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). The nonlithophysal rock is composed of strong, intact blocks of welded tuff separated by fracture planes (BSC 2004 [DIRS 166107], Section 6.4.1.1). Vibratory ground motion could cause jointed-rock motion that dislodges large rock blocks from the sides or crown of drifts in the nonlithophysal units. The potential damage to EBS components from large rock blocks in the nonlithophysal units is addressed and excluded in this FEP. Rockfall resulting from non-seismic causes is addressed in excluded FEP 2.1.07.01.0A (Rockfall).

In contrast, the lithophysal units encompass about 80% to 85% of the repository emplacement area (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). The lithophysal rock is characterized by low compressive strength due to widespread lithophysal voids interconnected by intense local fracturing. Large rock blocks are not expected in the lithophysal zone due to the presence of numerous lithophysal voids interconnected by densely spaced fractures. Individual lithophysal rock fragments are less massive than the large nonlithophysal rock blocks, and hence less damaging to EBS components. However, the total volume and resulting static load from lithophysal rubble fragments that accumulate during multiple seismic events are significantly greater than the rockfall volume and loads in the nonlithophysal zones (SNL 2007 [DIRS 176828], Section 6.7.2.1). Failure of EBS components could occur as a result of the static load from the accumulated lithophysal rubble amplified by the dynamic load during vibratory ground motion. The potential damage to EBS components from partial or complete drift collapse in lithophysal units is addressed in included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components).

Mechanical Failure Mechanisms—Impact-related dynamic loads may dent the drip shields and waste packages, resulting in residual stress from permanent structural deformation. High tensile levels of residual stress may lead to local degradation from stress corrosion cracking, potentially resulting in a network of through-going cracks that can form transport pathways for water or radionuclides. The dented area that exceeds the residual stress threshold is referred to as the

"damaged area" and is conceptualized to result in the immediate formation of a tightly spaced network of through-going stress corrosion cracks. Stress corrosion cracking of the waste packages' outer corrosion barrier and of the drip shield plates is discussed further in included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages) and in excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields). The combined failure mechanism of plastic deformation (which causes the residual stress) followed by accelerated stress corrosion cracking is hypothesized to be a primary cause of seismic-induced damage to the drip shields and waste packages (SNL 2007 [DIRS 176828], Section 6.1.4).

Damaged areas are distinct from structural failures, which correspond to the tearing or rupture of an EBS component. A rupture or tear may occur if the local strain exceeds the ultimate tensile strain, and would partly or completely negate the effectiveness of the EBS component as an impediment to the inflow of seepage water or the outward transport of radionuclides. The potential for structural failure of EBS components from a seismic event has been analyzed in detail in *Mechanical Assessment of Degraded Waste Packages and Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Section 6.2.2) and is modeled and abstracted in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.1.4).

Once stress corrosion cracks form, they could reduce the ultimate plastic load capacity of the drip shield framework in response to static rockfall loading and vibratory ground motion. However, the structural response calculations for the drip shields include several conservatisms that offset the potential reduction of plastic load capacity from a preexisting crack network: (1) stress relaxation from the creep of titanium could arrest crack growth if the local stresses drop below the residual stress threshold before the crack reaches a critical length for propagation (BSC 2005 [DIRS 174715], Section 5.5.3); (2) crack propagation will cause further deformation of the drip shields. This deformation will increase the reactive pressure from the rubble surrounding the drip shields, possibly arresting crack growth; (3) the ultimate plastic load capacity of the drip shield is based on a quasi-static approach that underestimates the plastic load capacity relative to dynamic calculations of drip shield response; and (4) the variability of the vertical component of the ground motion is overestimated by the postclosure ground motions (SNL 2007 [DIRS 178851], Section 6.4.7.3). The combined effect of these four conservatisms is expected to more than offset the potential reduction in plastic load capacity due to preexisting crack networks (SNL 2007 [DIRS 178851], Section 6.4.7.3), and the effect of a preexisting crack network on plastic load capacity of the drip shields is not included in the structural response calculations for the drip shields.

Drip Shield Damage Due to Rock Block Impacts—The computational approach for defining drip shield damage due to rock block impacts is described in detail in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Sections 6.10.2, 6.10.2.1, 6.10.2.2, and 6.10.2.3). This computational approach considers the potential for general corrosion to reduce the robustness of the drip shields over the period of geologic stability. In particular, the structural response is determined for three thicknesses of the drip shield components, as noted below. These three thicknesses represent the impact of general corrosion on the structural response of the drip shields throughout the period of geologic stability, as required by the proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]). The major features of the rockfall and structural response calculations are documented as follows:

- *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.3) provides a detailed description of the nonlithophysal rockfall calculations performed with 3DEC, a three-dimensional discontinuum computer program. The computational results define the size, velocity, and frequency of the multiple rock blocks that can be dislodged during seismic events at the 1.05, 2.44, and 5.35 m/s PGV levels.

- Structural response calculations were performed for a set of seven representative block sizes that span the range of block kinetic energies (SNL 2007 [DIRS 178851], Section 6.4.7.2.2), and for one intact and two degraded states of the drip shields. The intact state has no thickness reduction, and the degraded states have 5- and 10-mm thickness reductions for all drip shield components (SNL 2007 [DIRS 176828], Section 6.10.2.2). The results from these calculations form the basis for "catalogs" of damage areas, maximum plastic strains and maximum stiffener displacements for individual block impacts as a function of block kinetic energy and plate thickness (SNL 2007 [DIRS 176828], Table 6-51). The damaged area and maximum plastic strain from an individual block impact is calculated by interpolation within the catalog of damaged areas. The methodology of the calculations is described in detail in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Sections 6.10.2.2 and 6.10.2.3).

- The rock block is represented as an edge-on impact at the center of the drip shield, with the center of mass of the block directly above the impact point (SNL 2007 [DIRS 178851], Section 6.4.7.2.2). The center impact tends to overestimate seepage onto the waste packages or damage to the drip shields for the following reasons. First, seepage through a dented or failed plate at the center of the drip shields is more liable to result in water dripping onto the waste packages than seepage through a dent or failed plate at the "shoulder" (where the crown meets the vertical side) or sidewall of the drip shields. Second, an impact to the shoulder or sidewalls of the drip shields will generally create a crease that diverts the flow of seepage water toward the side(s) of the drip shields, rather than forming a central depression that could collect seepage water. The collection of seepage is potentially important because the resulting hydrostatic head from the pooled water could facilitate advective flow through stress corrosion cracks. Third, the alignment of the block's center of mass with the impact point maximizes deformation for a given kinetic energy, providing an upper bound for the calculated damage areas.

Multiple seismic events will cause the waste packages and emplacement pallets to reposition themselves beneath the drip shields. However, the limited clearance between the outside of the emplacement pallet and the inside of the drip shield, as shown in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Figure 4-1), acts to position the waste packages near the centerline of the drip shields after a seismic event. In other words, the lateral movement of the waste packages relative to the drip shields is limited by the lateral clearance between the pallets and drip shields. It follows that the reasoning in the preceding paragraph is applicable to block impacts after multiple seismic events.

Exclusion of Damaged Areas on the Drip Shield Plates—Damaged areas on the drip shield plates are excluded from the TSPA model because advective flow through stress corrosion cracks in the

drip shields is excluded from the TSPA model on the basis of low consequence (see excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield)). If advective flow is excluded, then the presence of stress corrosion cracks from seismic-induced rockfall does not compromise the ability of the drip shield to divert seepage away from the waste packages.

Exclusion of Tearing of the Drip Shield Plates—The tearing or rupture of drip shield plates from large block impacts is also excluded from the TSPA model because of low consequence. The dose that could result from rupture of the drip shield plates is estimated using the results of calculations estimating the results of early drip shield failure as discussed in Appendix E. The drip shield early failure calculations compute the dose that results from manufacturing defects or emplacement damage to drip shields. The effects of an early failure are simulated by removing a single drip shield as an impediment to seepage. If seepage occurs in a location with an early failed drip shield, the associated waste package is conservatively assumed to also have failed. Hence, the drip shield early failure calculations describe the dose that may result if a drip shield and its associated waste package fail simultaneously. The mathematical details of this calculation are documented in Appendix E.

The estimate of dose from rupture of the drip shield plates accounts for the frequency of occurrence of seismic-induced rock block impacts in the nonlithophysal units, and the extent of ruptured drip shields caused by these impacts. This estimate considers localized corrosion as the process that may fail the waste package subsequent to rupture of the drip shield plates. Sections E.6.1 and E.6.2 provide a detailed discussion of the technical approach and the mathematical formulation for the calculation. The mean annual dose due to nonlithophysal rockfall over a 10,000-year period is not significant in comparison to the mean annual dose due to seismic ground motion or in comparison to the regulatory limit of 15 mrem/yr (proposed 10 CFR 63.311(a)(1) (70 FR 53313 [DIRS 178394])), as shown in Section E.6.3. The mean annual dose due to nonlithophysal rockfall over the 10,000-year to 1,000,000-year period after closure is estimated to be less than 1% of the mean annual dose due to seismic ground motion, based on the analysis in Section E.6.3. The effects of nonlithophysal rockfall on the drip shield are therefore not included in the performance assessment on the basis of low consequence because the maximum mean dose from drip shield plate failures and seismic-induced nonlithophysal rockfall is a small fraction of the mean annual dose from seismic ground motion during the period of geologic stability.

Exclusion of Tearing of the Axial Stiffeners—Rupture of the axial stiffeners beneath the crown of the drip shields is also considered in the structural response calculations for drip shield response to rock block impacts (SNL 2007 [DIRS 178851], Section 6.4.7). The axial stiffeners rupture only for the impact of the largest of the seven representative rock blocks (SNL 2007 [DIRS 176828], block 1 in Tables 6-50 and 6-51). This statement is true for the intact drip shield and for degraded drip shields with 5-mm and 10-mm thickness reductions. Block 1 has the maximum kinetic energy (706,914 Joules) of any block from the rockfall analyses. The following observations are relevant here:

- The rock block that causes the axial stiffeners to fail occurs at the 5.35 m/s PGV level, which is beyond the maximum PGV level of 4.07 m/s on the bounded hazard curve (SNL 2007 [DIRS 176828], Section 6.4.3). In other words, the exceedance probability

for the 5.35 m/s PGV level seismic event is less than 10^{-8} per year, so this maximum block is not included in the TSPA model on the basis of low probability.

- The simplified representation of the blocks in the structural response calculation provides an upper bound on rockfall damage. For these calculations, the rock block is represented as a cubic block with an edge-on impact at the center of the drip shield, with the center of mass of the block directly above the impact point (SNL 2007 [DIRS 178851], Section 6.4.7.2.2). However, large rock blocks are expected to have a highly irregular shape, and the center of mass that will seldom be directly over the impact point. In this situation, the block will rotate upon impact, providing a larger contact surface that distributes the impact load over a larger area, thereby reducing the possibility of rupture of the axial stiffeners.

The prediction of rupture of the axial stiffeners is, therefore, not expected even for the maximum rock block. This failure mode is therefore not included in the TSPA model.

Exclusion of Waste Package Damage Due to Rock Block Impacts—Seismic-induced damage to the waste package and its internals from rock block impacts in nonlithophysal units is not included in the TSPA model on the basis of low probability.

The impact calculations show that block 1 would cause the drip shield to fail through rupture of its axial stiffeners, potentially contacting the waste packages (SNL 2007 [DIRS 176828], block 1 in Table 6-51). The maximum stiffener displacement for impact of block 1 on the drip shield is 0.204 m (20.4 cm) with a 5-mm thickness reduction (SNL 2007 [DIRS 176828], Table 6-51). For all other blocks, the maximum stiffener displacement is 0.0417 m (4.17 cm) for block 2 with the 10-mm thickness reduction (SNL 2007 [DIRS 176828], Table 6-51). When compared to the initial clearance between the drip shields and the waste packages of 14 inches (35.6 cm) to 27 inches (68.6 cm) (SNL 2007 [DIRS 179354], Figure 4-1, dimension D3), no contact between the drip shields and waste packages is predicted. However, the calculations for block 1 do not represent the complete mechanical response after rupture because the failed component (i.e., the axial stiffener) has not been removed from the calculation and because the calculation for block 1 with a 10-mm thickness reduction did not run to completion. In this situation, it is possible that the deformation of the drip shields may increase after rupture such that the drip shields contacts the waste packages. As the drip shields continue to deform, the energy of the rock block impact will be dissipated and any potential impact of the drip shields into the waste packages will be at a substantially reduced velocity. In addition, any contact between the drip shields and the waste packages as a result of a rock block impact will be spread over a large area, resulting in insignificant deformations to waste packages with intact internals, and fairly small deformations to waste packages with degraded internals (SNL 2007 [DIRS 178851], Section 6.4.7.3). It is possible to conclude that, should block 1 cause a drip shield to contact a waste package, there would be no rupture of the waste packages and any damaged areas would be insignificant (SNL 2007 [DIRS 178851], Section 6.4.7.3).

Failure of the drip shield plates from impacts by rock blocks 2 through 7 for the 0-, 5-, and 10-mm thickness reductions does not cause contact between the drip shields and the waste packages because the axial stiffeners do not tear or rupture (SNL 2007 [DIRS 176828], Table 6-51 and p. 6-185). So there is no potential for damage to the waste packages from rupture

of the drip shield plates due to impacts by rock blocks 2 through 7 because the framework of the drip shields remains structurally intact (i.e., the axial stiffeners remain intact) and is able to deflect rockfall away from the waste package and its internals (SNL 2007 [DIRS 176828], Section 6.10.2.11).

The waste packages could also be damaged by rock block impacts if the drip shields separate during vibratory ground motion. Drip shield separation is defined as an axial or vertical gap or space between two adjacent drip shields that allows in-drift seepage to flow directly onto waste packages. Separation is important because it negates the functionality of the drip shields as a barrier to seepage and rockfall for the waste packages. Drip shield separation is excluded from the TSPA model based on low probability of occurrence (SNL 2007 [DIRS 176828], Section 6.7.3).

Axial separation of adjacent drip shields is excluded from the TSPA model because: (1) ground motion amplitudes that are sufficient to cause axial separation are also large enough to partially or completely collapse drifts in the repository, (2) rockfall occurs within the first second or two of the arrival of these large amplitude ground motions, and (3) a kinematic study indicates that small static loads from rubble or frictional loads between EBS components are sufficient to eliminate axial separation of drip shields (SNL 2007 [DIRS 176828], Section 6.7.3.1). In this situation, rockfall provides restraints on the motion of the drip shields, preventing differential motion that could lead to separation. Axial separation is excluded from the TSPA model based on low probability.

Vertical separation of adjacent drip shields is excluded from the TSPA model because: (1) rockfall provides restraints on the motion of the drip shields, preventing differential motion that could lead to separation, as discussed above, and (2) the drip shield connector subassemblies provide a 320-mm-long (12.6-in-long) overlap at the joint between adjacent drip shields (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-01; SNL 2007 [DIRS 176828], Section 6.7.3.2). This overlap will protect the waste packages from direct seepage and direct rockfall that might result from a vertical displacement of a few inches between adjacent drip shields. Vertical separation is not included in the TSPA model on the basis of low probability.

Response During the Period of Geologic Stability—Performance assessment for seismic response must consider the damage to the drifts and failure of the waste package beyond the 10,000-year postdisposal period through the period of geologic stability subject to the probability limits in proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]). This screening justification must, therefore, consider the response of the EBS components beyond the 10,000 year postdisposal period. Two key aspects of the long-term response in the nonlithophysal units are considered here: (1) the exclusion of tearing of the drip shield plates, and (2) the potential for general corrosion to eliminate the drip shield as a mechanical structure, allowing rock blocks to directly impact the waste package.

The estimate of dose from tearing or rupture of the drip shield plates due to nonlithophysal rock block impacts is based on the technical approach and mathematical calculations discussed in Appendix E. As discussed previously, the mean annual dose due to nonlithophysal rockfall over the 10,000-year to 1,000,000-year period after closure is estimated to be less than 1% of the mean annual dose due to seismic ground motion, based on the analysis in Section E.6.3. The

effects of tearing or rupture of the drip shield plates due to nonlithophysal rock block impacts are, therefore, not included in the performance assessment on the basis of low consequence throughout the period of geologic stability.

The response of the drip shield and drifts beyond the postdisposal period through the period of geologic stability is considered next. This discussion demonstrates that the drip shield is expected to fail from general corrosion, rather than dynamic loading of the drip shields from a seismic event, potentially exposing the waste package to direct impact of rock blocks during the period of geologic stability.

The mean time for a 10-mm thickness reduction due to general corrosion on the top and bottom sides of the drip shield plates is 195,000 years after closure (SNL 2007 [DIRS 176828], Section 6.10.2.11). Since the initial plate thickness is 15 mm, the mean time for plate failure from general corrosion is (15 mm/10 mm)(195,000 years) = 293,000 years. Using 1 inch as a typical initial thickness for the components of the drip shield framework, the time for framework failure from general corrosion is estimated to be (25.4 mm/10 mm)(195,000 years) = 495,000 years. This is an estimate because the framework is fabricated from Titanium Grade 29, which has modestly higher corrosion rates than the Titanium Grade 7 plates. However, the estimate provides a reasonable time scale for this analysis. In summary, the mean time for failure of the drip shield plates from general corrosion is on the order of 300,000 years, and the estimated time for failure of the framework is on the order of 500,000 years.

Rockfall will accumulate in the nonlithophysal zones from multiple seismic events during these time periods. However, the volume of rockfall per seismic event is much smaller in the nonlithophysal units than in the lithophysal units (SNL 2007 [DIRS 176828], Figure 6-58 and Section 6.7.2.1). For example, the mean rockfall in the nonlithophysal units is only (0.24 m^3 per meter/7.8 m^3 per meter) = 3% of the mean rockfall in the lithophysal units at the 1.05 m/s PGV level (SNL 2007 [DIRS 176828], Table 6-32). It follows that the drifts in the nonlithophysal units are not expected to fill with a significant amount of rubble during the first 500,000 years after closure, and that the drip shields are not expected to be covered with a significant amount of rubble during this time frame.

If the drip shields are not covered with a significant amount of rubble, the failure mode of the drip shield is primarily from general corrosion, rather than the dynamic amplification of the static load from rubble during a seismic event. For example, the probability of failure of the drip shield plates with 10% of the rockfall load from a fully collapsed drift is 0 for a 5-mm-thick plate and only 0.036 for a 2-mm-thick plate at the 4.07 m/s PGV level (SNL 2007 [DIRS 176828], Table 6-36). Since the limited rubble volume in the nonlithophysal units will generally come to rest along the sides of the drip shields, a seismic event will not amplify the static vertical rockfall loads, and the primary failure mechanism is general corrosion.

After the drip shields fail from general corrosion in the nonlithophysal units, the waste packages become exposed to direct impact from large rock blocks because the rubble is not expected to cover the tops of the waste packages. However, direct impact of a large rock block on a degraded waste package is not expected to rupture the package because the structural response calculations for individual impacts of a waste package with degraded internals on an

emplacement pallet (SNL 2007 [DIRS 178851], Sections 6.3.2.2, 6.3.2.2.3, and 6.3.2.2.7) provide a bounding analogue for the rock block impact on a waste package, as explained next.

The nonlithophysal rock block with the maximum kinetic energy is a 28.29 MT rock block with a velocity of 7.07 m/s and a kinetic energy of 706,914 joules (SNL 2007 [DIRS 176828], Table 6-50). This is the largest rock block from the nonlithophysal rockfall calculations at the highest unbounded PGV level, 5.35 m/s, which has a probability of less than 10^{-8} per year probability of occurring based on the bounded hazard curve. The rock block volume is 11.7 m^3 (SNL 2007 [DIRS 176828], Table 6-50), equivalent to a cube 2.27 meters on a side. In reality, this block is expected to have a highly irregular, elongated shape, but its shape is not critical to this analysis.

Fully loaded waste packages are much more massive than this maximum rock block. For example, a fully loaded TAD canister-bearing waste package weighs 162,055 lbs (SNL 2007 [DIRS 176828], Table 6-48), equivalent to 73,700 kg. A fully loaded 5-DHLW/DOE SNF-Long codisposal waste package weighs 127,870 lbs (SNL 2007 [DIRS 176828], Table 6-48), equivalent to 58,100 kg. These masses are between 2 and 2.6 times greater than the mass of the maximum rock block. The range of impact velocities for the waste package-to-pallet impacts encompass the maximum impact velocities observed in the kinematic analyses, with a typical range of 0.2 to 10 m/s (SNL 2007 [DIRS 178851], Section 6.3.2.2.3 and Table 6-11). It follows that the kinetic energies for the most energetic waste package-to-pallet impacts are more than a factor of two greater than the nonlithophysal rock block with the maximum kinetic energy. Note also that the kinetic energy for waste package-to-pallet impacts will be orders of magnitude greater than for many of the smaller rock blocks shown in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Table 6-50).

Key results from the structural response calculations for waste package-to-pallet impacts are as follows:

- The structural response calculations for the TAD canister-bearing waste package with intact or degraded internals demonstrate that the strain in the outer corrosion barrier (OCB) from a single impact is always below the ultimate tensile strain for Alloy 22, and does not result in rupture (SNL 2007 [DIRS 178851], Section 6.3.4). These structural response calculations are based on spatially averaged OCB thicknesses of 23 and 17 mm, which represent the expected OCB thickness at several hundred thousand years and more than 1 million years after repository closure, respectively (SNL 2007 [DIRS 176828], Sections 6.5.1.2 and 6.5.2.2).

- The structural response calculations for the codisposal waste package with intact or degraded internals demonstrate that the strain in the OCB from a single impact is always below the ultimate tensile strain for Alloy 22, and does not result in rupture (SNL 2007 [DIRS 178851], Section 6.3.4). These structural response calculations are based on spatially averaged OCB thicknesses of 23 and 17 mm, which represent the expected OCB thickness at several hundred thousand years and more than 1 million years after repository closure, respectively (SNL 2007 [DIRS 176828], Sections 6.5.1.2 and 6.5.2.2).

These results demonstrate that an individual rock block impact will not rupture either a TAD canister-bearing or a codisposal waste package because the kinetic energy for a waste package-to-pallet impact is at least a factor of two greater than the kinetic energy for the largest rock block for the same impact velocity and because the impact process is similar, in the sense that the edge-on impact of a rock block onto the side of a waste package is functionally similar to the side-on impact of a waste package onto the vertical side of an emplacement pallet.

Although a single waste package-to-pallet impact cannot rupture the waste package, the seismic damage abstractions consider the potential for two or more severe impacts to fail a waste package (SNL 2007 [DIRS 176828], Sections 6.5.2.1 and 6.6.2.1). An initial impact with severe deformation of the OCB has the potential to weaken the OCB, potentially causing rupture if there is severe deformation from a subsequent impact. The second impact that causes severe deformation could occur during a single ground motion or during subsequent events. The accumulation of extreme deformation in the OCB is conceptualized to have the potential to rupture the OCB from multiple severe impacts.

A similar approach could be applied for rock block impacts in the nonlithophysal units. However, severe deformation will only occur for the most energetic rock blocks, which will come to rest on top of the waste package because of their large size and irregular shape (i.e., they cannot fit between the waste package and drift walls). In this situation, a large block will shield the waste package from subsequent impacts by distributing the loads over a large area and preventing severe deformation. The potential for rupture from multiple rock block impacts directly on the waste package is therefore not included in performance assessment for the period of geologic stability.

It should be noted that the rupture abstractions based on the kinematic response are applied to waste packages in all units of the repository, including those in the nonlithophysal units. Waste packages in nonlithophysal units can rupture during the period of geologic stability in the performance assessment, but not from the mechanism of rock block impact.

Summary—In summary, damage to the drip shields and waste packages as a result of seismic-induced rockfall from jointed-rock motion in nonlithophysal units is excluded from the TSPA model. The effects of rockfall on the drip shields have been quantified in terms of damaged areas and the probability of rupture of the drip shield plates. However, damaged area on the drip shields is excluded from the TSPA model because advective flow through stress corrosion cracks in the drip shields is excluded from the TSPA model (see excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield)), and failure of the drip shield plates is excluded because it has low consequence for the TSPA. Rupture of the axial stiffeners occurs only for an impact by a 28.3 MT rock block impact and is excluded on the basis of low probability. Finally, damage to the waste packages and waste package internals from seismic-induced rockfall in jointed rock in nonlithophysal units is excluded from the TSPA model because the drip shields do not separate and because the drip shields remain intact mechanically and can deflect rockfall away from the waste packages.

Based on the previous discussion, omission of FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible

environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.03.02.0C

FEP NAME:

Seismic-Induced Drift Collapse Damages EBS Components

FEP DESCRIPTION:

Seismic activity could produce jointed-rock motion and/or changes in rock stress leading to enhanced drift collapse that could impact drip shields, waste packages, or other EBS components. Possible effects include both dynamic and static loading.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The effects of seismic-induced drift collapse are included in the performance assessment to demonstrate compliance with the individual protection standard of the proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]). The effects of seismic-induced drift collapse are also included in the performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]), although seismic events having less than 1 chance in 10 of occurring in 10,000 years are excluded from these latter performance assessments, consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]). The effects of seismic-induced drift collapse are excluded from the performance assessments to demonstrate compliance with the human intrusion standard based on low consequence. As discussed in excluded FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion), the effects of such events would be insufficient to alter the material properties of the waste packages to the extent that an intersected waste package would not be noticed by a driller during the first 10,000 years after repository closure, and inclusion of the effects of seismic events on the EBS in the assessment of dose releases due to human intrusion would not significantly affect the calculated annual dose to the reasonably maximally exposed individual.

Introduction—Vibratory ground motions associated with seismic activity could cause failure of the host rock around emplacement drifts. The resulting rockfall coupled with the dynamic loads from vibratory ground motion could cause damage to the drip shields and possibly to the outer barriers of the waste packages (if the drip shields fail) through mechanical loading. The drift invert and emplacement pallet could also be damaged as a result of host rock failure induced by vibratory ground motion, but these components are not part of the EBS barrier to the release of radionuclides and, in this respect, such impacts do not require further consideration. Vibratory ground motion can also disrupt the EBS components through rigid body motion and impacts between adjacent EBS components. The effects of these impacts are addressed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components). The direct effects of fault displacement on the EBS components are discussed in included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components).

Rock Failure Mechanisms—The type of rock failure that could occur in an emplacement drift as a result of seismic activity depends on the local strata that the drift transects. At Yucca Mountain, the emplacement drifts will transect both nonlithophysal and lithophysal rock types. Nonlithophysal units are composed of strong, intact blocks of welded tuff that are separated by fracture planes (BSC 2004 [DIRS 166107], Section 6.4.1.1). Damage to the waste package and drip shield as a result of rock block impacts induced by vibratory ground motion is excluded from the TSPA model, as discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). Rockfall for the nominal (nonseismic) condition is addressed in excluded FEP 2.1.07.01.0A (Rockfall).

In contrast, the rock units in lithophysal zones, which encompass about 80% to 85% of the repository emplacement area (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03), are characterized by a lower compressive strength due to widespread lithophysal voids interconnected by intense fracturing. Rock failure in lithophysal zones is anticipated to generate relatively small fragmented rock particles and impact-related damage is anticipated to be less significant than in the nonlithophysal zones. However, en masse fall of rock fragments, which constitutes "drift collapse," could occur in the lithophysal zones. The volume of rock fragments generated by rock failure in lithophysal zones is significantly greater than the rockfall volume in nonlithophysal zones (SNL 2007 [DIRS 176828], Section 6.7.2.1). Failure of EBS components could occur as a result of the static load from the lithophysal rubble amplified by the dynamic load during vibratory ground motion. The dynamic response of the drip shield and waste package in partly or completely collapsed drifts in the lithophysal units is the focus of this FEP.

Lithophysal Rockfall Analyses—Rockfall analyses have been performed for emplacement drifts in lithophysal units under vibratory ground motion at horizontal PGV levels of 0.4, 1.05, and 2.44 m/s (BSC 2004 [DIRS 166107], Section 6.4). These PGV levels correspond to exceedance frequencies of 10^{-4} per year, 10^{-5} per year, and 4.5×10^{-7} per year, respectively, on the bounded hazard curve (SNL 2007 [DIRS 176828], Table 6-3). The volume of rock that must collapse to completely fill a drift is estimated to be 30 m^3 per meter to 120 m^3 per meter of drift length (SNL 2007 [DIRS 176828], Section 6.7.1.4). The uncertainty in this volume is represented in the TSPA model by a uniform distribution between 30 m^3 per meter and 120 m^3 per meter of drift length. Complete drift collapse was predicted for a single seismic event at or above the 2.44 m/s PGV level for drifts in lithophysal units (SNL 2007 [DIRS 176828], Section 6.7.1). The effect of multiple seismic events is incorporated into the TSPA model by defining the total lithophysal rockfall volume as the sum of the rockfall volumes from the individual seismic events.

Mechanical Failure Mechanisms—The rockfall loads from drift collapse may result in plastic deformation of EBS components. This plastic deformation and the associated residual stresses may lead to local degradation from stress corrosion cracking, potentially resulting in a network of through-going cracks that can form transport pathways for water or radionuclides. The area that exceeds the residual stress threshold is referred to as the "damaged area" and is conceptualized to result in the immediate formation of a tightly spaced network of through-going stress corrosion cracks. Stress corrosion cracking of the waste package outer corrosion barrier and of the drip shield plates is discussed further in included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages), and excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields). The combined mechanical-corrosion failure mechanism of plastic

deformation followed by stress corrosion cracking is expected to be a primary cause of damage to both waste packages and drip shields (SNL 2007 [DIRS 176828], Section 6.1.4).

Damaged areas are distinct from structural failures, which correspond to the tearing, rupture, or buckling of an EBS component. A rupture or tear may occur if the local strain exceeds the ultimate tensile strain, and may partly or completely negate the effectiveness of an EBS component as a barrier to the inflow of seepage water or the outward transport of radionuclides. Buckling of an EBS component may change the structural configuration and possibly compromise a component's effectiveness as a barrier to seepage or rockfall.

Drip Shield Damaged Area Due to Drift Collapse—Drip shields may accumulate damaged areas from vibratory ground motion and from lithophysal rockfall induced by vibratory ground motion until the drip shield plates fail. The damaged areas on drip shield plates have been analyzed as a function of the thickness of the plate, the rockfall load on the drip shield in a partly or completely collapsed drift, and the vertical component of peak ground acceleration for the seismic event (SNL 2007 [DIRS 176828], Section 6.10.1). However, damaged areas on the drip shield are excluded from the TSPA model because advective flow through stress corrosion cracks on the drip shield is excluded in FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield), so the presence of a crack network in the damaged areas does not compromise the drip shield's ability to divert seepage away from the waste package.

Drip Shield Failure Due to Drift Collapse—The accumulated rubble on the drip shield can also cause failure (rather than just damaged area) during a seismic event. The probability of failure is defined as a function of the thickness and ultimate plastic load capacity of the drip shield components, the static rockfall load on the drip shield, and the vertical component of PGA for the seismic event. The probability of failure is represented as fragility curves for two failure modes of the drip shield: (1) rupture or tearing of the drip shield plates, and (2) buckling or collapse of the sidewalls of the drip shield (SNL 2007 [DIRS 176828], Section 6.8).

Finite-difference calculations have been performed to define the ultimate plastic load bearing capacity of the curved plates on the crown of the drip shield (SNL 2007 [DIRS 178851], Section 6.4.4). These calculations define the magnitude of the uniform load that causes an area of the plate to exceed the ultimate tensile strain of Titanium Grade 7. The finite-difference calculations were performed for 100% rockfall loads on drip shield plates that are 15-mm, 10-mm, and 5-mm thick to represent one intact and two degraded states of the drip shields.

The probability of failure is evaluated for drifts that are 0%, 10%, 50% and 100% filled with lithophysal rock for seismic events at the 0.2, 0.4, 1.05, 2.44, and 4.07 m/s PGV levels (SNL 2007 [DIRS 176828], Sections 6.8.2.1 and 6.8.2.2). These PGV levels correspond to the 10^{-4} per year, 10^{-5} per year, 4.5×10^{-7} per year, and 10^{-8} per year exceedance frequencies, respectively, on the bounded hazard curve (SNL 2007 [DIRS 176828], Table 6-3). These results define the probability of failure in lookup tables that are interpolated for the PGV level of the seismic event and plate thickness at the time of the seismic event within the TSPA model.

Finite-difference calculations have also been performed to define the plastic load bearing capacity of the drip shield framework. The calculations determine the magnitude of the load on the crown that causes the sidewalls of the drip shield to buckle. The finite-difference

calculations were performed for 100% rockfall loads with 0-mm, 5-mm, and 10-mm thickness reductions of drip shield components, representing one intact and two degraded states of the drip shields. The probability of failure is evaluated for drifts that are 0%, 10%, 50% and 100% filled with lithophysal rock for seismic events at the 0.2, 0.4, 1.05, 2.44, and 4.07 m/s PGV levels (SNL 2007 [DIRS 176828], Sections 6.8.3.2 and 6.8.3.3). These results are represented as lookup tables within the TSPA model. The key parameters for the lookup tables are the PGV level of the seismic event and the frame thickness at the time of the seismic event, both of which are determined internally by the TSPA model.

Waste Package Damage and Puncture Due to Drift Collapse—The mechanical response of a waste package to a seismic event will depend on the configuration and structural integrity of the EBS components at the time of the seismic event (SNL 2007 [DIRS 176828], Section 6.1.2). The configuration of the EBS and the mechanical response of the waste packages to seismic events are defined for three states of the system: (1) an initial state in which the drip shield is intact, (2) an intermediate state in which the legs of the drip shield have buckled, but the drip shield plates remain intact, and (3) a final state in which the waste packages are surrounded by rubble after the drip shield plates have failed. The transition between these configurations is determined by the fragility curves for the drip shield framework and plates discussed above.

These three states lead to distinct damage mechanisms for waste packages (SNL 2007 [DIRS 176828], Section 6.1.3). In the first state, the waste packages are free to move beneath the drip shield and "kinematic" damage can occur. This damage mechanism is discussed in detail in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and is not discussed further here.

In the second state, the motion of the waste packages is restricted and the extent of damage is determined for a waste package beneath a buckled or collapsed drip shield. *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.8.4) provides an evaluation of the deformation and stresses in the OCB of a TAD canister-bearing waste package that is loaded by a collapsed drip shield. The entire drip shield was not explicitly represented in the model. Only the bulkhead flanges that are expected to contact the waste package after collapse of the framework were modeled, and the structural response of the OCB was calculated by moving the bulkhead flanges downward at a velocity that is sufficiently small to maintain a quasi-static response in the OCB. The response of the waste package with OCB thicknesses of 17 mm and 23 mm and intact or degraded internals provides the damaged area as a function of the effective vertical load (SNL 2007 [DIRS 176828], Section 6.8.4).

The resulting damaged areas for a waste package that is loaded by a collapsed drip shield are approximated by other damage abstractions because this intermediate state ceases to exist once the drip shield plates fail during a subsequent seismic event (SNL 2007 [DIRS 176828], Section 6.8.4). When the waste package internals are intact, the damage abstraction for a waste package surrounded by rubble (the final configuration of the EBS discussed below) provides a conservative bound for the damage to a waste package loaded by the drip shield framework. When the waste package internals are degraded, the kinematic damage abstractions for the waste package with degraded internals (see included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components)) provide a conservative bound for the damage to a waste package

loaded by the drip shield framework. These abstractions approximate the response of the waste package after the drip shield framework has collapsed, but before the drip shield plates fail.

In the third and final state, the drip shield plates have failed and the waste packages are surrounded by rubble. *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.9) provides abstractions for the mechanical response of a waste package to a seismic event for this EBS configuration. Two future states of the waste package have been considered: a 23-mm-thick OCB with degraded internals and a 17-mm-thick OCB with degraded internals. The 23-mm-thick OCB represents a reduction from the initial thickness of 25.4 mm to take account of the potential effects of general corrosion during the first few hundred thousand years after repository closure (SNL 2007 [DIRS 178851], Sections 6.5.1.2). The 17-mm-thick OCB represents a waste package that has undergone extensive corrosion during the period of geologic stability after repository closure (SNL 2007 [DIRS 178851], Section 6.5.2.2). The abstractions are based on the TAD canister-bearing waste package. As the response of the TAD canister-bearing waste package with degraded internals is expected to be similar (but conservative) to that of a codisposal waste package with degraded internals, a single damage abstraction has been developed for both types of waste packages (SNL 2007 [DIRS 176828], Section 6.9.10).

The calculated strain in the OCB is always below the ultimate tensile strain for Alloy 22 for the full range of PGV levels (SNL 2007 [DIRS 178851], Section 6.5.1.4.1). Therefore, the waste package surrounded by rubble is not anticipated to rupture. However, a severely deformed OCB may be punctured by the sharp edges of fractured or partly degraded internal components. The OCB may be deformed or even crushed as a result of the dynamic rubble load in response to vibratory ground motion. Calculated probabilities of puncture for the 17-mm-thick OCB and 23-mm-thick OCB are provided in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.9.1), based on calculations for 17 ground motions at each of the 0.4, 1.05, 2.44, and 4.07 m/s PGV levels. OCB puncture is not expected to occur on the 23-mm-thick OCB unless the PGV is at least 1.05 m/s, or on the 17-mm-thick OCB unless the PGV is at least 0.4 m/s.

When a waste package is determined to be punctured, the failed area is defined by sampling a uniform distribution with a lower bound of 0 m^2 and an upper bound of 0.10 m^2 (SNL 2007 [DIRS 176828], Section 6.9.1). This failed area is conceptualized to be located randomly on the surface of the OCB. The failed area allows flow through the punctured waste package and advective and diffusive transport of radionuclides out of the waste package.

Summary—In summary, damaged area on the waste package and failure of the waste package and drip shield as result of seismic-induced drift collapse in lithophysal zones is included in the performance assessments to demonstrate compliance with the individual protection standards after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). The effects of drift collapse on the drip shields are quantified in terms of fragility curves that are a function of the PGV value for a given seismic event and the thickness of the drip shield components at the time of the seismic event. The effects of drift collapse on waste packages surrounded by rubble are quantified in terms of damaged areas or puncture areas based on the PGV level for a given seismic event and the thickness of the waste package OCB at the time of the seismic event.

The effects of seismic-induced drift collapse are excluded from the performance assessments to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) based on low consequence.

FEP: 1.2.03.02.0D

FEP NAME:

Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology

FEP DESCRIPTION:

Seismic activity could produce jointed-rock motion and/or changes in rock stress leading to enhanced drift collapse and/or rubble infill throughout part or all of the drifts. Drift collapse could impact flow pathways and condensation within the EBS, mechanisms for water contact with EBS components, and thermal properties within the EBS.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Seismic-induced rockfall and seismic-induced drift collapse can alter the hydrologic and thermal environment in the drifts after a seismic event. The potential for drift collapse and its consequences are addressed in two steps. *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4) addresses rockfall and drift collapse responses to seismic ground motion. *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]) then quantifies the response of various EBS components to drift collapse. Thermal-hydrologic changes from drift collapse are described in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.17[a]).

The term "drift collapse" (in this discussion of the technical basis for inclusion of this FEP) refers to en masse fall of rock fragments that fill the drift, and only occurs in lithophysal zones. In contrast, "rockfall" is limited to relatively fewer and possibly larger blocks of rock and may constitute the full extent of seismic response for drifts in nonlithophysal rock.

Effects from rockfall and drift collapse on performance of engineered barriers such as the drip shield are addressed in excluded FEP 1.2.03.02.0B (Seismic-induced Rockfall Damages EBS Components) and included FEP 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components). The direct effects from ground motion are addressed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components). Effects from drift collapse on in-drift chemistry are addressed in excluded FEP 1.2.03.02.0E (Seismic-induced Drift Collapse Alters In-drift Chemistry).

The potential thermal-hydrologic consequences of seismic-induced drift collapse, relative to the uncollapsed case, are: (1) increased EBS temperatures and delayed cooling if collapse occurs during the thermal period; (2) lower relative humidity associated with increased temperatures; (3) changes in drift seepage caused by the increased span of collapsed openings and the irregular geometry of collapsed-opening profiles; and (4) decreased axial transport of water vapor and associated condensation effects. Each of these effects is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure

(proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). Consistent with the requirements of proposed 10 CFR 63.342(b) (70 FR 53313 [DIRS 178394]), the effects of drift collapse associated with seismic events that are estimated to be unlikely to occur have been excluded from the groundwater protection and human intrusion performance assessments. As discussed in excluded FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion), likely seismic events have also been excluded from the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

Conditions for Drift Collapse and Rockfall—Drift collapse will occur in the lithophysal host rock units, which are characterized by lithophysal voids interconnected by close fracturing as discussed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.4.1.1). Postclosure ground motion in lithophysal rock could result in substantial or complete drift collapse (SNL 2007 [DIRS 176828], Section 6.7.1) affecting the hydrologic and thermal environment in the EBS. For implementation in performance assessment calculations, partial drift collapse may occur at all ground motions with a PGV greater than 0.274 m/s (exceedance frequencies of about 2.5×10^{-4} per year) in the lithophysal units (SNL 2007 [DIRS 176828], Sections 6.4.3 and 6.7.1.1). The probability of occurrence of partial drift collapse increases with increasing PGV, and reaches a value of 1.0 at 1.05 m/s (an exceedance frequency of about 1×10^{-5} per year). If rockfall is predicted to occur, then the volume of rockfall and the bulking factor (a measure of the change in the diameter of the drift opening) are calculated as a function of the PGV. A PGV level of about 2.0 m/s (an exceedance frequency of about 9×10^{-7} per year) is generally sufficient to result in complete drift collapse in the lithophysal units (SNL 2007 [DIRS 176828], Section 6.7.1.4 and Table 6-3). In the case of multiple seismic events, the cumulative amount of rockfall is tracked through time until the drift is completely filled.

Seismic-induced rockfall will accumulate to a much lesser extent in the nonlithophysal host rock units (SNL 2007 [DIRS 176828], Section 6.7.2), which are stronger and composed of intact blocks delineated by fractures. Complete drift collapse is not observed in the nonlithophysal zones for ground motion amplitudes at or below a PGV of 5.35 m/s. Using the bounded hazard curve, the PGV is expected to be less than 4.07 m/s at the repository horizon (SNL 2007 [DIRS 176828], Section 6.4.3), so complete drift collapse due to a single seismic event will not occur. Within performance assessment, complete drift collapse within the nonlithophysal units is either not implemented, or, in submodels that do not distinguish between the lithophysal and nonlithophysal units, the lithophysal model for drift damage is conservatively applied to both lithologies. In the case of multiple seismic events, the cumulative amount of rockfall from partial drift collapse is tracked through time until the drift is completely filled.

Effect on Temperature and Relative Humidity—Once the drifts are completely filled with rubble, the in-drift thermal-hydrologic conditions used by TPSA are modified for drift collapse. The influence of a collapsed drift in lithophysal rock on in-drift temperature and relative humidity is evaluated in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.17[a]). The temperatures of the drip shields and waste packages as represented in the multiscale model will increase relative to uncollapsed drifts, because the drift rubble acts as an insulating blanket over the drip shield. The insulating effect increases peak temperatures and increases the duration of thermal conditions in the EBS. The effects of drift collapse are implemented in performance assessment calculations as a series of "deltas" relative to the open-

drift results for temperature and relative humidity, representing the differences between the open-drift and the rubble-filled cases (SNL 2008 [DIRS 184433], Section 6.3.17[a]). Without seepage, the rubble will dry out, then gradually rewet after hundreds to thousands of years, due to capillary condensation, with essentially zero percolation flux (SNL 2007 [DIRS 181244], Section 6.5.3). With seepage, the surface of the drip shield under collapse-rubble remains dry until the waste package surface has cooled to approximately 100°C (SNL 2008 [DIRS 184433], Sections 6.3.7.3 and Table 6.3-44). Uncertainty in the effects of drift collapse on the in-drift environment is propagated to performance assessment through use of two sets of "deltas" for the low- and high-thermal conductivity rubble, respectively, which are sampled epistemically for each realization.

Effects on Seepage—Changes in seepage behavior caused by seismically induced rockfall and drift collapse are also included in performance assessment calculations for the lithophysal host rock only. A seepage abstraction is used to represent the range from intact (uncollapsed) to fully collapsed openings (SNL 2007 [DIRS 181244], Section 6.2[a]). The approach interpolates linearly between the uncollapsed and collapsed abstractions using rockfall volume as modeled in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.7.1) to define the extent of collapse; in the case of multiple seismic events, the cumulative rockfall volume is used. *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.2.4.2) and *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.6.3) represent the fully collapsed opening as a circular profile with twice the intact diameter, filled with rubble. Capillary properties for the rubble are different from the host rock, forming a capillary barrier to seepage. Seepage into collapsed drifts can occur at any temperature (not constrained to temperatures less than 100°C as for intact drifts) because no "vaporization barrier effect" at the boundary of the intact rock was observed in simulations (SNL 2007 [DIRS 181244], Section 6.5.3). The "vaporization barrier effect" involves evaporation of water in the host rock above the drift opening, and condensation elsewhere, with the effect of diverting liquid flow around the drift. It acts in concert with capillary diversion of liquid flux. With doubled diameter in the collapsed-drift simulations, the intact rock was much cooler at the crown and sides of the degraded opening. In other respects, the collapsed drift abstraction is similar to that for intact drifts.

Seepage simulations conducted to evaluate parametric sensitivity for the collapsed-drift case showed that the effects from local rockfall in nonlithophysal units are small (SNL 2007 [DIRS 181244], Section 6.4.2.4.2). Therefore, no explicit change is made in the seepage abstraction to represent rockfall in nonlithophysal units. The seepage abstraction for intact drifts is already increased by 20% to account for the possibility of irregular opening geometry associated with minor drift degradation (SNL 2007 [DIRS 181244], Section 6.7.1.2).

Temperature Limit for Seepage Contact with Waste Packages in Rubble—A temperature constraint is applied to the flow conditions within the drift after drift collapse. Seepage can enter the drift and be diverted through the rubble to the invert beneath the waste package, but cannot contact the waste package surface until the waste package surface temperature drops below 100°C. This threshold temperature of 100°C is based on sensitivity studies (SNL 2008 [DIRS 184433], Section 6.3.7.3 and Table 6.3-44; SNL 2007 [DIRS 181244], Section 6.5.3) of conditions required for seepage to penetrate the rubble in a collapsed drift and contact the drip shield. The value of 100°C is a reasonable upper bound from the sensitivity studies, and

therefore an appropriate threshold to limit the seepage of liquid water to the drip shield, and, in the event of drip shield failure, to the waste package.

Drift-Wall Condensation—Condensation is expected to occur in an intact drift as discussed in included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts/Drift-Scale Cold Traps) and included FEP 2.1.08.04.0B (Condensation Forms at Repository Edges/Repository-Scale Cold Traps), and locally in a collapsed, rubble-filled drift. However, the presence of rubble will inhibit the long-range axial transport of water vapor along the drift axis. The presence of rubble has a strong insulating effect (SNL 2008 [DIRS 184433], Section 6.3.7.3) that increases the temperature differences between the waste package and the adjacent drift wall in comparison to an uncollapsed drift. The temperature difference under these conditions can be as high as 100°C at waste-package peak temperatures, although this diminishes with time (BSC 2005 [DIRS 172232], Figure 6.2.5-3). This steep gradient will drive water vapor toward cooler locations such as the drift wall, where it can condense locally rather than migrate for significant distances axially in the rubble-filled drift. The relatively large surface area of the cool rubble at the drift wall will rapidly absorb latent heat of vapor and promote local condensation. Because axial transport is minimized and evaporation/condensation are localized, resulting in no net change in the flux through the invert at any given location, the effects of condensation are not implemented in performance assessment calculations in the collapsed drift case.

In summary, the thermal-hydrologic effects from drift collapse (or partial drift collapse in the case of seepage) are included in the performance assessment model as: (1) increased EBS temperatures and delayed cooling; (2) lower relative humidity associated with increased temperatures; (3) changes in drift seepage caused by the increased span of collapsed openings and the irregular geometry of collapsed-opening profiles; and (4) decreased axial transport of water vapor and associated condensation effects. Seismic-induced drift collapse is possible in the lithophysal host rock, but not the nonlithophysal rock, which is limited to minor rockfall. However, in cases where these two lithologies are not distinguished, the lithophysal drift damage model is implemented.

FEP NAME:

Seismic-Induced Drift Collapse Alters In-Drift Chemistry

FEP DESCRIPTION:

Seismic activity could produce jointed-rock motion and/or changes in rock stress leading to enhanced drift collapse and/or rubble infill throughout part or all of the drifts. Drift collapse, and the associated changes in seepage and in-drift thermohydrology could impact in-drift chemistry.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

In-drift chemistry is a function of incoming seepage water composition, the local conditions of temperature, relative humidity, and carbon dioxide activity, and water–rock interaction as described in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.9). The composition of potential incoming seepage is evaluated with the near-field chemistry model (SNL 2007 [DIRS 177412], Section 6.3.2), while the effects of evaporation/dilution in the drift are estimated using the seepage dilution/evaporation abstraction (SNL 2007 [DIRS 177412], Section 6.3.3). Widespread rockfall induced by vibratory ground motion could alter the hydrologic and thermal environment in the drifts, which could affect the in-drift chemistry. The indirect effects from collapse-induced changes in temperature and relative humidity on the in-drift chemical environment are included in the TSPA through use of the seepage dilution/evaporation abstraction, and are discussed further in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology). This screening justification evaluates the effects of drift collapse on factors that directly control in-drift chemistry, including the composition of incoming seepage and the composition of dust on the waste package surface.

Although limited rockfall may occur in nonlithophysal host rock units, drift collapse is expected to occur in the lithophysal host rock units, which are characterized by lithophysal voids interconnected by intense fracturing as discussed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.4.1.1). Postclosure ground motion in lithophysal rock could result in substantial or complete drift collapse (SNL 2007 [DIRS 176828], Section 6.7.1) affecting the hydrologic and thermal environment in the EBS. Seepage could increase because the greater span and irregular shape of collapsed drift openings will reduce the effectiveness of the drift wall due to the capillary barrier effect (SNL 2007 [DIRS 181244], Section 6.2). The temperature of the drip shields and waste packages will increase relative to uncollapsed drifts because the drift rubble acts as an insulating blanket over the drip shield (SNL 2008 [DIRS 184433], Section 6.3.17[a]).

In the case of drift collapse, rock dust generated by comminution of host rock fragments will be deposited on waste package surfaces. This dust is expected to resemble dust samples collected

from the ESF, which consist largely of powdered rock generated during tunneling and underground activities, with very small amounts (<<1%) of relatively chloride-rich salts representing dried pore water (SNL 2007 [DIRS 181267], Section 6.1.2.4). It is compositionally distinct from dust deposited during the ventilation period, which is anticipated to have a large, nitrate-rich atmospheric dust component, and contain more than 10% soluble salts (SNL 2007 [DIRS 181267], Section 6.1.2.4). As discussed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence), brines formed by both tunnel dusts and atmospheric dusts are generally benign with respect to localized corrosion of Alloy 22. In addition, the smaller salt load in the rock dust will increase capillary retention of brine by the dust, minimizing contact with the waste package surface and reducing the continuity of the deliquesced liquid phase within the dust. This inhibits development of the separate anodic and cathodic zones necessary for localized corrosion (SNL 2007 [DIRS 181267], Section 6.4). Hence, the screening justification presented in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence) remains valid in the event of drift collapse. A similar justification is presented for dust deposited on the drip shield in excluded FEP 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces Due to Deliquescence). Drip shields are emplaced after ventilation, and the predominant dust is anticipated to be powdered rock; hence, the discussion in excluded FEP 2.1.09.28.0B (Localized Corrosion on Waste Package Outer Surface due to Deliquescence) applies directly to dust deposited by drift collapse.

The presence of collapsed drift rubble in contact with the drip shield and the resulting change in in-drift thermal hydrologic conditions (included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-drift Thermohydrology)) will not influence the representation of drip shield corrosion in TSPA. The principal corrosion mode for the drip shield is general corrosion, and the rate is independent of temperature and relative humidity. In addition, no distinction in the corrosion rate is made for humid-air versus aqueous environments; the same rate is used for both conditions in TSPA calculations (SNL 2007 [DIRS 180778], Section 8.1[a]).

The near-field chemistry model (SNL 2007 [DIRS 177412], Section 6.3.2), evaluates the composition of potential seepage water at the drift wall as a function of the interactions with minerals in the rock and the thermal evolution of the percolating water. Drift collapse has no effect on the mineralogy of the tuff and a negligible effect on the accessible mineral surface area (which is largely exposed in matrix pores). In addition, the presence of a rubble-filled, collapsed drift produces an insignificant change in the overall thermal evolution of the water as it percolates downward to the drift, effectively only changing the length of the reaction path by a few meters (SNL 2007 [DIRS 177412], Section 6.15.1). Therefore, the effects of drift collapse on potential seepage water composition are insignificant, and the near-field chemistry model can be used to represent potential seepage composition in the collapse-rubble, even though model simulations do not directly evaluate this condition. This conclusion is also applicable to conditions after drip shield failure, which is expected to occur at some time after 10,000 years.

The influence of a collapsed-drift on in-drift temperature and relative humidity and the indirect effects on in-drift chemistry are discussed in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-drift Thermohydrology). Thermal-hydrologic effects are considered in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.17[a]), and in *Postclosure Analysis of the Range of Design Thermal Loadings* (SNL 2008 [DIRS 179962], Section 6.4.2). Without seepage, the rubble will dry out and then gradually rewet after hundreds

to thousands of years due to capillary condensation, with zero or very small liquid flux (SNL 2007 [DIRS 181244], Section 6.5.3). With seepage, the hydrologic conditions at the surface of the drip shield under collapse-rubble will remain dry until the surface has cooled to approximately 100°C (SNL 2008 [DIRS 184433], Section 6.3.7.3), after which contact with aqueous solutions is possible. In-drift chemistry is determined with the seepage dilution/evaporation abstraction (SNL 2007 [DIRS 177412], Section 6.3.3), using an in-drift temperature and relative humidity modified for the drift collapse condition.

Based on the preceding discussion, omission of FEP 1.2.03.02.0E (Seismic-Induced Drift Collapse Alters In-Drift Chemistry) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.03.03.0A

FEP NAME:

Seismicity Associated with Igneous Activity

FEP DESCRIPTION:

Seismicity associated with future igneous activity in the Yucca Mountain region may affect repository performance.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Seismicity associated with igneous activity was explicitly considered and included as part of the PSHA for Yucca Mountain (CRWMS M&O 1998 [DIRS 103731]). In that analysis, which involved a formal expert elicitation process, expert teams either defined specific seismic sources for igneous-related seismicity, specified that such seismicity was included as part of the characterization of background seismicity, or indicated that such seismicity was insignificant relative to other seismic sources in the region (BSC 2004 [DIRS 168030], Table 5). Because the effects are included in the hazard curves and derived ground motions used to evaluate seismic consequences, igneous-related seismicity is included in the TSPA.

At Yucca Mountain, earthquakes associated with igneous activity would be related to basaltic intrusion and volcanism. Volcanic eruption is commonly preceded and accompanied by swarms of earthquakes that indicate progressive rock-strength failure as magma migrates to the Earth's surface, as, for example, reported in a study by Smith et al. (1998 [DIRS 118967], p. 158). That study specifically mentions that magma intrusion into the seismogenic crust tends to supplant large tectonic earthquakes with swarms of low to moderate magnitude earthquakes. Smith et al. (1998 [DIRS 118967], Table 1) summarize published accounts of observed seismicity that is clearly associated with dike intrusion, including the maximum magnitude assocaited with each series of earthquakes. This summary indicates that dike-induced earthquakes in volcanic rift zones worldwide have a mean maximum magnitude of 3.8 with a standard deviation of 0.8, and are generally less than magnitude 5. In *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260], Section 6.3.3.2), the dike length distribution based on analogue studies in the Yucca Mountain region is used as a proxy for surface-fault lengths to calculate maximum magnitudes of dike-induced earthquakes. Calculations indicated maximum magnitudes of 4.6, 5.4, 6.0, and 6.1 for dike lengths of 0.4 km (minimum), 2.0 km (mean), 6.0 km (95th percentile), and 8.0 km (cutoff). An analysis of the ground motion associated with earthquakes of magnitude 4.8, 5.8, and 6.2, covering the assessed range of maximum dike-induced earthquakes at Yucca Mountain, is presented in *Development of Earthquake Ground Motion Input for Preclosure Seismic Design and Postclosure Performance Assessment of a Geologic Repository at Yucca Mountain, NV* (BSC 2004 [DIRS 170027], Section 6.5).

The method used to estimate the ground motion hazard for the PSHA is described in *Characterize Framework for Seismicity and Structural Deformation at Yucca Mountain, Nevada* (BSC 2004 [DIRS 168030], Section 6.5.1). Seismicity related to volcanic processes, particularly basaltic volcanoes and dike injection, was explicitly modeled as volcanic source zones by two of the six expert teams working on the PSHA (as summarized in BSC 2004 [DIRS 168030], Table 5). The maximum magnitudes assigned by the two expert teams put greater weight on magnitudes from 5.4 and 5.8, which is consistent with the range of maximum earthquake magnitudes calculated based on dike length distributions (SNL 2007 [DIRS 174260], Section 6.3.3.2). The other PSHA expert teams concluded either that the low magnitude and frequency of igneous-related seismicity was accounted for by the areal source zone evaluation used for the PSHA or was insignificant.

Seismicity associated with igneous activity is included in the TSPA because seismicity associated with igneous activity is included in the PSHA results (through volcanic source zones or areal source zones). Consequently, all seismic inputs developed to support postclosure seismic analyses account for the igneous component of the seismic hazard.

Unlikely events (events having less than one chance in 10 of occurring in 10,000 years) are included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])), but are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]). Therefore, the effects of seismicity associated with igneous activity that are estimated to be unlikely to occur have been excluded from the groundwater protection and human intrusion performance assessments.

The effects of likely seismicity associated with igneous activity (having a probability of occurrence greater than 10^{-5} per year) have also been excluded from the human intrusion performance assessment. As discussed in excluded FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion), the effects of such events would be insufficient to alter the material properties of the waste packages to the extent that an intersected waste package would not be noticed by a driller in 10,000 years. Further, as discussed in excluded FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion), inclusion of the effects of seismic events on the EBS in the assessment of the stylized human intrusion scenario would not affect the calculated annual dose to the RMEI significantly. Therefore, seismic events are excluded from the assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), based on low consequence.

Waste package damage due to an igneous intrusion into the repository is addressed separately in included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components).

FEP: 1.2.04.02.0A

FEP NAME:

Igneous Activity Changes Rock Properties

FEP DESCRIPTION:

Igneous activity near the underground facility may cause extreme changes in rock stress and the thermal regime, and may lead to rock deformation, including activation, creation, and sealing of faults and fractures. This may cause changes in the rock hydrologic and mineralogic properties. Permeabilities of dikes and sills and the heated regions immediately around them can differ from those of country rock. Mineral alterations can also change the chemical response of the host rock to contaminants.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This justification is based on information that shows that changes in rock properties associated with igneous activity have little effect on flow and transport in the saturated and unsaturated zones at Yucca Mountain. The technical basis for the exclusion from the TSPA of the effects of future igneous activity on rock properties relies in part on studies of analogue sites in the Yucca Mountain Region. In addition, analyses of igneous activity and analyses of the effects of fault displacement on the unsaturated zone are utilized. This FEP is concerned with post-intrusion effects on rock properties and the following paragraphs of this justification consider the zone of influence around an igneous intrusion, the effects on permeability, the effects on faults and fractures, and the effects on mineralogy. Impacts of an igneous intrusion on the repository and the EBS are addressed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) and included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components).

Limited Zone of Influence Around Igneous Intrusions—Sills and dikes initially intrude into the country rock as molten material and then cool and solidify. In the Yucca Mountain area, the dikes typically range in width from 1 to 12 m (SNL 2007 [DIRS 174260], Table 7-1) and tend to be variably continuous along strike. Cooling joints are formed both within the intrusive body (a dike or a sill) and in the country rock adjacent to the intrusion, due to a combination of thermal and stress effects. The resulting permeabilities of these jointed rocks may be greater than, equivalent to, or less than the surrounding unaffected country rocks (see section entitled *Potential Effects on Flow in the UZ*). However, the scale of these effects and the associated changes in properties are limited to a few meters around the sill or dike (Valentine and Krogh 2006 [DIRS 177282]). Laboratory analytical data and field observations of mineral alterations around igneous intrusions at natural analogue sites show that alteration extends less than 10 m away from the intrusion-host rock contact (CRWMS M&O 1998 [DIRS 105347], pp. 5-41 to 5-71). Two appropriate analogues for understanding the components of a potential future igneous event at Yucca Mountain are the Paiute Ridge intrusive/extrusive center (Byers and Barnes 1967 [DIRS 101859]) on the northeastern margin of the Nevada Test Site and the Grants

Ridge site in western New Mexico (CRWMS M&O 1998 [DIRS 105347], p. 5-57). The Paiute Ridge center is a small-volume Miocene volcanic center comparable in volume and composition to Quaternary volcanoes near Yucca Mountain (SNL 2007 [DIRS 174260], Section 6.3.3.1). Paleomagnetic, geochronologic, and geochemical data indicate that the entire intrusive/extrusive complex formed during a brief magmatic pulse and, thus, represents a single volcanic event. The vents and associated dike system formed within a north-northwest-trending extensional graben, and exposures exist at a variety of system depths, including remnants of surface lava flows, volcanic conduits, and dikes and sills intruded into tuff country rock at depths of up to 300 m. Evidence of shallow structural control of dike emplacement exists at Paiute Ridge, including dike emplacement along fault planes (Byers and Barnes 1967 [DIRS 101859]; Valentine and Krogh 2006 [DIRS 177282]). Dike lengths at Paiute Ridge range from less than 1 km to 5 km, which is comparable to the range estimated for post-Miocene volcanism near Yucca Mountain (SNL 2007 [DIRS 174260], Table 7-1).

Valentine and Krogh (2006 [DIRS 177282], pp. 221 to 223) described the margins of the Paiute Ridge dike complex and the interaction of dikes and faults. The description is as follows (note that the dike designators PR, M, and E in the following text refer to the Paiute Ridge, Middle, and East dikes, respectively, as described by Valentine and Krogh 2006 [DIRS 177282]):

> PR dike contains ubiquitous near-vertical joints that result in a pervasive platy texture with plates parallel to the dike-host contact. Conversely, with the exception of local cooling joints in fused wall rock (extending 10-20 cm into the wall rock, perpendicular to the dike margin), joints are nowhere visible in the host rock along the length of the dike. The contact between basalt and the tuff host rock is consistently smooth and shows no brecciation. Along strike at this contact, the tuff host rock is fused or welded to varying degrees …. In places the tuff is densely welded and forms black vitrophyre that grades rapidly away from the contact, over a distance of ~20 - 100 cm, into nonwelded tuff that is apparently unaffected by the dike. In other places the tuff is only partially welded at the contact and black fiamme are flattened parallel to the contact. We infer that this "contact welding" is the combined result of heat from the dike and compressive stress exerted by the magma on the wall rocks.... Welded host rock commonly contains vesicles that are elongated vertically and parallel to the margin. In some places, welded tuff coats the basalt and displays rills or elongate smooth ridges (flutes). Most rills plunge nearly vertically, however, a sub-horizontal rill is present in the central part of the dike …. The two eastern dikes, M and E … show geometries and textures similar to those of PR, however, M dike is much shorter and does not feed a sill, and E dike feeds two sills. M dike radiates out from the neck-like body mentioned above … and visibly occupies a normal fault, oriented N25-40°W, 61°E, that displaces the Tertiary tuff. M dike varies in width between 2 and 4 m, and has an exposed length of 400 m. Its host rocks are only Tertiary tuffs that show no brecciation or jointing near the dike contact. Near the neck M dike is a single continuous dike, whereas farther from the neck it is composed of several segments. The north end of the dike veers west and narrows before terminating. Dike texture is characterized by a vertical platy fabric that parallels the dike margins.

> E dike is the eastern-most dike studied within the graben. Like M dike, it extends from the neck, and was emplaced into Tertiary tuffs. Near the neck the dike visibly occupies a NNW-trending, E-dipping normal fault that displaces bedded tuffs 3.5 m and does not cut the dike. The exposed dike length is 2020 m and the width varies from 3 m near the northern tip, to 6 m near the southern (ES) sill. A zone comprising about 30 m along strike forms a pod with about 20 m width, presumably representing localized wall rock erosion, between the neck and ES sill. E dike is less segmented than PR dike, and is composed of fewer than a dozen segments. In at least three places near the contact with the Timber Mountain Tuff…and one location near the neck, the dike locally diverges to form two segments that engulf an 8 meter wide lens of the tuff host rock. The texture of E dike is characterized by the pervasive vertical platy fabric common to M and PR dikes. Adjacent host tuffs are neither jointed nor brecciated, except for local vertical jointing of the Rainier Mesa member of the Timber Mountain Tuff (related to post-emplacement cooling of that ignimbrite) that is intruded by the dike at its shallowest level. The contact of the dike and host tuff is well exposed in places and varies from partially to densely welded in the same manner as described above for the PR dike. Where dense welding has occurred, vesicles in the host tuff are vertical and parallel the dike margin. Contact welding of the host tuffs formed oblate fiamme that parallel the dike-host contact. Visible thermal effects on the wall rocks disappear within one meter of the dike margin.

This analogue study demonstrates that zones of change in rock properties (i.e., formation of vitrophyres and/or various degrees of welding of the host rock and formation of fiamme, which are flattened glassy inclusions) are limited to a few tens of centimeters to, at most, a meter perpendicular to the dike. Also, features such as the platy texture along the dike margins and vesicles in the welded tuff are oriented parallel to the dike margins.

Another good analogue site for the various rocks in the vadose zone at Yucca Mountain is Grants Ridge, New Mexico, where a thick sequence of rhyolite ignimbrite, fallout, and reworked volcaniclastic deposits were intruded by a basaltic plug. Erosion of the Grants Ridge site has since produced a natural cross section through the scoria cone, its feeding system, and the pyroclastic host rocks. Similar to the Paiute Ridge site, the basaltic intrusion at Grants Ridge shows limited alteration of the host rock caused by hydrothermal circulation and no brecciation or other deformation related to basaltic intrusion into the vitric and zeolitized tuffs. Field and analytical evidence from the localized contact metamorphic aureoles and devitrification of the silicic tuffs adjacent to the intrusions, minimal hydrothermal alteration, and presence of low-temperature minerals close to the intrusions also suggest insignificant thermal and chemical effects of the shallow basaltic intrusions on the vitric and zeolitized tuffs (CRWMS M&O 1998 [DIRS 123201], p. 5-57).

Potential Effects on Flow in the SZ—Although uncertainty exists regarding the impacts of past basaltic intrusions on the SZ site-scale groundwater flow system, no such features have been explicitly included as having an impact on the calibration of the saturated zone site-scale flow model (SNL 2007 [DIRS 177391], Tables 6-7 and 6-9). The following discussion on the potential for a future intrusion to impact permeability includes an evaluation of the orientation of a possible future dike, because orientation could affect the consequences of an intrusion. Most

researchers conclude that when ascending dikes enter the shallow upper crust, their location and orientation are influenced by the orientation of the local stress field and the presence of faults that may locally control alignment (SNL 2007 [DIRS 174260], Section 6.3.3.1). The evidence cited for this conclusion, in addition to the interaction of faults and dikes at the Paiute Ridge center described above, includes several northeast-oriented vent alignments in the Yucca Mountain region and the association of eruptive centers with known or inferred faults (CRWMS M&O 1996 [DIRS 100116], Appendix E, p. AM-4; Connor et al. 1996 [DIRS 135969], p. A-192; SNL 2007 [DIRS 174260], p. 6-17). Mapping of dikes in Crater Flat found dike orientations between N10°W and N5°E (SNL 2007 [DIRS 174260], p. 6-18). The separate volcanic cones in Crater Flat appear to be controlled by individual dikes occupying north-south faults formed during the east-west extension of Crater Flat basin (SNL 2007 [DIRS 174260], p. 6-18). The only dike mapped at Yucca Mountain was found to be oriented along Solitario Canyon Fault to the south and along Drill Hole Wash Fault to the north (BSC 2004 [DIRS 169989], Figure 6-5; SNL 2007 [DIRS 184614], Figure 6.1-1).

In the saturated zone in the Yucca Mountain region the direction of maximum principal transmissivity is approximately N15°E (SNL 2008 [DIRS 183750], Section 6.5.2.10), which is generally consistent with the fault orientations. A north-to-northeast orientation parallels or sub-parallels the faults active in the present-day in situ stress field. Dike features that may form in the future, such as the platy texture and welded surfaces that could affect permeability, will parallel the dike orientation and are expected to be aligned in a north-to-northeast orientation. Hence, any releases of radionuclides into the saturated zone are expected to move generally toward the south (SNL 2008 [DIRS 184806], Figure 6.5-2). Within the 18-km compliance boundary, the southern region of Yucca Mountain contains faults with orientations that are approximately north to northeast (SNL 2007 [DIRS 177391], Figures 6-3 and 6-17).

The dike widths, described previously, are small relative to the width of the areally extensive saturated zone flow and transport domain (approximately 1,350 km^2) and the predicted widths of the contaminant plume flow path (in excess of hundreds of meters; SNL 2008 [DIRS 184806], as inferred from Figure 6.5-2).

The narrow widths of future dikes and their expected parallel to subparallel orientation relative to the direction of maximum principal transmissivity, combined with the expected limited affected volume of material around the dikes, indicates that, even if differing in permeability, dikes will not significantly affect groundwater flow patterns at the mountain scale. Given the scale of the SZ flow and transport model (18 km to the discharge point) and the uncertainties in the flowing interval properties and anisotropy incorporated in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Table 6-8), smaller-scale effects caused by igneous activity would have negligible impacts on the saturated zone flow field.

Potential Effects on Flow in the UZ—Changes in fault and fracture properties due to igneous activity (i.e., activation, creation, and sealing of faults and fractures) might affect UZ flow processes. The UZ flow model results show that flow is principally through the fractured rock mass rather than faults in the TCw, PTn, and TSw (SNL 2007 [DIRS 184614], Tables 6.6-1 and 6.6-2). Because of these flow patterns, faults have very limited impact on flow behavior above the base of the TSw. The narrow, tabular dikes observed in the Yucca Mountain region (SNL 2007 [DIRS 174260], Section 6.3.3.1) are similar, geometrically, to faults. Furthermore,

dikes in the region are often found occupying faults (SNL 2007 [DIRS 174260], p. 6-18). Because of their geometrical similarity to faults, dikes would be expected likewise to have very little impact on vertical flow in the unsaturated zone between the ground surface and the base of the TSw. Lateral flow has been postulated to occur in the PTn as a result of capillary barriers (SNL 2007 [DIRS 184614], Section 6.2.2.1). Given the expected geometry of a dike, one with lower permeability could act as an impediment to lateral flow in the PTn. However, the UZ flow model results indicate that lateral flow above the repository is small. This conclusion is supported by the similar infiltration and percolation maps over the repository footprint (SNL 2007 [DIRS 184614], Figures 6.1-1 to 6.1-5 and 6.6-1 to 6.6-4) and by the small fraction of flux through faults at the TCw/PTn interface and at the repository (SNL 2007 [DIRS 184614], Tables 6.6-1 and 6.6-2).

Strong lateral diversion occurs where the TSw contacts zeolitic CHn; perched water bodies are observed near the same contact (SNL 2007 [DIRS 184614], Section 6.6.2.2 and Table 6.6-3). The lateral flow is diverted into sub-vertical faults resulting in substantial unsaturated zone flow in faults from the base of the TSw to the water table (SNL 2007 [DIRS 184614], Table 6.6-3). However, transport sensitivity analyses indicate that most of the delay in radionuclide movement to the water table occurs within the TSw and above the zone of strong lateral diversion (SNL 2007 [DIRS 177396], Sections 6.9.1.5 and 6.10.1.4). Hence, any changes in lateral diversion resulting from dikes would have negligible effects on radionuclide transport times.

The potential effects of changes in fracture and rock matrix hydrologic properties on unsaturated zone flow may be evaluated from sensitivity studies performed in *Parameter Sensitivity Analysis for Unsaturated Zone Flow* (BSC 2005 [DIRS 174116]). The sensitivity studies considered changes in properties for permeability and capillary strength for fractures, faults, and rock matrix. The changes were investigated as individual parameter variations (e.g., an increase in matrix permeability) that were applied globally over the unsaturated zone domain; changes in fracture properties also included changes in fault properties. The average variation in fracture and matrix permeabilities were factors of 9 and 42, respectively, and the variations in fracture and matrix capillary strength were 3 and 7, respectively (averaged from values given in BSC 2005 [DIRS 174116], Table 6.2-1). The integrated effects of these changes are most readily understood through their effects on transport from the repository to the water table because transport integrates the effects of flow over the domain. The breakthrough curves in Figures 6-25 to 6-32 in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748]) were computed using the flow fields generated in *Parameter Sensitivity Analysis for Unsaturated Zone Flow* (BSC 2005 [DIRS 174116]). These results demonstrate that transport behavior is relatively insensitive to changes in fracture and matrix capillary strength, only moderately sensitive to changes in fracture permeability, and most sensitive to increases in matrix permeability (with decreases in matrix permeability having little effect). The effects of infiltration uncertainty on transport behavior are found to be much larger (SNL 2007 [DIRS 184614], Figures 6.7-1 and 6.7-2). These sensitivity studies only considered changes in properties of the entire UZ model domain. In a second sensitivity study, the effect of changes in fracture aperture within fault zones was examined for the unsaturated zone (Appendix I). This sensitivity study correlated the changes in fault-fracture porosity, capillary strength, and permeability through scaling relationships for these properties with fracture aperture. Apertures were varied by a factor of 10 and 0.2, resulting in similar changes in fault-fracture porosity and capillary strength. The same variations in aperture resulted in changes in fault permeability of

factors of 1,000 and 0.008, respectively (Section I3.2.4). The results of this sensitivity study found a negligible effect on transport between the repository and the water table (Figures I-7 and I-8); changes in fault properties were excluded from further consideration in TSPA on that basis (Appendix I).

Seismicity Associated With Igneous Activity—The effects of seismicity associated with igneous activity were included in the development of the descriptions of background seismic sources used in the PSHA (CRWMS 1998 [DIRS 103731]) as described in *Characterize Framework for Seismicity and Structural Deformation at Yucca Mountain, Nevada* (BSC 2004 [DIRS 168030], Table 5) and are included implicitly in the probabilistic assessment of seismic ground motion hazards (see included FEP 1.2.03.03.0A (Seismicity Associated with Igneous Activity)). The PSHA (CRWMS 1998 [DIRS 103731]) seismic source characterization was also used as the basis for the approach to estimating probabilistic fault displacements. Thus, displacements from igneous events have been implicitly included in evaluation of probabilistic fault displacement (i.e., reactivation and creation of new faults) described in Appendix I and further consideration is unwarranted.

Potential Effects on Perched Water—The possibility of perched water forming near low-permeability intrusive bodies, and the potential for a dike to prevent or slow the rate of flow and/or cause impoundments, are addressed in *Synthesis of Volcanism Studies for the Yucca Mountain Site Characterization Project* (CRWMS M&O 1998 [DIRS 105347], p. 5-56). In the unsaturated zone, the primary direction of groundwater flow is vertically downward through the fractures (BSC 2004 [DIRS 169734], Section 7). Because the joints on a dike margin would be near vertical (e.g., SNL 2007 [DIRS 174260], Section 6.3.3.3), the formation of a significant perched water zone associated with a dike is not expected.

Perched water could also be associated with an intrusion that results in sill formation. Most sills studied at sites that are considered suitable analogues for Yucca Mountain are small and are directly connected to a parent dike (SNL 2007 [DIRS 174260], Section 6.3.3.1 and Sections F.2.1, F.2.4, and F.3). These sills are too small and their associated zones of changed rock properties are too localized to have significant effects on hydrologic properties at the scale of the UZ model. The spatially variable hydrologic properties of the UZ model are calibrated so that model predictions match perched water observations, as discussed in included FEP 2.2.07.07.0A (Perched Water Develops). Therefore, the calibrated UZ flow model output used in TSPA includes the effects of perched water.

Based on analogue information, sills with lateral extents exceeding a few tens of meters from their parent dikes are not expected to occur at Yucca Mountain (SNL 2007 [DIRS 174260], Section 6.3.3.1 and Appendix F). *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260], Appendix F) describes analogue sites where erosion has exposed the uppermost ~250 m of intrusive bodies associated with small-volume basaltic volcanoes. One site, East Basalt Ridge, has no evidence for the presence of sills. A second site, Basalt Ridge, has one minor sill that extends about 30 m from its parent dike at a depth of about 35 m below the pre-basaltic land surface. Grants Ridge has a few minor subhorizontal intrusions that extend no more than a few meters from the main (vertically oriented) intrusive body. Only Paiute Ridge has sills that are more than 10 m thick and with lateral extents of several tens of meters to about one kilometer. However, these sills are thought to be related to the specific structural setting at

Paiute Ridge where a combination of normal faulting and rocks with highly contrasting mechanical properties, at relatively shallow depths associated with sill formation, caused localized rotation of the stress field and injection of sills (Valentine and Krogh 2006 [DIRS 177282]). This setting does not exist at shallow depths in Yucca Mountain. The most reasonable scenario for a potential future volcanic event at Yucca Mountain would consist mainly of one or a few vertical to subvertical dikes that feed an eruption. Any sills that form would have lateral extents limited to a few tens of meters from the dikes, which is not sufficient to alter water flow and transport pathways or generate significant amounts of perched water. The effects of larger sills on flow and transport pathways are not considered because such features are not expected to form. The potential impact of sill formation as a result of igneous intrusion into a repository drift is addressed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository).

In some locations, such as in Hawaii (USGS 2000 [DIRS 183277]), the presence of numerous dikes have been observed to cause the perching or impoundment of groundwater, but at Yucca Mountain, this kind of perching is not expected to occur even if an igneous event intersected the repository. For the Yucca Mountain region, dike size and orientation distributions are summarized in *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260], Section 6.3.3.1 and Table 7-1). Dikes are expected to have a mean width of 8 m (minimum of 1 m and 95th percentile of 12 m) and a mean length of 2 km (minimum of 0.4 km, maximum of 8 km). Up to five parallel dikes, spaced up to 1,500 m apart, might occur in a future event, but the most reasonable number is one or two dikes. Dikes are expected to be vertical or subvertical (i.e., if a dike follows a preexisting steeply dipping fault) in orientation with azimuths centered on N10°E (±15°) and N20°W (±15°), reflecting both the roles of the stress field and of pre-existing faults in determining dike orientation. Comparison of characteristics of dikes and associated volcanic systems in the Yucca Mountain region with the large, long-lived Hawaiian volcanic systems shows that the numerous cross-cutting dikes, which resulted from long-lived, high-flux activity in the Hawaiian system, are not compatible with the small, monogenetic volcanoes with their associated subparallel, thin dikes found in the Yucca Mountain region. Hence, the volcanic features characteristic of the Yucca Mountain region could not produce impoundment of groundwater and local elevation of the groundwater system, similar to features observed in Hawaiian volcanic systems.

Potential Effects on Mineralogy—It is possible that the thermal and geochemical influence of igneous activity could affect the mineralogy of the host rock surrounding the igneous intrusion and thus alter the response of the host rock to contaminants. Mineral alterations around igneous intrusions at natural analogue sites are generally confined to relatively thin zones (CRWMS M&O 1998 [DIRS105347], pp. 5-41 to 5-57). In particular, natural analogue studies in similar host rocks at the Nevada Test Site show that alteration is limited to a zone less than 10 m away from the intrusion/host rock contact (CRWMS M&O 1998 [DIRS 105347], pp. 5-41 and 5-71). *Synthesis of Volcanism Studies for the Yucca Mountain Site Characterization Project* (CRWMS M&O 1998 [DIRS 105347], p. 5-42) further states, "Based on natural-analogue sites, there is no indication for extensive hydrothermal circulation and alteration, brecciation and deformation related to magmatic intrusion, and vapor phase recrystallization during the magmatic intrusion into the vitric and zeolitized tuffs." Because the alteration zone around dikes is limited to the immediate proximity of the dike, then (at the scale of the repository) the changes

in mineralogy would have negligible effects on host rock mineralogy and on the chemical response of the host rock to contaminants.

These results may be generalized to evaluate the effects of changes in mineralogy on UZ radionuclide transport. Changes in mineralogy can result in changes in sorption characteristics for radionuclides and therefore may affect radionuclide transport. For the unsaturated zone, sensitivity studies have been conducted for changes in sorption coefficients within different hydrologic units, where the sorption coefficients have been set to zero within individual hydrologic units. These sensitivity studies have found that transport behavior has low sensitivity to changes in sorption in the zeolitized and vitric CHn, although transport behavior is sensitive to sorption in the TSw (SNL 2007 [DIRS 177396], Figures 6-37 and 6-44). Because dikes are not expected to significantly impact flow in the TSw and because flow is generally dispersed in the fractured rock in this unit, radionuclides would have very limited contact with dikes or zones affected by dikes within the TSw. Greater contact could occur between dikes and radionuclides in the CHn, particularly if the dikes are present in faults where focused flow and transport occur. However, the impact of changes in sorption in this part of the unsaturated zone is negligible (SNL 2007 [DIRS 177396], Figures 6-37 and 6-44).

Similarly, the limited small volume of material around the dike affected in terms of mineral alteration compared with the volume of saturated zone transport pathways and the relatively small impact of dike flow in the saturated zone would result in the altered zones associated with dikes having a negligible effect on saturated zone transport.

Summary—In summary, each element of the FEP description has been evaluated based on site data and analyses or information from natural analogues. For saturated zone flow, the subparallel orientation of potential future dikes to transmissivity, coupled with the expected limited affected volume, indicate that dikes, even if differing in permeability, will not significantly affect groundwater flow patterns. For unsaturated zone flow, the typical vertical orientation of dikes along with the insensitivity of flow behavior to fracture and fault properties leads to the expectation that alterations in such properties by an igneous intrusion would have negligible effect on flow behavior. The effects of an igneous intrusion with respect to the formation of additional perched water bodies are expected to be negligible because of the expected extent and configuration of any dikes or sills that might form. Furthermore, natural analogue studies show that mineral alteration is limited to a zone less than 10 m away from the contact, and due to the limited extent of the alteration, such zones, even if formed, would not have adverse impacts on radionuclide transport in the saturated and unsaturated zones. Consequently, changes in rock properties due to igneous activity do not provide mechanisms to significantly affect exposure or release of radionuclides to the accessible environment. Therefore, the effects of igneous activity on rock properties are excluded from the TSPA on the basis of low consequence.

Based on the previous discussion, omission of FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.04.03.0A

FEP NAME:

Igneous Intrusion into Repository

FEP DESCRIPTION:

Magma from an igneous intrusion may flow into the drifts and extend over a large portion of the repository site, forming a sill, dike, or dike swarm, depending on the stress conditions. This intrusion could involve multiple drifts. The sill could be limited to the drifts or a continuous sill could form along the plane of the repository, bridging between adjacent drifts.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The primary focus of this FEP is magmatic intrusion directly into the repository. The following discussion addresses the potential for such an intrusion and the resulting damage to EBS components. The damage potential is included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). Related FEPs discuss changes in hydrology (excluded FEP 1.2.10.02.0A (Hydrologic Response to Igneous Activity)) and rock properties (excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties)). A volcanic eruption featuring the development of one or more eruptive conduits within the repository footprint, which might intersect one or more drifts or waste packages, is discussed in included FEP 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository).

The technical basis for inclusion of igneous intrusion into the repository in the TSPA is founded on the results of the PVHA (CRWMS M&O 1996 [DIRS 100116]) described in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1), which indicates that the computed mean annual frequency of intersection of the repository footprint by a dike is 1.7×10^{-8}. The computed 5th and 95th percentiles of the uncertainty distribution for frequency of intersection are 7.4×10^{-10} and 5.5×10^{-8}, respectively. The PVHA presented a slightly lower annualized mean annual frequency of intersection of 1.5×10^{-8} (CRWMS M&O 1996 [DIRS 100116], p. 4-10) than the current estimate (1.7×10^{-8}/yr) (BSC 2004 [DIRS 169989], Table 7-1), but the difference is the result of using a somewhat different and smaller repository footprint.

Igneous intrusion into the repository has the potential to affect the thermal, geochemical, and hydrologic characteristics of the site (see included FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties) and excluded FEP 1.2.10.02.0A (Hydrologic Response to Igneous Activity) for discussions of rock properties and hydrologic impacts, respectively). Igneous intrusion into the repository could damage EBS components and the waste packages because of extreme changes in the in-drift environment. This damage could result in the release of radionuclides and affect the radiological exposure of the RMEI.

Because the probability of igneous intrusion is greater than the FEP screening probability threshold of 10^{-8} per year (proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394])) and because waste package damage cannot be constrained due to the thermal, mechanical, and geochemical environment associated with an intrusion into an emplacement drift, igneous intrusion into the repository is included within the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]). The environmental conditions and their effect on waste packages are discussed in included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components).

However, disruptive igneous events have estimated frequencies of occurrence that are less than 10^{-5} per year, and therefore such events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) based on low probability of occurrence. The exclusion of unlikely events (events having less than one chance in 10 of occurring in 10,000 years) from these assessments is consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

Total System Performance Assessment Model/Analysis for the License Application describes the approach for considering igneous intrusion and documents the implementation of the igneous intrusion abstractions (SNL 2008 [DIRS 178871], Sections 6.5 and 8.2.3). The two types of igneous activity (with individual probabilities and consequences) modeled are:

- An igneous intrusion featuring the ascent of a basaltic dike or dike system (i.e., a set, or swarm, of multiple dikes comprising a single intrusive event) to the repository level where it intersects drifts (this FEP)

- A volcanic eruption featuring the development of one or more volcanoes within the repository footprint, each with a conduit that may intersect waste packages (included FEP 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository)).

The overall concept represented in the TSPA is that of a dike propagating toward the surface and intersecting the repository. If the rising magma encounters the repository, it flows into and along the intersected repository drifts (this FEP). Coincident with dike intersection, one or more conduits may form within the repository footprint that have the potential to bring waste to the surface (included FEP 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository)). The characteristics and properties of magma that are used as input to the analyses and models are identified and described in *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260], Table 7-1). The consequences of the dike intersecting the repository drifts and magma flow into the drifts are addressed in *Number of Waste Packages Hit by Igneous Events* (SNL 2007 [DIRS 177432], Table 7-1), and damage to EBS components is described in *Dike/Drift Interactions* (SNL 2007 [DIRS 177430], Section 6.4).

Dike/Drift Interactions (SNL 2007 [DIRS 177430], Sections 6.2, 6.3, and 6.4) documents the analyses that represent potential processes included in TSPA associated with propagation of a dike migrating upward toward the surface, including the potential for sill development, intersection of the dike with repository drifts, and the environment in drifts after intrusion. The

analyses of the dike/drift interaction conceptual model provide the technical basis for assessing the potential impacts of an igneous intrusion on repository performance, including those FEPs related to dike/drift interaction (this FEP and included FEPs 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Component), 1.2.04.04.0B (Chemical Effects of Magma and Magmatic Volatiles), and 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository)).

The consequences of igneous intrusion into the repository are included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) for the period of geologic stability.

FEP: 1.2.04.04.0A

FEP NAME:

Igneous Intrusion Interacts with EBS Components

FEP DESCRIPTION:

An igneous intrusion in the form of a dike may occur through the repository, intersecting the repository drifts, resulting in magma, pyroclastic debris, and volcanic gases entering the drift and interacting with the EBS components (drip shields, waste packages, pallet, and invert). This could lead to accelerated drip shield and waste package failure (e.g., attack by magmatic volatiles, damage by flowing or fragmented magma, thermal effects) and dissolution or volatilization of waste.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The primary focus of this FEP is interactions between the intrusion, the waste, and the waste packages. These interactions are included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) because magma could interact with the elements of the EBS and the waste packages could be impaired due to perturbations of the drift environment, thereby resulting in damage to the waste packages and mobilization of waste.

As discussed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository), disruptive igneous events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because they are unlikely events (events having less than one chance in 10 of occurring in 10,000 years). The exclusion of unlikely events from the groundwater protection and human intrusion performance assessments is consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

The technical basis for including igneous intrusion into the repository (i.e., igneous activity) in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) is that igneous intrusion would cause changes in the in-drift environment that could damage EBS components and the waste packages. Such events have the potential to affect both the geochemical and hydrologic characteristics of the site (see excluded FEPs 1.2.04.02.0A (Igneous Activity Changes Rock Properties) and 1.2.10.02.0A (Hydrologic Response to Igneous Activity) for discussions of rock properties and hydrologic impacts, respectively). This damage could result in the release of radionuclides and affect the radiological exposure of the RMEI. The environmental conditions and their effect on waste packages are discussed in this FEP. Environmental conditions affecting the waste form and subsequent dissolution and transport of

radionuclides by groundwater after seepage has been reestablished are considered under included FEP 1.2.04.04.0B (Chemical Effects of Magma and Magmatic Volatiles).

The two types of igneous event (with individual probabilities and consequences) being modeled by the TSPA are:

- An igneous intrusion featuring the ascent of a basaltic dike or dike system (i.e., a set of one or more dikes comprising a single intrusive event) to repository level where it intersects drifts

- A volcanic eruption featuring the development of one or more volcanoes within the repository footprint, each with a conduit that may intersect waste packages.

These are treated separately within TSPA for two reasons: (1) the transport pathways that might produce radiation dose to the RMEI are very different; (2) as described below, while any igneous event that intersects the repository is assumed to result in both intrusion and eruption, not all eruptions carry waste to the surface. As a consequence of igneous intrusion into the repository, waste from packages that are contacted by magma may provide a source of radionuclides when groundwater moves through the damaged packages at some time in the future (igneous intrusion). The potential consequence of the volcanic eruption is that waste packages entrained within a conduit may be breached, releasing radionuclides in an erupting ash plume where they can be dispersed downwind to the RMEI. The location of the RMEI is defined as being approximately 18-km south of the repository (10 CFR 63.312 and 63.302 [DIRS 180319]). It is assumed that any igneous event that intersects the repository will also result in an eruption. However, the conduit(s) for that eruption may or may not intersect repository drifts. A dike intersection with a drift is assumed to result in flooding of the entire repository with magma, and this is the starting point for the evaluation of the consequences of igneous intrusion. However, only a fraction of such events will also have eruptive conduits that intersect a drift and are therefore able to erupt radioactive waste onto the surface. *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 178871], Section 6.5) describes the approach for considering igneous intrusion and documents the actual implementation of the igneous intrusion abstractions.

Dike/Drift Interactions (SNL 2007 [DIRS 177430], Section 6.4.8.3) provides an analysis of magma interactions with the EBS. The analysis indicates that an igneous intrusion would damage drip shields, waste packages, and cladding materials in magma-flooded drifts such that they would no longer protect the waste form. In particular, following contact by magma, the Alloy 22 and stainless steels in the waste package would lose their tensile strength and deform plastically at magmatic temperatures (up to about 1,200°C). Waste packages could fail in response to external or internal pressures and temperatures as creep strains exceed the strain limits of the end cap materials, and magma could enter the failed waste packages (SNL 2007 [DIRS 177430], Section 8.1.2). Waste packages also could be subjected to corrosive vapor, which could have a significant impact on the corrosion rates of metals embedded in the cooling magma (SNL 2007 [DIRS 177430], Sections 6.4.8.3.1 and 6.4.8.3.3). Once the drift has filled with magma, the magma is apt to stagnate. Because of this stagnation and subsequent cooling and solidification of the magma, significant flow of magma through the affected waste packages is not anticipated (SNL 2007 [DIRS 177430], Section 8.1.2). The forces generated by magma

would not be sufficient to move intact waste packages along a drift into an errupting conduit (SNL 2007 [DIRS 177430], Section 6.4.8.3.2). The evaluation of potential damage mechanisms supports the TSPA assumption that waste packages in magma-flooded drifts will provide no protection for the contained waste. Therefore, TSPA assumes that all waste packages and drip shields are failed (SNL 2007 [DIRS 177432], Table 7-1). Within the TSPA, no credit is taken for any partial protection that residual elements of the waste package shells and the encapsulating basalt might provide.

Commercial SNF, which is a ceramic composed of UO_2, will not melt or volatilize in a basalt magma (SNL 2007 [DIRS 177430], Section 6.4.8.3.3). The melting temperature of the ceramic ranges from approximately 2,600°C to 2,800°C, while the temperature of the magma is over a thousand degrees less (up to approximately 1,150°C; SNL 2007 [DIRS 177430], Section 8.1.2). However, when waste packages fail, the fuel pellets may be assimilated into cooling basalt magma (no credit is taken for cladding) (SNL 2007 [DIRS 180616], Section 6.2.1.2[a] and Table 7-2[a]).

Glass waste is contained within waste packages and would be expected to re-melt and re-solidify as the drift is intruded and then cools (SNL 2007 [DIRS 177430], Section 6.4.8.3.3). Some interaction would be expected between the exposed and partially degraded glass waste and basalt magma given the melting temperature of glass waste (melting begins at about 915°C (BSC 2004 [DIRS 169988], Section 6.5.5.3) compared to basalt magma at about 1,150°C (SNL 2007 [DIRS 177430], Section 8.1.2), and the large difference in composition between glass waste (e.g., BSC 2004 [DIRS 169988], Section 6.5.2.2) and basalt magma (SNL 2007 [DIRS 174260], Section 6.3.2). For TSPA, once intrusion occurs, all waste is assumed unprotected, instantaneously degraded, and the radionuclides are assumed immediately available for mobilization by groundwater (SNL 2008 [DIRS 178871], Section 6.5.1.1.1).

Interactions of the intrusion with repository drifts are implemented within the TSPA for intrusions occurring within the period of geologic stability. These interactions are incorporated into the TSPA as assumptions or parameters as follows:

- Assumptions underlying the consequences of igneous intrusion on the waste package and waste form
- Parameters related to resumption of seepage following cooling of the drift after the magmatic intrusion.

Within the TSPA, lookup tables are used to model magma temperature as a function of time for the center of the cooling magma body. These lookup tables determine when seepage is reestablished, exposing the encased waste form to seepage flux. The abstraction considers the temperature of the waste form for a period of 100 years following intrusion, after which the intrusion-related temperature perturbation is negligible. The decline in temperature of the waste form and magma body is related to the temperature due to waste heat alone at 25°C, 50°C, 100°C, 150°C, and 200°C (SNL 2007 [DIRS 177430], Section 6.4.7.2).

Dike/Drift Interactions (SNL 2007 [DIRS 177430], Section 6.6) contains a summary of analogue compositions of water in contact with basalt. Included FEP 1.2.04.04.0B (Chemical Effects of

Magma and Magmatic Volatiles) describes the TSPA method used to simulate basalt–seepage water reactions within the drift for the igneous intrusion model. *Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 177431]) provides a description of a potential eruption through the repository. Included FEPs 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository) and 1.2.04.07.0A (Ashfall) describe how eruptions are incorporated into the TSPA.

Volatilization of Waste—Volatilization of some fission products (cesium and strontium) by magmatic temperatures is identified as a process that could affect waste forms (SNL 2007 [DIRS 177430], Sections 6.4.8.3.3 and 8.1.2). Although not included in the above description, iodine could also be volatilized by magmatic temperatures. If any of these radionuclides were volatilized, it is expected that as those gas species moved away from the waste form, they would be incorporated, in part, into the magma and in part redissolved into water (e.g., matrix pore water) at its closest location to the drift perimeter because of their high solubilities. It is further expected that these volatilized radionuclides would be located preferentially, and possibly exclusively, above the emplacement drifts because the hot gases would generally rise as they move down the temperature gradient.

Waste form volatilization processes are not directly included in TSPA. Rather, when intersection of the repository occurs, magma engulfs all drip shields and waste packages in the repository and neutralizes their abilities to inhibit flow of seepage (percolation) (SNL 2008 [DIRS 178871], Section 6.5.5.1) and protect the waste. Waste forms in the engulfed waste packages are instantly degraded during the intrusion event (SNL 2008 [DIRS 178871], Section 6.5). Hence, upon intrusion, the entire waste inventory of the repository is immediately available for transport through normal mobilization processes once the magma cools below the boiling point of water and seepage returns to the basalt filled drifts (SNL 2008 [DIRS 178871], Section 6.5.1.1.1). Since the entire waste inventory is assumed to be completely degraded at the time of intrusion, any contribution to degradation that would be associated with volatilization processes is already included. Furthermore, the cooled basalt is assumed to provide no additional impediment to water flow (SNL 2008 [DIRS 178871], Section 6.5.1.3), and the percolation flux contacts all the radionuclides of the degraded waste form which are available for advective transport of radionuclides from the EBS (SNL 2008 [DIRS 178871], Section 6.5.1.3) once flow is restored to the basalt-filled drifts.

In summary, FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components), which includes interactions between igneous intrusions, waste, and waste packages are included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). However, disruptive igneous events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because they have been determined to be unlikely events (proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394])).

FEP: 1.2.04.04.0B

FEP NAME:

Chemical Effects of Magma and Magmatic Volatiles

FEP DESCRIPTION:

An igneous intrusion into the repository may be accompanied by the release of magmatic volatiles. The volatiles may affect in-drift chemistry (potentially leading to increased waste package corrosion), or may be absorbed by the host rock, where they could change the chemistry of the water seeping back into the drift following the intrusive event. Seepage water chemistry following magma cooling could also be affected by flowing through and interacting with the intruded basalt.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP is concerned with magmatic volatiles and their potential effects on in-drift chemistry and on water chemistry, and with the basaltic magma that may fill one or more repository drifts and its effect on water chemistry. The FEP is included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). The effects of magmatic volatiles on in-drift chemistry and specifically effects on EBS components have been analyzed (SNL 2007 [DIRS 177430], Section 6.4.8.3).

As discussed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository), disruptive igneous events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because they are unlikely events (events having less than one chance in 10 of occurring in 10,000 years). The exclusion of unlikely events from the groundwater protection and human intrusion performance assessments is consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

The effects of magmatic volatiles on water chemistry are not relevant because the temperatures that accompany intrusion are much greater than the boiling temperature of water, and any water present in the host rock would be displaced away from the drift perimeter by the increased temperatures and would not return until temperatures had fallen below boiling temperatures. Based on analysis results (SNL 2007 [DIRS 177430], Table 8-2), the period of time required for temperatures to return to sub-boiling depends on the pre-intrusion drift temperature, which is related to the amount of heat from emplaced waste. The results (SNL 2007 [DIRS 177430], Table 8-2) show that the amount of time needed for drift temperatures to return to sub-boiling levels varies from 2 to 3 years for drifts initially at 25°C to more than 100 years for drifts initially at 200°C. In any case, by the time water flow is reestablished near the drift perimeter,

magmatic gases would no longer be present and therefore could not alter groundwater chemistry. However, changes in water chemistry associated with interaction with cooled basalt are included in the TSPA.

As stated in included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Component), if any drift in the repository is intersected by a basaltic dike, all drifts are assumed to flood with magma, and all waste packages are compromised.

Assuming that an igneous intrusion occurs and the magma subsequently cools to ambient conditions, seepage water is expected to flow through and react with the basalt in the intruded emplacement drifts. The chemical interaction of the seepage water chemistry with the basalt is included in the TSPA.

Because transport of radionuclides by groundwater is included in TSPA and since radionuclide mobility is influenced by groundwater chemistry, the analysis requires consideration of the chemistry of groundwater that has been in contact with the basalt surrounding the waste packages. For development of the pH and ionic strength abstractions that are used in TSPA, three groundwater samples from large fractured basalt reservoirs were selected for sensitivity analyses that examined pH and ionic strength of water that has reacted with cooled basalt (SNL 2007 [DIRS 180506], Section 4.1.2[a]). These sensitivity studies described in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.6.2[a]) were used to estimate solution development during reactions between basalt-equilibrated water and the in-package materials. The analyses showed that in-package chemistry is insensitive to seepage water composition and subsequent reaction with basalt. Therefore, in-package chemistry abstraction for nominal conditions is used in the TSPA to simulate the waste form chemical conditions following an igneous intrusion.

The TSPA parameters for pH and ionic strength have been described in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 8.2[a] and Table 6-21[a]), and the details for TSPA implementation of these abstractions are also provided (SNL 2007 [DIRS 180506], Section 6.10.9[a]). Uncertainties in the values of pH and ionic strength are quantified and propagated in TSPA as described in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.10.8[a]).

FEP: 1.2.04.05.0A

FEP NAME:

Magma or Pyroclastic Base Surge Transports Waste

FEP DESCRIPTION:

As a result of an igneous intrusion, extrusive processes may result in a pyroclastic density current (base surge), effusive lava flows, and/or development of a volcanic cone at the land surface. Some of the waste (entrained, dissolved, or volatized) could then be transported away from the repository. Of most concern is transport directly along the land surface to the RMEI.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is focused on near-surface eruption-related phenomena and transport of entrained wastes by lava flows and base surges (also referred to as pyroclastic surges). Hydrovolcanic phenomena also are addressed in this FEP. Due to the distance to the RMEI, and the limited distance that basaltic lavas and hydrovolcanic deposits are expected to flow, hydrovolcanic phenomena are excluded based on low consequence. Transport directly to the receptor by aerial dispersal and/or subsequent reworking of the deposited ash following an eruptive event are addressed separately in included FEP 1.02.04.07.0A (Ashfall) and its companion included FEP 1.02.04.07.0C (Ash Redistribution Via Soil and Sediment Transport).

The technical basis for exclusion for this FEP begins with definition of the term RMEI, which specifies that the affected individual is located no closer to the repository than 18 km to the south (which is in the direction of groundwater flow) and over a contaminated groundwater plume (10 CFR 63.312 and 63.302 [DIRS 180319]). For flowing lava or a pyroclastic base surge (potentially containing entrained waste) to be of consequence to the accessible environment or the RMEI, it would have to travel across the land surface a distance of 18 km. In contrast to this distance, the eight Quaternary volcanoes in the vicinity of Yucca Mountain are small volume (approximately 0.1 km^3 or less) (SNL 2007 [DIRS 174260], Table 6-2), and typically consist of a single main basaltic scoria cone surrounded by one or two small lava flow fields that, in most cases, extend about 1 km from the source (SNL 2007 [DIRS 174260], Section 6.1.3.3; Valentine and Perry 2006 [DIRS 177495], Table 1). The Quaternary volcanism continues the well-documented record of waning monogenetic volcanism that began in the Miocene within the Yucca Mountain region (BSC 2004 [DIRS 169989], Section 6.2; Valentine and Perry 2006 [DIRS 177495], Table 1). Consequently, it is not credible to presume that future extruded basalts with entrained wastes would extend to the RMEI located 18 km south of the repository. Potential pyroclastic (base) surge deposits are also of limited geographic extent as described below.

Pyroclastic deposits are characterized by a wide range of materials, transport mechanisms, and depositional environments. Two main types of pyroclastic activity are recorded in Quaternary

volcanoes of the Yucca Mountain area (SNL 2007 [DIRS 174260], Section 6.3.1): (1) Strombolian eruptions in which discrete bursts eject coarse lapilli, blocks, and bombs, which accumulate within a few hundred meters of the vent; and (2) violent Strombolian eruptions that produce sustained columns of gas, ash, and lapilli that can extend to several kilometers altitude above the vent. Ash and lapilli fall out of violent Strombolian eruption columns (or plumes) as the plumes are dispersed downwind. For example, the ash deposited during the Lathrop Wells eruptions (~77,000 years ago) has been traced to distances of about 20 km from the vent (SNL 2007 [DIRS 174260], Appendix C). Pyroclastic eruptive mechanisms associated with violent Strombolian eruptions may result in transport of pyroclastic tephra (e.g., lapilli and ash) to distances sufficient to reach the RMEI. This aspect of an igneous event has been included and is addressed separately in included FEP 1.02.04.07.0A (Ashfall) and its companion included FEP 1.02.04.07.0C (Ash Redistribution via Soil and Sediment Transport); they are not discussed further in this section.

A third type of explosive eruptive phenomenon, which is recorded very rarely in deposits of Quaternary volcanoes in the Yucca Mountain region, is pyroclastic density currents or base surges (SNL 2007 [DIRS 174260] Appendix C). Base surges are mixtures of gas and pyroclasts that are denser than the atmosphere and therefore travel along the ground as density currents. They may be produced by the following mechanisms: (1) fountaining of a violent Strombolian eruption column if it is unable to buoyantly rise into the atmosphere; and (2) localized lateral flow of ash and fine lapilli and entrained air during very heavy fallout of particles from an eruption column that is otherwise buoyant, and (3) collapse of pyroclast-steam clouds that are ejected by explosive interaction of magma with ground or surface waters (hydrovolcanic eruptions).

Only two localized deposits that have indicators of lateral transport such as a base surge mechanism have been found in the eight Quaternary volcanoes of the Yucca Mountain region. Both of these deposits are found at the Lathrop Wells volcano. One of the occurrences is a thin (~40 cm maximum thickness) sequence of laminated and cross-laminated deposits near the summit of the Lathrop Wells cone. The lateral extent of this sequence is on the order of several tens of meters (SNL 2007 [DIRS 174260], Section C.6.1). The interpretation for this deposit is emplacement by weak density currents adjacent to the vent due to locally heavy ash fallout from an eruption column (second mechanism listed in preceding paragraph). The second occurrence of deposits that might have been emplaced by a base surge mechanism is found on the cone-facing side of a hill at distances of ~200 to 300 m northwest of the base of the cone (SNL 2007 [DIRS 174260]), Section C.6.2). The origin of this deposit is uncertain. It might have been produced by any of the three mechanisms listed in the preceding paragraph or it might have been produced by eolian reworking of preexisting ash deposits during a pause in explosive activity at the vent.

Given the lateral scale of the observed Quaternary deposits that might have been produced by base surges (on the order of 1 km or less from the vent), it is not credible to presume that pyroclastic surges with entrained waste particles would reach from the vent to the RMEI located 18 km south or to the controlled area boundaries at no greater than 5 km from the repository in other directions. This implies that base (pyroclastic) surges from a volcanic eruption at the Yucca Mountain site would have no consequence to the RMEI.

A related issue is whether a large steam explosion could occur, such that a large phreatic or a hydrovolcanic crater (maar) might form. Theoretically, such a process could excavate to the depth of the repository (~300 m) and disperse waste over a large area of the surrounding surface. Hydrovolcanic activity requires that rising magma encounter water in an aquifer(s) or a shallow water body at the ground surface (BSC 2004 [DIRS 174260], Section 6.1.3.2; Fisher and Schmincke 1984 [DIRS 162806], pp. 231 to 264; Wohletz and Heiken 1992 [DIRS 105544], pp. 85 to 154). The resulting steam explosion finely fragments the magma and produces large amounts of kinetic energy. If the encounter occurs below the ground surface, the host rocks are fragmented and are incorporated in the eruption products, which become elevated in lithic clast content. For such a disruptive steam explosion to occur, magma must come in rapid contact with a large volume of water at a shallow depth. Confining pressures must be sufficiently low to permit the formation of steam and to allow disruption of the surrounding rock as the steam violently expands. Crowe et al. (1986 [DIRS 101532], p. 47) suggest that a limited area of contact, such as a dike projecting through a thin (less than 10 m) perched aquifer, does not allow development of explosive instability, whereas contact with a standing body of surface water or thick (greater than 30 m) horizon of water-saturated rock permits water to vaporize at explosive rates. Additionally, magma–water mixing and explosion associated with maars, tuff rings, and tuff cones generally occur at depths less than 200 m, which corresponds to a confining pressure of 5 MPa or less. However, the distribution of potential Quaternary hydrovolcanic deposits in the Yucca Mountain region is limited to areas proximal to vents (SNL 2007 [DIRS 174260], Sections C.6.2 and E.6.1), and the extents of such deposits are insufficient to reach the RMEI. Consequently, transport by a hydrovolcanic cratering event is excluded from the TSPA based on low consequence.

Based on the previous discussion, omission of FEP 1.2.04.05.0A (Magma or Pyroclastic Base Surge Transports Waste) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.04.06.0A

FEP NAME:

Eruptive Conduit to Surface Intersects Repository

FEP DESCRIPTION:

As a result of an igneous intrusion, one or more volcanic vents may form at land surface. The conduit(s) supplying the vent(s) could pass through the repository, interacting with and entraining waste.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP is included in the performance assessment to demonstrate compliance with the individual protection requirements of proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) and is addressed by the modeling of an eruption. The probability of occurrence of this event is less than 1×10^{-5} per year and is thus excluded from the performance assessments conducted to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) and the groundwater protection standard (10 CFR 63.331 [DIRS 180319]), consistent with the requirements in proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]). The consequences of an igneous intrusion through the repository and an associated eruptive event are explicitly included in TSPA through modeling of aerial dispersion followed by deposition and redistribution of potentially contaminated pyroclastic materials; the consequences are appropriately weighted by the probability of occurrence of the event.

The technical basis for inclusion of this FEP relies on the definition of an igneous event, which includes eruption at the Earth's surface (BSC 2004 [DIRS 169989], Section 5.2), and on the results described in *Number of Waste Packages Hit by Igneous Events* (SNL 2007 [DIRS 177432], Table 7-1). Those results indicate that the proportion of calculated intrusive igneous events in which eruption also occurs is 0.28 (SNL 2007 [DIRS 177432], Table 7-1), representing a mean annual probability of about 4.8×10^{-9}. Even though the estimated mean annual probability is less than the probability screening threshold in 10 CFR 63.114(d) [DIRS 180319], the consequences of volcanic eruption are evaluated because the event definition is based on the mean annual frequency of intrusion (BSC 2004 [DIRS 169989], Section 5.2) (see included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) and BSC 2004 [DIRS 169989], Table 7-1).

Total System Performance Assessment Model/Analysis for the License Application describes the approach for considering igneous intrusion and documents the actual implementation of the igneous intrusion abstractions (SNL 2008 [DIRS 183478], Section 6.5). Igneous consequences modeled by the TSPA are:

- An igneous intrusion featuring the ascent of a basaltic dike or dike system (i.e., a set or swarm of multiple dikes comprising a single intrusive event) to the repository level where it intersects drifts (included FEP 1.2.04.03.0A (Igneous Intrusion into Repository))

- A volcanic eruption featuring the development of one or more eruptive conduits within the repository footprint, each of which might intersect waste packages (this FEP).

The potential consequences of the volcanic eruption are that waste packages intersected by a conduit may be breached, releasing radionuclides in an erupting ash plume followed by dispersal downwind to the RMEI, and redistribution by surface transport processes after deposition. The location of the RMEI is approximately 18-km south of the repository (10 CFR 63.312 and 10 CFR 63.302 [DIRS 180319]).

Properties and characteristics of typical basaltic eruptions are described in *Characterize Eruptive Processes at Yucca Mountain*, *Nevada* (SNL 2007 [DIRS 174260], Section 6). The eruption characteristics used in the TSPA model are based on the characteristics of preserved basaltic eruption products in the Yucca Mountain region and other observed analogous eruptions. For the volcanic eruption, a dike rises to the repository level, intersects one or more drifts in the repository, and proceeds vertically toward the surface. After magma in the dike encounters the ground surface, a fissure eruption develops, which proceeds to focus to one or more eruption sites as conduits develop from the surface downward. Conduits within the repository footprint are presumed to be located randomly along the dikes. It is presumed that where conduits intersect drifts, the waste packages in the intersected areas no longer provide any protection for the waste, which is then entrained in the erupted materials. Section 6.5.2.15 of *Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 177431]) provides the basis for assuming that the erupted waste materials are finely divided particles amenable for airborne transport, and Section 6.5.2.22 of that report provides the basis for partitioning the contaminated eruption products among lava, cone-forming material, and aerially dispersable material.

Dike/Drift Interactions (SNL 2007 [DIRS 177430], Sections 6.4.7.1.5, 6.4.7.2.2, 6.5.1.5, and 6.5.4), provides conclusions related to various conceptual models for magma flow in drifts, including consideration of the "dog-leg scenario." That scenario involves magma flow from the point of the dike/drift intersection to the end of the drift, and development of a secondary dike that continues to the land surface at some location along the drift and away from the intersection. With regard to the secondary breakout, *Dike/Drift Interactions* (SNL 2007 [DIRS 177430], Section 6.5.2) states:

> Based on the discussion in this section, effusive magma will continue along the trajectory of the original dike after intruding the drift complex. Even if an existing joint at the drift periphery is invaded by magma, the flow will be interrupted by magma freezing long before it is able to reach the surface. Therefore, it is concluded that the dog-leg scenario is not credible for effusive magma.

The analysis of dike propagation potential, including the formation of a secondary breakout and pyroclastic flow, is extended in *Magma Dynamics at Yucca Mountain, Nevada* (BSC 2005 [DIRS 174070]) and the study by Dartevelle and Valentine (2007 [DIRS 182090]). The analyses

include potential initial and boundary conditions and the resulting effect on magma freezing (BSC 2005 [DIRS 174070], Section 6.3.2). The work also includes simulated pyroclastic magma flow into pre-existing cracks, and evaluates characteristics of a more energetic dike/drift intersection at repository depth, specifically recognizing the two-phase nature of the hawaiitic magma that could contain from 1 wt % to 5 wt % water (SNL 2007 [DIRS 174260], Section 6.3.2.2). The studies conclude the following:

- Magma attempting to open a secondary dike by intruding a preexisting crack will solidify before the crack can grow to an appreciable width, even considering elevated temperatures for the wall rock (BSC 2005 [DIRS 174070], Section 6.3.2).

- In the event a drift is intersected by a dike with two-phase (pyroclastic) magma, the simulated presence of a secondary opening down-drift from the main dike results in only minor calculated differences in the flow dynamics of the magma-drift interaction relative to a drift with no secondary opening (BSC 2005 [DIRS 174070], Section 6.4.2).

Thus, multiple analyses conclude that the main dike is the preferred pathway through which effusive or pyroclastic magma will flow into or out of an intersected drift (SNL 2007 [DIRS 177430], Section 6.5.2). Consequently, the "dog-leg" alternative conceptual model of a secondary breakout is is not further considered in the TSPA.

Atmospheric transport of the ash–waste mixture is modeled directly in TSPA using ASHPLUME, the atmospheric ash dispersal model. *Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada,* (SNL 2007 [DIRS 177431], Section 6.5.2) describes the technical basis for input parameters required for the ASHPLUME model. The model is based on assumed incorporation and entrainment of waste fuel particles into the ash cloud associated with a volcanic eruption through the Yucca Mountain repository, and evaluates downwind transport of contaminated tephra and deposition of radioactive waste or ash on the ground surface. The ASHPLUME model is based on a model of Suzuki (1983 [DIRS 100489]) that Jarzemba et al. (1997 [DIRS 100987]) refined to represent the entrainment of radioactive waste in the convective eruptive plumes associated with violent Strombolian eruptions. The ASHPLUME model is implemented in TSPA as a DLL, ASHPLUME_DLL_LA V2.1 [DIRS 178870]. Values for the 36 ASHPLUME input parameters are provided as constants, stochastic ranges, or tables (SNL 2007 [DIRS 177431], Section 6.5.2). The TSPA model for atmospheric dispersal and deposition of waste-containing tephra uses a parameter, magma partitioning factor, which acts as a fractional multiplier on the mass of waste available for transport. This magma partitioning factor is provided as a range (0.1 to 0.5, uniform probability (SNL 2007 [DIRS 177431], Section 6.5.2.22). In a given TSPA realization, the initial value of total waste mass available for transport is derived from sampling the number of waste packages hit (SNL 2007 [DIRS 177432], Table 7-1). The number of waste packages hit by an eruption is multiplied by the magma partitioning factor to produce a value for the input parameter *mass of waste available for transport*.

Redistribution of radionuclide-contaminated ash after an eruption intersects the repository drifts is addressed in *Redistribution of Tephra and Waste by Geomorphic Processes Following a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 179347]). The tephra redistribution model is implemented in TSPA as a DLL (FAR V1.2 [DIRS 182225],

STN: 11190-1.2-00). Values for the FAR input parameters are provided as constants, stochastic ranges, or tables (SNL 2007 [DIRS 179347], Section 6.5). The FAR V1.2 code ([DIRS 182225], STN: 11190-1.2-00) redistributes contaminated ash down Fortymile Wash and its distributaries to the depositional fan where the RMEI is located. The concentration of waste particles within the redistributed ash volume at a given location is influenced by the number of waste packages impacted by intersection of the repository drifts by the ascending magmatic dike, the volume of erupted ash, the magma partitioning factor, wind direction, how the contaminated ash is distributed upon the landscape, and surface transport processes, among others. TSPA uses this information to calculate dose to the RMEI.

The consequences of an eruptive conduit intersecting the repository are included in the TSPA from the perspectives of dike intersection, ash/waste eruption to the atmosphere, deposition from an eruptive ash cloud, and redistribution by surface processes. The associated processes of ash/waste eruption to the atmosphere, deposition from an eruptive ash cloud, and redistribution by surface processes are described in included FEP 1.2.04.07.0A (Ashfall) and in excluded FEP 1.2.04.07.0B (Ash Redistribution in Groundwater).

FEP: 1.2.04.07.0A

FEP NAME:

Ashfall

FEP DESCRIPTION:

Finely divided waste particles may be carried up a volcanic vent and deposited on the land surface from an ash cloud.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Ashfall is included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). This FEP is addressed through the modeling of an eruption that includes airborne transport and tephra (ash) deposition. (The preferred term "tephra" refers to pyroclasts resulting from a volcanic eruption, regardless of size, in contrast to the term "ash" which refers only to pyroclasts less than 2-mm in diameter.) Consequences of the resulting tephra fall are explicitly included in the TSPA and are appropriately weighted by the probability of occurrence of the event.

The technical basis for inclusion of this FEP relies on the definition of an igneous event, which includes eruption at the Earth's surface (BSC 2004 [DIRS 169989], Section 5.2), and on the results described in *Number of Waste Packages Hit by Igneous Events* (SNL 2007 [DIRS 177432], Table 7-1). Those results indicate that the proportion of calculated intrusive igneous events in which eruption also occurs is 0.28 (SNL 2007 [DIRS 177432], Table 7-1), representing a mean annual probability of about 4.8×10^{-9}. Even though the estimated mean annual probability is less than the probability screening threshold in 10 CFR 63.114(d) [DIRS 180319], volcanic eruption is included in the TSPA because the event definition is based on the mean annual frequency of intrusion (BSC 2004 [DIRS 169989], Section 5.2) (see included FEP 1.2.04.03.0A (Igneous Intrusion into a Repository) and BSC 2004 [DIRS 169989], Table 7-1).

The lateral extent of tephra fall from such activity is sufficient to reach the location of the RMEI, so the FEP has been included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). Radioactive waste-containing volcanic tephra is the initial source of contamination for the volcanic scenario. However, as discussed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository), disruptive igneous events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because they are unlikely events (events having less than one chance in 10 of occurring in 10,000 years). The exclusion of this

FEP from the groundwater protection and human intrusion performance assessments is consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

Total System Performance Assessment Model/Analysis for the License Application (SNL 2008 [DIRS 178871], Section 6.5) describes the approach for considering volcanic eruption and documents the implementation of the volcanic eruption abstractions. The two types of igneous activity (with individual probabilities and consequences) are considered:

- An igneous intrusion featuring the ascent of a basaltic dike or dike system (i.e., a set or swarm of multiple dikes comprising a single intrusive event) to the repository level where it intersects drifts (included FEP 1.2.04.03.0A (Igneous Intrusion into Repository))

- A volcanic eruption featuring the development of one or more volcanoes within the repository footprint, each with a conduit that may intersect waste packages (included FEP 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository)).

The potential consequence of a volcanic eruption is that waste packages entrained within a conduit may be breached to form a well-mixed suspension in the rising magma and comprising a component of the tephra upon magma fragmentation at the vent. The resulting waste-containing tephra is dispersed downwind in the tephra plume and may be deposited at the RMEI location. The location of the RMEI is assumed to be approximately 18-km south of the repository (10 CFR 63.312 and 63.302 [DIRS 180319]). *Total System Performance Assessment Model/Analysis for the License Application* implements this airborne pathway and assesses its impact on the RMEI (SNL 2008 [DIRS 178871], Section 6.5.2.2). The conceptual model for the eruptive process is discussed under included FEP 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository). The following discussion is focused on the eruption of a tephra-waste mixture into the atmosphere and subsequent transport and deposition.

Eruption parameters described in *Characterize Eruptive Processes at Yucca Mountain*, *Nevada* (SNL 2007 [DIRS 174260], Table 7-1) are based on the observed characteristics of past basaltic eruptions in the Yucca Mountain region and other analogous eruptions. This report includes the results of field investigations dealing with physical volcanology and tephra distribution and includes the conceptual models for eruptive processes. This information is used to develop parameter value distributions appropriate for analysis of the consequences of volcanic eruptions through a proposed repository at Yucca Mountain, Nevada. The parameters related to this FEP include the following (SNL 2007 [DIRS 174260], Table 7-1):

- Eruption duration for formation of an entire volcano

- Duration of a single explosive phase constituting a violent Strombolian eruptive phase

- Tephra fall or ash volume

- Standard deviation of particle size distribution for a given mean

- Clast characteristics
- Density of erupted particles
- Tephra deposit density
- Magmatic temperatures, viscosities, densities, and water contents
- Magma ascent rate below fragmentation depth
- Mean ash particle diameter
- Ash particle diameter standard deviation for particle size distribution
- Ash particle shape factor
- Ash particle density variation with particle size.

The results of the analysis in Table 7-1 of *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260],) do not directly feed to the TSPA model; rather the results provide the technical basis for inputs to *Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 177431], Table 6-3). Many other outputs from *Characterize Eruptive Processes at Yucca Mountain, Nevada* (SNL 2007 [DIRS 174260], Table 7-1) support analyses resulting in parameter distributions that are used in analyses that support the TSPA (e.g., conduit diameter in SNL 2007 [DIRS 177432], Table 4-1) or support the conceptual model implemented in the TSPA (e.g., magma chemistry).

Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada (SNL 2007 [DIRS 177431], Table 6-3) lists parameters used to implement this FEP within the TSPA. The technical bases developed within that report (SNL 2007 [DIRS 177431], Section 6.5.2) include, but are not limited to, the following parameters:

- Eruptive power and eruption duration
- Column diffusion constant, which affects the distribution of particles within the tephra column
- Waste incorporation ratio, a mathematical construct used to transport a density-corrected "combined" tephra and fuel particle
- Waste particle size (min, max, mode)
- Maximum particle diameter for transport
- Wind speed and wind direction, based on site-specific data collected over the appropriate range of tephra column height
- Initial rise velocity of plume

- Eddy diffusivity constant, with the simplification made that particle diffusion time equals particle fall time
- Magma partitioning factor
- Model grid parameters.

Atmospheric transport of the tephra–waste mixture is modeled directly in TSPA using ASHPLUME, the atmospheric tephra dispersal model. The model is based on assumed incorporation and entrainment of waste fuel particles associated with a volcanic eruption through the Yucca Mountain repository, and it evaluates downwind transport of contaminated tephra and radioactive waste and their deposition on the ground surface. The ASHPLUME model for Yucca Mountain is based on a model of Suzuki (1983 [DIRS 100489]) that Jarzemba et al. (1997 [DIRS 100987]) refined to represent the entrainment of radioactive waste in the convective eruptive plume associated with violent Strombolian eruptions. The ASHPLUME model is implemented in TSPA as a DLL, ASHPLUME_DLL_LA V2.1 (2006 [DIRS 178870], STN: 11117-2.1-00). Values for the 36 ASHPLUME input parameters are provided as constants, stochastic ranges, or tables. The TSPA model for atmospheric dispersal and deposition of waste-containing tephra uses a parameter that acts as a fractional multiplier on the mass of waste available for transport and accounts for the waste-containing magma that would form lava flows and scoria cones and would therefore not be available for atmospheric transport. This "magma partitioning factor" is provided as a range (0.1 to 0.5, uniform; see SNL 2007 [DIRS 177431], Table 8-2). In a given TSPA realization, the initial value of total waste mass available for transport derived from sampling the number of waste packages hit (SNL 2007 [DIRS 177432], Table 7-1) is multiplied by the magma partitioning factor to produce a value for the input parameter, "mass of waste available for transport."

Volcanic tephra is the source of inhalation dose during a volcanic eruption and all-pathway dose following the tephra fallout (SNL 2007 [DIRS 177399], Sections 6.3.2 and 6.15.2). The TSPA model, using ASHPLUME, estimates concentrations of radioactive waste in tephra falling at and redistributed to the location of the RMEI, based on incorporation of the waste into the volcanic tephra, the eruption of the tephra plume into the atmosphere, and the atmospheric transport and deposition of the tephra and entrained waste. Redistribution of waste-containing tephra from the Fortymile Wash watershed to the RMEI area via fluvial processes is calculated in TSPA using the FAR (Fortymile wash Ash Redistribution) V1.2 code ([DIRS 182225]) (SNL 2007 [DIRS 179347]). Radionuclides in the contaminated volcanic tephra may be inhaled, incorporated into the food chain, or may result in external radiation doses. The effects of inhalation of radioactive waste-containing volcanic tephra during a tephra fallout event are evaluated separately from the annual all-pathway doses resulting from tephra deposition and redistribution to the compliance location. The former are evaluated for inclusion in the TSPA model using the inhalation dose factors. The latter are incorporated in the TSPA through the use of volcanic ash exposure scenario BDCFs. BDCFs include inhalation exposure to resuspended tephra and contaminated soil, external exposure, and ingestion exposure, and are calculated on the annual basis, regardless of the actual eruption time and day (SNL 2007 [DIRS 177399], Section 6.5). The eruption phase is treated separately from the effects of deposition of contaminated tephra. Its consequences are evaluated as those arising from the exposure occurring during an event of a limited duration (acute or near-acute exposure), rather than from a

long-term, chronic exposure thereafter. The inhalation dose factors are used in TSPA assessments to evaluate whether the doses received by the RMEI during an eruption need to be included in calculation of the expected dose (SNL 2007 [DIRS 177399], Section 6.15.2).

Surface soil contaminated by the deposition or redistribution of radioactive waste-containing volcanic tephra is the initial source of radionuclides in the reference biosphere under the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Sections 6.1.3, 6.3.2, and 6.5). In the biosphere model, this source is represented by the quantity of radionuclide concentration in volcanic tephra deposited on the ground per unit surface area of the surface soil and per unit mass of the resuspendable layer of the surface soil. In the mathematical model, this FEP is directly addressed in the soil and air submodels (SNL 2007 [DIRS 177399], Table 6.7-1) through the use of the following model input parameters: mass loading for crops (BSC 2006 [DIRS 177101], Sections 6.2.5 and 6.3.5), soil-to-plant transfer factor (BSC 2004 [DIRS 169672], Sections 6.2.1.2 to 6.2.1.5), mass loading for receptor environments (BSC 2006 [DIRS 177101], Section 6.3), and mass loading time decay function (BSC 2006 [DIRS 177101], Section 6.4). It is also considered in developing inhalation dose factors (SNL 2007 [DIRS 177399], Section 6.15.2).

Because variations in radionuclide concentrations in the soil contaminated by the deposited and redistributed volcanic tephra are not part of the biosphere model, BDCFs are calculated based on a unit radionuclide concentration in the surface soil (SNL 2007 [DIRS 177399], Section 6.5). Initial ashfall depth is considered in development of the atmospheric mass loading parameters (BSC 2006 [DIRS 177101], Sections 6.3 and 6.4). The TSPA model calculates annual radiation dose as a product of the time-dependent source terms, the source-independent BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided as inputs to the TSPA model. The first component accounts for exposure to sources external to the body, ingestion, and inhalation of radon decay products. The second and third BDCF components (the short-term and long-term inhalation components) account for inhaling airborne particulates. The short-term inhalation component is numerically equal to the inhalation exposure during the first year following a volcanic eruption. This term is used together with the time function to calculate short-term increase in inhalation exposure. This increase is due to elevated levels of airborne particulate matter after a volcanic eruption and is calculated relative to the conditions existing before and long after an eruption. With time, particulate concentration in air returns to the pre-eruption level. These conditions are described by the long-term inhalation component, which represents long-term inhalation of resuspended particulates under nominal conditions (i.e., when the mass loading is not elevated as the result of volcanic eruption) (SNL 2007 [DIRS 177399], Section 6.12.3). As noted above, FEP 1.2.04.07.0A (Ashfall) is also considered in the inhalation dose factors (SNL 2007 [DIRS 177399], Section 6.15.2), which are used to evaluate the dose contribution of inhalation of particulate matter during an ashfall for inclusion in the TSPA.

FEP: 1.2.04.07.0B

FEP NAME:

Ash Redistribution in Groundwater

FEP DESCRIPTION:

Following deposition of contaminated ash on the surface, contaminants may leach out of the ash deposit and be transported through the subsurface to the compliance point.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP evaluates the effect of an eruption that intersects the repository, deposition of contaminated ash on the ground surface, leaching of the contaminants into the ground, and contamination of the groundwater. This FEP does not evaluate doses due to exposures from the contaminated ash above ground. Other FEPs related to exposure of the RMEI resulting from volcanic ash are included FEPs 1.2.04.07.0A (Ashfall), 1.2.04.07.0C (Ash Redistribution Via Soil and Sediment Transport), and 1.2.04.06.0A (Eruptive Conduit to Surface Intersects Repository) (SNL 2007 [DIRS 174260]; SNL 2007 [DIRS 177431]). The probability of the disruption of the repository by igneous activity (intersection of the repository by a basaltic dike) has a mean annual probability of 1.7×10^{-8} (BSC 2004 [DIRS 169989], Table 7.1). If igneous intrusion intersects the repository, there is an additional probability that the repository will be disrupted by an eruption as well. The probability that the repository will be disrupted by an eruption is the product of the annual probability of an igneous event intersecting the proposed repository and the probability of an eruptive conduit intersecting the repository footprint given an igneous event. The probability of an eruptive conduit being produced within the repository footprint is 0.28 (SNL 2007 [DIRS 177432], Table 7-1). This results in an annual frequency of occurrence of about 4.8×10^{-9}. This FEP is not excluded based on a probability justification because eruptive events are included in TSPA (consistency is maintained).

The modeling of igneous intrusion (SNL 2008 [DIRS 183478], Section 6.5.1) describes the consequences of magma that intrudes into repository emplacement drifts, damages waste packages in the intruded drifts, and solidifies. Because the flow characteristics of the magma could cause it to intrude into every drift within the repository, every waste package and drip shield in the repository is assumed to be incapable of protecting its contents. Conceptually, the engineered features are treated in TSPA as if they were no longer present, leaving radionuclides available for transport through normal dissolution processes when seepage re-enters the drift.

For the modeling of volcanic eruption (SNL 2008 [DIRS 183478], Section 6.5.2), the mass of waste incorporated in the tephra plume from an eruptive event depends on the waste inventory, the number of waste packages intersected, and the fraction of waste-containing magma that is erupted as a tephra plume instead of as a lava flow or deposited as a scoria cone. There is a 72% probability that no waste packages will be hit by a volcanic eruption intersecting the repository.

In the 28% of cases where one or more packages is hit, the number of waste packages hit ranges from one to seven with a median of four (SNL 2007 [DIRS 177432], Section 7.1).

The modeling of volcanic eruption (SNL 2008 [DIRS 183478], Section 6.5.2) considers the mass of waste in the waste packages that are hit, and the proportions of each kind of waste released from the repository to the erupting volcanic magma. The mass of waste hit is multiplied by the magma partitioning factor to account for the partitioning of magma into surface lava flows, scoria cone, and tephra plume. The magma partitioning factor is specified as a uniform distribution from 0.1 to 0.5 and represents the fraction of magma that is erupted into the tephra plume to be considered when modeling volcanic eruption (SNL 2007 [DIRS 177431], Table 8-2).

Because the number of packages entrained in an eruption is very small (seven or less) compared to the number of packages damaged by intrusion (all waste packages in the repository), and not every intrusive event is accompanied by an eruptive event, the TSPA simplifies the analysis and overestimates the consequences of intrusive events by not reducing the inventory released by intrusions by the amount that could be released by an associated eruption (SNL 2008 [DIRS 183478], Section 6.1.3). Thus, the consequences of any radionuclides that could leach out of the ash deposit and be transported in groundwater through the subsurface to the compliance point are bounded by the consequences of igneous intrusion, for which the radionuclide inventory from all packages (including those which might be included in an eruption) are available for transport in groundwater.

This conclusion is based on the observation that the simulated consequences of releases from any given number of waste packages (e.g., seven) should igneous intrusion occur are greater than the potential consequences of radionuclides that might enter the groundwater by leaching from the same number of packages (e.g., seven) involved in a volcanic eruption. This is reasonable given the following considerations: (1) all of the waste in the packages that would be subject to eruptive release is included in the release resulting from intrusion, but up to half of that waste would be released due to the magma partitioning factor (SNL 2007 [DIRS 177431], Section 6.5.2.9); and (2) not all of the waste that is erupted would fall on the land surface above the saturated zone flow pathways between the repository and the accessible environment. Consequently, not all of the waste would be available for leaching of radionuclides back to the water table for subsequent migration to the RMEI. Furthermore, as discussed above, the probability of eruptive events intersecting the repository is less than the probability of intrusion. The transport pathways and mechanisms for radionuclides leached from ash close to the vent, which is the large majority of the radionuclides included in the eruption (SNL 2007 [DIRS 177431], Section 6.5.2.9), are generally similar to those from the exposure to seepage following igneous intrusion, including downward migration through the unsaturated zone followed by lateral transport in the saturated zone. Thus, the probability-weighted consequences of leaching from ash would be less than the probability-weighted consequences of exposing the same number of waste packages to direct seepage.

Overall, this FEP is excluded on low consequence because the consequences associated with leaching of radionuclides from the basis of an ashfall into groundwater are small compared with the consequences of directly exposing the same inventory of radionuclides to seepage following igneous intrusion. The latter pathway is explicitly modeled in the TSPA and there could be no

additional increment to the total mean annual dose to the RMEI if the leaching pathway to groundwater from ashfall was included in the TSPA.

Based on the previous discussion, omission of FEP 1.2.04.07.0B (Ash Redistribution in Groundwater) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.04.07.0C

FEP NAME:

Ash Redistribution via Soil and Sediment Transport

FEP DESCRIPTION:

Following deposition of contaminated ash on the surface, ash deposits may be redistributed on the surface via aeolian and fluvial processes.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Ashfall is included in the performance assessment to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and is addressed through the modeling of an eruption that includes airborne transport of waste-contaminated tephra (ash) and subsequent deposition of the tephra on the land surface. (The preferred term "tephra" refers to pyroclasts resulting from a volcanic eruption, regardless of size, in contrast to the term "ash" which technically refers only to pyroclasts less than 2 mm in diameter. Both terms are used in the discussion of this FEP.) Ashfall and associated aerial dispersal of contaminated tephra is addressed in included FEP 1.2.04.07.0A (Ashfall), and ashfall characteristics are discussed in detail in *Atmospheric Dispersal and Deposition of Tephra from a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 177431]). In addition to the initial ashfall, the performance assessment also includes consideration of exposure from contaminated tephra that could be redistributed to the RMEI location from other locations by sediment transport processes.

As discussed in included FEP 1.2.04.03.0A (Igneous Intrusion into Repository), disruptive igneous events are not included in performance assessments to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because they are unlikely events. The exclusion of this FEP from the groundwater protection and human intrusion performance assessments is consistent with the requirements of proposed 10 CFR 63.342(b) and (c)(1) (70 FR 53313 [DIRS 178394]).

The technical basis for inclusion of FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport) in the performance assessment relies on analysis results presented in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1). The volcanic hazard is the annual frequency of intersection of the repository by a volcanic dike. The annual frequency of an igneous event ranges from approximately 7.4×10^{-10} to 5.5×10^{-8} for the 5th and 95th percentiles, respectively, with a mean annual frequency of 1.7×10^{-8} (BSC 2004 [DIRS 169989], Table 7-1). Since the mean annual frequency of intersection is greater than the screening criterion value (1 in 10,000 in 10,000 years; proposed 10 CFR 63.342(a) (70 FR 53313 [DIRS 178394])) an igneous event must be included in the

performance assessment, and the consequences of such an event must be evaluated. This FEP deals with one possible consequence of such an event, transfer of contaminated tephra to the RMEI location by sediment transport processes.

Eruptions involving the intersection of an eruptive conduit with the repository could result in the atmospheric dispersal of waste-contaminated tephra and subsequent deposition on the ground surface. The quantity of waste ejected into the atmosphere in any one eruption would depend on many factors, such as the volume and power of the volcanic eruption, the distribution of waste packages in the emplacement drifts, the location, number, and size of eruptive conduits intersecting the drifts, the degree of damage to the waste packages, the amount of waste from the waste packages that is entrained into the erupting material, and the fraction of magma that is erupted into the atmosphere (SNL 2007 [DIRS 177432], Section 6.3.2.2; SNL 2007 [DIRS 177431], Table 6-3).

Waste-contaminated tephra that has been deposited on the ground surface in the Fortymile Wash drainage basin by atmospheric transport immediately following the eruption could potentially be redistributed to the RMEI location by a combination of eolian and fluvial processes.

Based on the results of analogue studies, eolian transport of contaminated tephra to the RMEI location is assumed to be negligible when compared to the potential for fluvial transport. The basis for the assumption is described in *Redistribution of Tephra and Waste by Geomorphic Processes Following a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 179347], Section 5.2.2). The prevailing wind direction at the RMEI location is generally to the north toward Yucca Mountain. Significant eolian transport from Yucca Mountain to the RMEI location is therefore precluded. Other more complicated pathways are considered insignificant when compared to the potential magnitude of fluvial transport. For example, fine material may be transported as suspended load in Fortymile Wash during large floods and deposited in Franklin Lake Playa, a significant depozone for such material in this region. Following deposition in the playa, some of the fine material is remobilized by eolian processes, and examples of this process have been described. Studies show that thicknesses of eolian deposits on interchannel divides 1 to 2 km downwind (north) of Franklin Lake Playa are 0.5 to 3 cm on early Holocene to late Pleistocene surfaces. This range of thicknesses results in an estimated eolian deposition rate on the order of only 1 cm/10 kyr north of Franklin Lake Playa, and this rate is considered to be a maximum rate for deposition at the RMEI location because Franklin Lake Playa is one of the most emissive playas in the western United States, and Franklin Lake Playa is about 30 km upwind from the RMEI location. Another eolian mechanism involves contaminated tephra that is transported to the RMEI location as bedload, blown out of the channels, and deposited on the interchannel divides. Several sand streaks from this process are visible in aerial photos of the alluvial fan that represents the RMEI location. The deposition is localized to narrow margins along active channels that extend only 10 to 20 m from the active channels (SNL 2007 [DIRS 179347], Section 5.2.2). The relatively limited extent of the sand streaks indicates that their contribution to the amount of material redistributed to interchannel divides by eolian processes would not be significant.

For the other (non-eolian) components, the conceptual model for tephra redistribution includes hillslope, fluvial, and diffusion processes that address: (1) mobilization of tephra from hillslopes; (2) mixing and dilution with uncontaminated sediments during channel transport; and

(3) diffusion of radionuclides into the soil column at the RMEI location. A detailed description of the tephra redistribution conceptual model can be found in *Redistribution of Tephra and Waste by Geomorphic Processes Following a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 179347], Section 6.2).

The conceptual tephra redistribution model divides the Fortymile Wash drainage area into two domains: the drainage basin and the alluvial fan (SNL 2007 [DIRS 179347], Section 6.2). The drainage basin includes the vent location and the tephra and waste deposited on the landscape following a hypothetical volcanic eruption through the repository. The RMEI location is on the Fortymile Wash alluvial fan south of the fan apex. The drainage basin and the alluvial fan are divided at the fan apex.

The tephra redistribution model uses a spatially distributed analysis of hillslopes and channels in the drainage basin upstream of the fan apex to provide an estimate of the mass of tephra and waste that could be transported from the upper drainage basin to the RMEI location by hillslope and fluvial processes (SNL 2007 [DIRS 179347], Section 6.2). The model mobilizes and transports tephra and waste deposited on steep slopes or in active channels that connect to the main Fortymile Wash channel. Before the mobilized tephra and waste are deposited at the RMEI location, they are transported through the alluvial channel system where mixing with uncontaminated channel sediments leads to dilution. Mixing occurs during flood events as sediment and tephra are entrained from the bed, mixed by turbulent flow, and redeposited on the bed. The depth to which tephra and channel sediment are mixed is the scour depth. A divergent flow-routing algorithm is used to estimate the tephra (and waste) concentration in the bedload sediments at the fan apex (SNL 2007 [DIRS 179347], Section 6.3).

The tephra and waste transported from the upper drainage basin and primary tephra and waste deposited at the RMEI location provide the initial conditions for redistribution of radionuclides within the soil column at the RMEI location (SNL 2007 [DIRS 179347], Section 6.3.3, Step 6). The tephra redistribution model represents the migration of radionuclides within the soil at the RMEI location with a one-dimensional diffusion model. The actual mechanisms that lead to vertical radionuclide migration include suspension and redeposition of fine particles by infiltration, and physical mixing of soil particles by freeze/thaw cycles and bioturbation. Studies have shown that the resulting radionuclide concentration profiles can be represented as a diffusion process in a variety of climate and soil environments. The time-dependent average concentration within a depth interval resulting from the diffusion process is used by the volcanic ash exposure submodel (SNL 2007 [DIRS 177399], Section 6.3.2) to calculate dose to the RMEI.

FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport) is implemented for performance assessment using the computer code FAR V.1.2 ([DIRS 182225], STN: 11190-1.2-00). The FAR V.1.2 code is implemented as a DLL and is incorporated directly within the TSPA computational structure. The mathematical description of the FAR V.1.2 code is provided in *Redistribution of Tephra and Waste by Geomorphic Processes Following a Potential Volcanic Eruption at Yucca Mountain, Nevada* (SNL 2007 [DIRS 179347], Section 6.3.3).

FEP: 1.2.05.00.0A

FEP NAME:

Metamorphism

FEP DESCRIPTION:

If it occurs, metamorphism has the potential to affect the long-term performance of the repository. Metamorphism is defined as solid state changes to rock properties and geologic structures by means of recrystallization through the effects of heat and/or pressure.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This justification will address regional and contact metamorphism. Regional metamorphism refers to the processes by which rocks are changed through the effects of heat and pressure at depths of a few kilometers beneath the surface of the earth. Metamorphism may also occur in conjunction with intrusive igneous activity (referred to as contact metamorphism). Changes in sediments and rocks at lower temperatures and pressures are referred to as diagenesis (see excluded FEP 1.2.08.00.0A (Diagenesis); see also Bates and Jackson (1984 [DIRS 128109], pp. 137 and 322; and Berry and Mason 1959 [DIRS 135236], p. 240 for additional definitions).

Conditions conducive to the onset of regional metamorphism correspond to temperatures of 150°C to 200°C and pressures of 0.5 to 1 kilobars, which occur at depths of 4 to 5 km (Ehlers and Blatt 1972 [DIRS 167802], p. 566). The geothermal gradient at convergent plate boundaries may range from less than 10°C per km to greater than 25°C per km (Ehlers and Blatt 1982 [DIRS 167802], pp. 684 and 685), while at Yucca Mountain, which lies in an extensional terrain, the geothermal gradient, as measured in 300- to 600-m-deep boreholes, is approximately 30°C/km (Sass et al. 1988 [DIRS 100644], p. 35). These measurements at Yucca Mountain are consistent with the occurrence of regional metamorphism at depths of 4 to 5 km as described by Ehlers and Blatt (1972 [DIRS 167802], p. 566). The potential for regional metamorphism at Yucca Mountain depends on regional-scale tectonic deformation and, therefore, the strain accumulation rates and slip rates. The rate of subsidence (vertical movement leading to deep burial) is controlled by movement along fault-bounded blocks. Savage et al. (1999 [DIRS 118952], p. 17,627) presented an evaluation of the strain accumulation rate at Yucca Mountain during 1983 to 1998, indicating that the strain rate in the Yucca Mountain area is low, equivalent to 2 nanostrain/yr. Savage et al. (1999 [DIRS 118952], p. 17,627) also addressed alternative interpretations indicating higher strain rates on the order of 50 nanostrain/yr (Wernicke et al. 1998 [DIRS 103485]). Regardless of which strain rate is used, the result has been cumulative fault slip rates at Bare Mountain and Yucca Mountain of 0.001 to 0.05 mm/yr (BSC 2004 [DIRS 168030], Table 6). The higher slip rate of 0.05 mm/yr would result in a vertical movement of approximately 0.5 m in 10,000 years. Such vertical movement is insufficient to result in pressure and temperature conditions at the repository depth (minimum of 200 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06) which would be

conducive to regional metamorphism, as this is well above the necessary depth of 4 to 5 km at which metamorphism may occur (Ehlers and Blatt 1972 [DIRS 167802], p. 566). Additionally, the locus of any regional subsidence has moved to the southwest corner of the Crater Flat basin, away from Yucca Mountain (Fridrich 1999 [DIRS 118942], p. 189). Transport simulations of particles released at the repository show that transport occurs south-southeast of Yucca Mountain a few hundred meters to a kilometer (DTN: SN0704T0510106.008 [DIRS 181283], file: *sz06-1000.sptr2*) below the surface, considerably removed from the region where regional metamorphism is possible. Thus, any effects from regional metamorphism would be inconsequential on flow and transport and dose to the RMEI.

Contact metamorphism results from the thermal interaction between an intruding body of magma and the surrounding rock. Contact metamorphism is more fully addressed as part of excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties), which gives a detailed justification for a low-consequence exclusion of all effects on rock properties by igneous activity, including dikes. To summarize some important points from excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties), dikes at Yucca Mountain are typically 1 to 12 m in width (SNL 2007 [DIRS 174260], Section 6.3.3.1) and tend to be variably continuous along strikes, parallel or subparallel to the direction of maximum principal transmissivity. The resulting effects of dike intrusion may be to increase, decrease, or not change permeabilities as compared to the host (unaffected) rock. The scale at which permeabilities would change is limited to a few meters around the dike (Valentine and Krogh 2006 [DIRS 177282], p. 221). The dike widths and associated volume of metamorphized rock described above are small relative to the 30 km width of the saturated zone flow domain and the 1- to 5-km width and depth of the region in which radionuclide transport occurs near the repository (DTN: SN0704T0510106.008 [DIRS 181283], file: *sz06-1000.sptr2*). The predicted width over which radionuclide transport occurs is in excess of hundreds of meters (SNL 2008 [DIRS 184806, as inferred from Figure 6.5-2), and the distance downgradient over which transport occurs to the RMEI is at least 18 km. Given the small scale of the affected rock and its alignment relative to the direction of principal transmissivity, the effect of local metamorphism on flow and transport in the saturated zone is negligible.

If contact metamorphism occurs, it might affect infiltration through the unsaturated zone to the repository. Average infiltration to the repository is principally limited by surface precipitation and evapotranspiration. Computations show that the average flux flowing to the repository is within 3% of the average flux specified at the ground surface over the projected repository area (SNL 2007 [DIRS 184614], Section 6.1.4). The UZ flow model results show that flow is principally through the fractured rock mass rather than faults in the TCw, PTn, and TSw hydrologic units (SNL 2007 [DIRS 184614], Tables 6.6-1 and 6.6-2) above the repository. Flow is modeled as isothermal and steady below the highly porous nonwelded PTn unit since it is relatively unfractured. Dike penetration and contact metamorphism of this unit could change the timing and spatial distribution of infiltration pulses to the repository, but the scale of the rock affected by contact metamorphism is much smaller than the repository footprint and the average infiltration is controlled by surface processes, so the effects would not be significant.

UZ Flow Models and Submodels (SNL 2007 [DIRS 184614], Section 6.6.2.2) states that in the northern half of the Yucca Mountain domain below the repository, flow is focused significantly into major faults. Over the entire model, the percentage flow in major faults increases with depth, beginning at 12% to 32% at the repository horizon and reaching 44% to 65% at the water table

(SNL 2007 [DIRS 184614], Section 6.6.2.3). The narrow, tabular dikes observed in the Yucca Mountain region (SNL 2007 [DIRS 174260], Section 6.3.3.1) are similar, geometrically, to faults. Furthermore, dikes in the region are often found occupying faults (SNL 2007 [DIRS 174260], p. 6-18). Thus, the effects of contact metamorphism in this area would not be significant since flow and transport is already dominated by major faults. Finally, we note that the radionuclide travel time through the 300 meter zone between the repository and the water table (SNL 2008 [DIRS 184433], Section 5.1.5) is a very small component of the total travel time through the entire 18 km distance to the RMEI, so that even if contact metamorphism introduced a major change in the unsaturated zone below the repository, the effect over the entire flow and transport domain would be insignificant.

In summary, regional metamorphism requires greatly increased pressure (generally resulting from burial on the order of kilometers) and increased temperatures (greater than 150°C to 200°C). Development of these conditions on a regional scale in the rocks surrounding the repository would require many millions of years at current rates of subsidence. Regional metamorphism during the next 10,000 years will be limited to rocks far below the repository and the associated groundwater flow system. Contact metamorphism, should it occur, would introduce changes to rock parameters at a scale that is insignificant with that of the overall scale of flow and transport to the RMEI. Based on the above discussion, omission of metamorphism will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment.

Based on the previous discussion, omission of FEP 1.2.05.00.0A (Metamorphism) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radiological releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.06.00.0A

FEP NAME:

Hydrothermal Activity

FEP DESCRIPTION:

Naturally occurring high-temperature groundwater may induce hydrothermal alteration of minerals in the rocks through which the high-temperature groundwater flows.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Hydrothermal activity is the circulation and release of high-temperature water by a buried source of heat. The source of heat is either an igneous intrusion or a high thermal gradient associated with thinned and extending crust (Blackwell et al. 2000 [DIRS 183582], p. 1). Hydrothermal activity can result in mineral alteration that affects flow and transport characteristics of the rock.

Non-Magmatic Hydrothermal Activity

Hydrothermal activity associated with non-magmatic heat sources are common in the Basin and Range province (Blackwell et al. 2000 [DIRS 183582], p. 1), which includes almost all of Nevada and portions of other states (DOE 2002 [DIRS 155943], Figure 1-7). These hydrothermal systems have been found to be highly correlated to regional heat flow when that flow is in excess of 80 mW/m^2 (Blackwell et al. 2000 [DIRS 183582], Section 2.3). However, heat flux values within the Topopah Spring welded unit at Yucca Mountain in boreholes NRG-7a, UZ-7a, and SD-12 are about 37, 39, and 32 mW/m^2, respectively (Rousseau et al. 1997 [DIRS 100178], Section 5.2). This gives an average of 36 mW/m^2, and a standard deviation of 3.6 mW/m^2, substantially below a heat flow of 85 mW/m^2 characteristic of the Basin and Range province (Sass et al. 1988 [DIRS 100644], p. 3).

Any change that may result in the circulation of hydrothermal fluids below Yucca Mountain would not be able to drive significant temperature changes in the repository area over 10,000 years. Hydrothermal systems have been found to circulate to depths of at least 4 km (Blackwell et al. 2000 [DIRS 183582], Section 3.5) and high heat-flow areas of the Great Basin have heat flux rates in excess of 120 mW/m^2 (Flynn et al. 1996 [DIRS 112530], p. 11). The rock mass heat capacity is approximately 1,000 J/kg-K (BSC 2004 [DIRS 170003], Table 6-9) and the bulk rock density of approximately 2,000 kg/m^3 (SNL 2008 [DIRS 184748], Table 6-6). Assume that the heat flux increases by 200 mW/m^2 as a result of new deep circulation patterns. The time required to raise the temperature 10°C along the new circulation path is computed from the heat capacity multiplied by the bulk rock density, circulation path length of 4 km, and temperature change, divided by the increase in heat flux. This gives a time in excess of 10,000 years. These results are consistent with simulations of transient geothermal systems in the Basin and Range (McKenna and Blackwell 2003 [DIRS 185042], Figure 8). Drift wall temperatures are computed

to be about 25°C to 60°C at 10,000 years as a result of waste heat (SNL 2008 [DIRS 184433], Figure 6.3-76[a]). Measured ambient temperatures at repository elevations of 1,040 to 1,100 m (BSC 2007 [DIRS 183743], Table 1-5) are approximately 20°C to 25°C (SNL 2007 [DIRS 184614], Figures 6.3-2 to 6.3-6). Therefore, a temperature rise of 10°C at the water table over the 10,000-year period is expected to have a negligible influence on the repository environment because temperatures at the drift wall are about 20°C above ambient at 10,000 years as a result of waste heat. Therefore, the effects of temperatures changes associated with any future hydrothermal activity from a nonmagmatic heat source are expected to be negligible.

Hydrothermal Activity Associated with Magmatic Activity

The earliest volcanism in the Yucca Mountain region was dominated by a major episode of caldera-forming, silicic volcanism that occurred primarily between approximately 15 and 11 million years ago (Ma), forming the southwestern Nevada volcanic field (Sawyer et al. 1994 [DIRS 100075]). Yucca Mountain is an uplifted, erosional remnant of voluminous ash-flow tuff deposits formed during the early phase of silicic volcanism (BSC 2004 [DIRS 169989], Section 6.2). Silicic volcanism was approximately coincident with a major period of extension, which occurred primarily between 13 and 9 Ma (Sawyer et al. 1994 [DIRS 100075], Figure 4). The southwestern Nevada volcanic field ceased silicic eruptive activity about 7.5 Ma (BSC 2004 [DIRS 169989], Section 6.2). Basaltic volcanism within the Yucca Mountain region commenced during the latter part of the caldera-building phase, around 9 Ma, as extension rates waned. Postcaldera basaltic igneous activity within the Yucca Mountain region has been declining since about 7 Ma. Small-volume basaltic volcanism continued into the Quaternary (BSC 2004 [DIRS 169989], Section 6.2).

Since the cessation of silicic magmatism about 11.4 Ma, basaltic igneous activity has been characteristic of the Yucca Mountain region. Silicic volcanism during the regulatory period is therefore not expected (Reamer 1999 [DIRS 119693], p. 5). Although basaltic magmatism could occur during the 10,000-year regulatory period the effects of any related hydrothermal system would be of limited scale as described in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties). Due to the limited scale of effects from basaltic intrusions, the potential effects of hydrothermal alteration are negligible. With significant thermal perturbations limited to less than 100 years and alteration limited to zones on the order of a meter around a basaltic intrusion, the effects of basaltic magmatism on unsaturated zone transport pathways, advective velocities, and sorption coefficients (K_ds) are also considered to be negligible.

The focus of igneous-related FEPs is on the potential for small-scale basaltic volcanism to occur in the future. The mean probability of a basaltic dike intersecting the repository footprint has been calculated to be 1.7×10^{-8} per year (BSC 2004 [DIRS 169989], Table 7-1). The negligible difference in the north-south dimension of the repository footprint between the design in effect in 2003 and the current design (BSC 2007 [DIRS 179640]) would have a negligible effect on the frequency of intersection. If future igneous activity within the Crater Flat basin occurs, it is expected to take the form of basaltic dike-like intrusions with average widths on the order of one meter (CRWMS M&O 1996 [DIRS 100116], Section 3.2.3). Although intruding dikes could induce alteration of the in situ mineralogy adjacent to the intruded rock (i.e., the contact zone), the alteration in this contact zone is expected to be minimal. This assumption is supported by investigations at the Grants Ridge analogue site, which indicates that basaltic intrusion produced

only localized formation of volcanic glass within the contact zone (CRWMS M&O 1998 [DIRS 105347], Section 5, p. 74). Investigations of basaltic intrusions at Paiute Ridge (Carter Krogh and Valentine 1996 [DIRS 160928], pp. 7 to 8) suggest that igneous activities altered rock properties by decreasing permeability only out to a few tens of centimeters to, at most, a meter perpendicular to an intruding dike. The time scales for significant thermal perturbations from such intrusions are on the order of 100 years as discussed in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties). Given the small length and time scales associated with basaltic igneous activity in the region, any hydrothermal activity associated with basaltic intrusions is expected to be negligible.

Evidence Concerning Hydrothermal Activity in the Unsaturated Zone

Yucca Mountain is located outside the margin of the Timber Mountain caldera complex (BSC 2004 [DIRS 169989], Figure 6-1). The Timber Mountain magmatic activity represents the last significant heating event for Yucca Mountain (Whelan et al. 2006 [DIRS 179305]). The level of heating at Yucca Mountain associated with the Timber Mountain volcanic center (and its associated hydrothermal system) was relatively minor, with peak fluid inclusion homogenization temperatures near 90°C occurring at >9 Ma (BSC 2004 [DIRS 170004], Figure 6-199; Whelan et al. 2006 [DIRS 179305], Section 5.2.2 and Table 4). This heating event at Yucca Mountain did not result in pervasive hydrothermal alteration of the tuffs.

Studies of secondary minerals at Yucca Mountain using petrography, fluid-inclusion thermometry, and uranium-lead dating indicate that temperatures have remained close to the current ambient values over the past 2 to 5 Ma (Wilson et al. 2003 [DIRS 163589], Section 8). Mineral coatings composed primarily of calcite, opal, chalcedony, and quartz provide evidence of the thermal-hydrothermal history of Yucca Mountain. The minerals were deposited under unsaturated conditions as evidenced by the fact that they are found only on fracture footwalls and lithophysal cavity bottoms (Marshall and Whelan 2000 [DIRS 154415]). Various lines of evidence, including (1) stable oxygen isotope data of calcite, which indicates the temperature of mineral precipitation; (2) homogenization temperatures of fluid inclusions, which indicate the temperature at which the inclusions were trapped; and, (3) uranium and lead isotope ratios in opal associated with the calcite (Neymark et al. 2003 [DIRS 163681]), which constrain the age of deposited minerals, altogether suggest that temperatures in the unsaturated zone decreased over time from approximately 90°C at >10 Ma to near ambient temperatures at 2 Ma. These secondary minerals were interpreted to have been deposited from downward percolating meteoric water and not the result of upwelling groundwaters (Wilson et al. 2003 [DIRS 163589], Sections 7.3 and 8; Whelan et al. 2003 [DIRS 163590]; National Research Council 1992 [DIRS 105162], p. 3).

Additional evidence of elevated paleotemperatures at Yucca Mountain may be provided by observations of thick-twinned calcite samples in discrete narrow faults (2 to 20 cm) (Gray et al. 2000 [DIRS 171202]). Thick-twinned calcite was interpreted to indicate deformation at temperature above 170°C (Ferrill et al. 2004 [DIRS 171196]), which is higher than the temperatures indicated by calcite fluid inclusions reported by Whelan et al. (2003 [DIRS 163590]) and Wilson et al. (2003 [DIRS 163589], Section 8). If the higher temperatures indicated by thick twins (which have not been confirmed by studies of fluid inclusions in the same samples) are correct, they may indicate that the twinned calcite was formed during an

early, higher-temperature event. It is expected that such temperatures would have occurred shortly after emplacement of the ash-flow tuff deposits at Yucca Mountain, when degassing and cooling of the ash-flow tuff could have resulted in devitrification, vapor-phase alteration, and development of localized meteoric-hydrothermal activity in the upper parts of ash-flow sheets (Holt 2002 [DIRS 162326]). Gray et al. (2000 [DIRS 171202]) note that the calcite mineralization observed in the narrow faults is not encountered in the intrablock and block-bounding faults, which would be good candidates for fluid flow and mineralization in the event of widespread hydrothermal alteration. The absence of pervasive hydrothermal mineralization of the Yucca Mountain tuffs is consistent with the interpretation that large-scale hydrothermal activity has not occurred in the Yucca Mountain area.

Evaluation of Unsaturated Zone Thermal History at Yucca Mountain

Whelan et al. (2006 [DIRS 179305]) present a conceptual model of heat transfer from the Timber Mountain magma chamber to explain the temperature history of Yucca Mountain that was inferred from geological evidence. The conceptual model is implemented in a computational analysis of the thermal history of Yucca Mountain (Whelan et al. 2006 [DIRS 179305], Section 6.3). This analysis expands upon a previous analysis presented by Marshall and Whelan (2001 [DIRS 171061]). The model used a 7-km thick, 30-km diameter, 5,000 km^3 magma chamber at depths of 5 or 2.5 km from the top of the magma chamber to the ground surface (shallower depth yields faster cooling of the magma). In the model, the diameter of the magma chamber is spatially restricted to the caldera margin. The magma chamber was filled at 12.8 Ma, corresponding to the Paintbrush Group eruptions, and again at 11.6 Ma, corresponding to the Timber Mountain Group eruptions. The depth of the magma chamber is highly uncertain, hence, the use of two distinct values. Heat transfer by conduction and hydrothermal convection are represented in the model; convection was limited to shallower zones between 10 Ma and 8 Ma. Predicted temperatures are generally representative of the observed thermal history given the large uncertainty in the timing of many of the observations. Certain aspects of the observations, in particular the maximum temperature at the base of borehole G-2 and deposition temperatures of early/intermediate stage secondary minerals at the top of the TSw, appear to be underestimated by the model. However, uncertainties concerning the volume and extent of the magma chamber could explain the differences in the maximum temperature at borehole G-2. Preliminary results incorporating the additional process of vapor-phase convection appears to explain the higher temperature, early/intermediate stage secondary minerals at the top of the TSw (Whelan et al. 2006 [DIRS 179305], Section 6.3). Similarly, high-temperature, secondary mineral deposition observations in the TCw, just tens of meters below the surface, appear to be consistent with shallow-rooted fumarolic systems (Whelan et al. 2006 [DIRS 179305], Section 6.2).

The spatial and temporal extents of magmatic activity of the Timber Mountain system are significant uncertainties in the model. While only minor volcanic activity is associated with Timber Mountain after 11.4 Ma, it is possible that the system received continued injections of mantle-derived mafic magmas that would have provided additional heating to the region (Farmer et al. 1991 [DIRS 153024]). Continuing silicic volcanism at the Black Mountain caldera (9.4 Ma) and Stonewall Mountain volcanic center (7.5 Ma), both located northwest of the Timber Mountain caldera, indicates that regional silicic magmatism and associated heating persisted beyond 11 Ma (Sawyer et al. 1994 [DIRS 100075]). The size of the magma chamber

may be underestimated given the uncertainties in the size of the magma chamber relative to the erupted volume. Furthermore, the lateral extent of the magma chamber relative to the Timber Mountain caldera margin may also be underestimated based on comparison with analogous spatial relationships in the Yellowstone volcanic system (Whelan et al. 2006 [DIRS 179305], Section 6.3).

Evidence Concerning Hydrothermal Activity in the Saturated Zone

Evidence of hydrothermal alteration and mineralization that followed the deposition of the Paintbrush Group is present within a few kilometers of the Yucca Mountain site in the Calico Hills, in Claim Canyon, and along the south flank of Shoshone Mountain (SNL 2007 [DIRS 177391], Section 6.3.1.11, Figures 6-13 and A6-3; BSC 2004 [DIRS 169989], Figure 6-1; Whelan et al. 1994 [DIRS 100091]). The spatial and temporal patterns of thermal alteration of clays in the Yucca Mountain region are also consistent with the evidence of magmatism and associated hydrothermal activity (Bish and Aronson 1993 [DIRS 100006]; McKee and Bergquist 1993 [DIRS 106339]). None of the three past hydrothermal areas (SNL 2007 [DIRS 177391], Figures A6-1, A6-3, and 6-13) where mineralogical changes may have occurred that could alter flow and transport are along the saturated zone flow path from the repository to the RMEI, so there is no impact on flow and transport to the RMEI. Yucca Mountain is located outside the caldera margin that encompasses Claim Canyon and Shoshone Mountain; hence, it was never within this ancient hydrothermal source (SNL 2007 [DIRS 177391], Figures A6-1, A6-3, and 6-13).

Given the lack of evidence of any past hydrothermal activity along Crater Flat (SNL 2007 [DIRS 177391], Appendix A, Figure A6-3), coupled with the relatively small widths of igneous intrusions that would intersect the saturated zone flow domain and small contact zone where the in-situ rock's mineralogy would be thermally altered, it is concluded that any associated hydrothermal activity produced from any future igneous activity would be localized and of low consequence to saturated zone flow paths.

Flow and transport processes in the saturated zone could potentially be impacted by hydrothermal activity associated with the intrusion of igneous dikes. The effects of hydrothermal activity could include mineralogical changes and changes of sorption coefficient values in response to elevated temperatures. However, as noted in the section entitled *Hydrothermal Activity Associated with Magmatic Activity*, mineralogical changes would be localized around any igneous intrusions and would not affect a significant portion of the entire volume of the tuff aquifer within the saturated zone. Furthermore, the time scale for elevated temperatures associated with basaltic intrusions is on the order of 100 years. Given the small length and time scales associated with basaltic igneous activity in the region, any hydrothermal activity associated with basaltic intrusions is expected to be negligible.

Dublyansky (2007 [DIRS 185029]) presents a review of a previous version of the screening analyses for this FEP (BSC 2004 [DIRS 170012]; BSC 2004 [DIRS 170013]). The review is critical of the screening analyses, particularly that previous thermal history modeling results (Marshall and Whelan 2001 [DIRS 171061]) do not match the inferred temperature history. The review does not recognize the fact that the primary support for exclusion of the FEP is the evidence indicating that hydrothermal waters have not risen from the saturated zone into the

unsaturated zone, where waste emplacement is contemplated (see *Evidence Concerning Hydrothermal Activity in the Unsaturated Zone*). Furthermore, the analyses presented here indicate that any significant heating of the unsaturated zone as a result of silicic or basaltic magmatism or non-magmatic mechanisms is not expected within the time frame addressed by the FEP. The more recent results from Whelan et al. (2006 [DIRS 179305]) concerning numerical modeling of the thermal history (recognizing associated uncertainties) are closer to the measurements than those reported by Marshall and Whelan (2001 [DIRS 171061]).

Conclusion

In summary, there is no evidence for large scale hydrothermal activity in the unsaturated zone at Yucca Mountain or along potential saturated zone radionuclide transport pathways since the formation of the tuff deposits between 11.6 and 13.5 Ma. Secondary minerals that are present indicate that temperatures have been close to current ambient levels for the last 2 to 5 Ma. Available evidence indicates these minerals were deposited from downward percolating meteoric water in the unsaturated zone, rather than hot, upwelling groundwater. Peak fluid temperatures of around 80°C to 90°C due to the Timber Mountain volcanic center occurred >10 Ma, but were not sufficient to cause pervasive hydrothermal alteration. There is some evidence to suggest hydrothermal activity at up to 170°C, but if this is the case, evidence indicates it (Solitario Canyon Fault and Bow Ridge Fault) to have occurred shortly after formation of the Yucca Mountain tuff deposits. Any igneous activity within the 10,000-year regulatory timeframe is expected to be basaltic and will cause only localized heating/alteration. Based on the previous discussion, exclusion of FEP 1.2.06.00.0A (Hydrothermal Activity) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.07.01.0A

FEP NAME:

Erosion/Denudation

FEP DESCRIPTION:

Erosion and weathering are processes which can cause significant changes to the present day topography through denudation and are thus capable of affecting both local and regional hydrology. Weathering refers to physical and chemical processes that alter and degrade rocks and soil at and near the land surface. Erosion involves the transport of surficial material away from the site by various mechanisms including glacial, fluvial, eolian (involving wind), and chemical processes. Surficial materials, including weathering products, are also subject to gravity, and erosion can take place by mass wastage processes (e.g., landslides). The extent of denudation depends to a large extent on climate and the rate of local uplift.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Weathering and erosion are processes that will be ongoing at Yucca Mountain. Within the terrain of Yucca Mountain, erosion and erosional processes occur in the high, steep, and relatively wet uplands, whereas deposition and depositional processes are more dominant in the low, relatively arid lowlands (BSC 2004 [DIRS 169734], p. 2-3).

The calculated maximum possible erosion rates for bedrock outcrops using a ^{10}Be cosmogenic dating technique is 0.4 to 2.7 cm/10,000 years (Stuckless and Levich 2007 [DIRS 181507], p. 83). The long-term erosion rates of stripping of unconsolidated material from Yucca Mountain hillslopes were calculated to be 0.2 to 6 cm/10,000 years using both the rock-varnish carion ratio and the in situ, ^{36}Cl cosmogenic dating methods (Stuckless and Levich 2007 [DIRS 181507], p. 84). Large-scale erosion of 6 cm is within the range of existing surface irregularities (or surface roughness) and is negligible compared to the minimum distance of 200 m from the ground surface to the repository emplacement areas (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06).

Erosion of surface soils can affect local net infiltration rates because the net infiltration model (MASSIF) was found to be sensitive to soil depth in the shallow soil depth class, which ranges in thickness from 0.1 to 0.5 m (SNL 2008 [DIRS 182145], Section 6.5.2.4.1[a]). However, any increased localized net infiltration will have an insignificant effect on seepage, as a result of the damping and homogenizing of downward-moving percolation fluxes by the Paintbrush nonwelded hydrogeologic unit (SNL 2007 [DIRS 184614], Section 6.1.2).

Weathering of bedrock can lead to soil development. Increases in soil depth as a result of soil development from weathering of bedrock is expected to result in a decrease in net infiltration. This is supported by the Yucca Mountain infiltration model (MASSIF), which was found to be

sensitive to soil depth in the shallow soil depth class where infiltration decreases with increasing soil depth (SNL 2008 [DIRS 182145], Section 6.7). Increased soil depth as a result of weathering of bedrock is analogous to the process of deposition, and the deposition process (FEP 1.2.07.02.0A (Deposition)) is excluded from TSPA by low consequence.

Denudation also includes mechanisms other than erosion and weathering, in particular dissolution and glaciation. The effects of dissolution are discussed in excluded FEP 1.2.09.02.0A (Large Scale Dissolution) and the effects of glaciation are discussed in excluded FEP 1.3.05.00.0A (Glacial and Ice Sheet Effect). *Site Characterization Plan, Yucca Mountain Site, Nevada Research and Development Area, Nevada* (DOE 1988 [DIRS 100282], Section 1.1.3.3.2) indicates that mass wasting processes, such as landslides, do not play a significant role in the present erosional regime at Yucca Mountain.

Debris flows (as opposed to large-scale mass wasting processes such as landslides) are the primary mechanism for hillslope erosion of unconsolidated deposits in the Yucca Mountain region (YMP 1995 [DIRS 102215], Section 2.5.2). However, the effects of debris flows are generally restricted to channelized areas (YMP 1995 [DIRS 102215], Section 4.2) and are not an effective erosion mechanism for unweathered bedrock. Therefore, debris flows have a limited influence on the evolution of surficial materials at Yucca Mountain.

Climatic conditions exert a strong influence on geomorphic processes and, thus, are a factor in controlling depositional and erosional patterns (BSC 2004 [DIRS 169734], p. 3-5). In the present-day climate, eolian processes of sand movement and dust deposition are active around Yucca Mountain (BSC 2004 [DIRS 169734], p. 3-46). Intense local thunderstorms commonly produce flash floods, during which the flow of water and rock debris typically causes hillslope erosion and the deposition of coarse debris on alluvial fans and in stream channels (BSC 2004 [DIRS 169734], p. 3-46). This type of deposition should be more common during the monsoon climate than the present-day or glacial transition climates due to the predicted higher frequency of intense thunderstorms (BSC 2004 [DIRS 170002], p. 6-50). Although present-day deposition and erosion generally occur at very low rates and sporadically because of the arid climate, the middle to late Pleistocene depositional record (indicative of a wetter climate than present-day) indicates a highly variable and localized succession of sedimentary deposits (BSC 2004 [DIRS 169734], p. 2-15). In general, colluvial deposits that are produced during pluvial climates (wetter than present-day) dominate hillslopes. The erosion and redistribution of these deposits takes place during drier climates, when hillslopes are no longer stabilized by vegetation. Hence, most of the alluvial map units in the basins and valleys that dominate the landscape at Yucca Mountain were deposited during interpluvial (i.e., present-day climate) episodes (BSC 2004 [DIRS 169734], p. 3-45). In summary, climate conditions exert a strong influence on depositional and erosional patterns, with deposition generally occurring during wetter periods and erosion generally occurring during drier periods. The 10,000-year period after repository closure is dominated by the glacial-transition climate (8,000 years). Therefore, deposition is expected to be the dominant geomorphic process for the 10,000-year period after repository closure (excluded FEP 1.2.07.02.0A (Deposition)). The extent of denudation also depends on the rate of local uplift. However, local rates of uplift are low, generally on the order of 0.01 mm/yr (BSC 2004 [DIRS 169734], Section 3.3.7.5).

The effects of surface construction and characterization activities at the ground surface on future erosion will also be negligible because of the planned reclamation of the site ground surface. As stated in *Reclamation Implementation Plan* (YMP 2001 [DIRS 154386], Section 5.2.2.1):

> Recontouring and erosion control practices include backfilling spoil material and grading disturbed sites, so that a stable land form is created that blends with the surrounding topography. Following site decommissioning, disturbed areas will be graded such that the natural drainage pattern (predisturbance drainage) is restored. The sites will be stabilized and recontoured to blend into the natural topography of the area.

In addition, reclamation of lands disturbed by the repository is a design constraint listed in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 09-04).

Based on the previous discussion, omission of FEP 1.2.07.01.0A (Erosion/Denudation) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.07.02.0A

FEP NAME:

Deposition

FEP DESCRIPTION:

Deposition is a process that causes significant changes in the present-day topography and thus affects local and regional hydrology. Deposition of surficial materials can occur by a variety of means, including fluvial, eolian, and lacustrine deposition and redistribution of soil through weathering and mass wasting processes.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Deposition is a process that will be ongoing at Yucca Mountain. Within the terrain of Yucca Mountain, erosion and erosional processes occur in the high, steep, and relatively wet uplands, whereas deposition and depositional processes are more dominant in the low, relatively arid lowlands (BSC 2004 [DIRS 169734], p. 2-3).

Climatic conditions exert a strong influence on geomorphic processes and, thus, are an important factor in controlling depositional and erosional patterns (BSC 2004 [DIRS 169734], p. 3-5). In the present-day climate, eolian processes of sand movement and dust deposition are active around Yucca Mountain (BSC 2004 [DIRS 169734], p. 3-46). Intense local thunderstorms commonly produce flash floods, during which the flow of water and rock debris typically causes hillslope erosion and the deposition of coarse debris on alluvial fans and in stream channels (BSC 2004 [DIRS 169734], p. 3-46). This type of deposition should be more common during the monsoon climate than the present-day or glacial transition climates due to the predicted frequency of intense thunderstorms (BSC 2004 [DIRS 170002], p. 6-50). Although present-day deposition and erosion generally occur at very low rates and sporadically because of the arid climate, the middle to late Pleistocene depositional record (indicative of a wetter climate than present-day) indicates a highly variable and localized succession of sedimentary deposits (BSC 2004 [DIRS 169734], p. 2-15). In general, colluvial deposits that are produced during pluvial climates (wetter than present-day) dominate hillslopes. The erosion and redistribution of these deposits takes place during drier climates, when hillslopes are no longer stabilized by vegetation. Hence, most of the alluvial map units in the basins and valleys that dominate the landscape at Yucca Mountain were deposited during interpluvial (i.e., present-day climate) episodes (BSC 2004 [DIRS 169734], p. 3-45).

Deposition of surface soils can affect local net infiltration rates because the net infiltration model (MASSIF) was found to be most sensitive to soil depth in the shallow depth class (soil depth class 4), where net infiltration is inversely related to soil depth class 4 (SNL 2008 [DIRS 182145], Section 6.7). Therefore, in areas with shallow soils (0.25-m nominal value), deposition will result in deeper surface soils that will lead to a reduction in localized net

infiltration. In areas with intermediate (3.26-m nominal value) and moderately deep soils (16.47-m nominal value), deposition will have no significant impact on net infiltration rates based on MASSIF model sensitivity results (SNL 2008 [DIRS 182145], Section 7.1.4). Altered topography from erosion or deposition may result in slight changes to the runoff and local net infiltration, but these changes are insignificant compared with the uncertainties associated with estimating net infiltration and runoff and therefore can be considered negligible.

Deposition is believed to be a dominant process in Fortymile Wash (YMP 1993 [DIRS 100520], Section 3.4). This drainage is part of the saturated zone model domain, but the accumulation of sediment as a result of depositional processes will not affect recharge rates because calculated recharge rates for all climate states are independent of deep soil depths or depth to water table (BSC 2007 [DIRS 177391], Section 6.6.4).

The effects of igneous disruptive events and the possibility of subsequent ash deposition altering the surface topography are discussed in excluded FEP 1.2.10.02.0A (Hydrologic Response to Igneous Activity).

Based on the previous discussion, omission of FEP 1.2.07.02.0A (Deposition) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.08.00.0A

FEP NAME:

Diagenesis

FEP DESCRIPTION:

This FEP addresses natural processes that alter the mineralogy or other properties of rocks after the rocks have formed under temperature and pressure conditions normal to the upper few kilometers of the earth's crust. Diagenesis includes chemical, physical, and biological processes that take place in rocks after formation but before eventual metamorphism or weathering. This FEP refers to natural diagenetic processes only.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Diagenesis is defined as physical or chemical changes in sediment brought about by chemical, physical or biological processes after a soil has been deposited and buried under another layer of sediment or after rock formation but before metamorphism or weathering. Diagenesis could affect repository performance by changing the infiltration in the unsaturated zone above the repository or unsaturated zone flow/transport below the repository and could act on surficial material deposited above the repository from postclosure through the period of geologic stability. This FEP discusses the diagenesis of newly deposited material; the effect of compaction, cementation, bacteria, and climate change on diagenesis in shallow sediments above the repository; and diagenesis of rocks below the repository and along the flowpath to the RMEI.

Possible effects of diagenesis on newly deposited material at the surface above the repository are excluded as deposition is expected to be of low consequence (see excluded FEP 1.2.07.02.0A (Deposition)). Erosion and weathering effects on rocks are considered in excluded FEP 1.2.07.01.0A (Erosion/Denudation). Possible effects on diagenesis due to the thermal excursion induced by emplaced repository waste are addressed in excluded FEPs 2.2.10.01.0A (Repository-Induced Thermal Effects on Flow in the UZ); 2.2.10.05.0A (Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository); 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures near Repository); 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)); 2.2.10.09.0A (Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre); and 2.2.10.07.0A (Thermo-Chemical Alteration of the Calico Hills Unit), all of which have been excluded on the basis of low-consequence.

Yucca Mountain is composed primarily of pyroclastic deposits with rare lava flows as well as colluvium, alluvium, and soils (BSC 2004 [DIRS 169734], Section 3.3.5), and was selected in part for its arid to semi-arid climate (BSC 2004 [DIRS 169734], Executive Summary). Diagenesis in the shallow environment (extending from the surface to the downward limit of evapotranspiration) may occur in desert environments (Lattman and Simonberg 1971

[DIRS 129306], p. 277; Krystinik 1990 [DIRS 135295], p. 8-1), especially in areas where the water table is close to the surface. The two primary stages for diagenetic changes are compaction and cementation. Compaction may reduce the porosity of eolian sediments by as much as 20% to 30% (Krystinik 1990 [DIRS 135295], p. 8-2), but after this initial stage, "compaction does not become an important factor in diagenesis until the onset of grain deformation and pressure solution during deeper burial diagenesis" (Krystinik 1990 [DIRS 135295], p. 8-3). The geologic setting of Yucca Mountain, however, is characterized by relatively shallow soils and one of low subsidence rates (as discussed in excluded FEPs 1.2.07.02.0A (Deposition) and 1.2.05.00.0A (Metamorphism), and in BSC 2004 [DIRS 169734], Section 7.1.3.3), and therefore deep burial and significant compaction of alluvial, colluvial, and/or eolian deposits is not a plausible diagenetic mechanism at Yucca Mountain during the next 10,000 years.

Cementation, however, may be of significance in shallow diagenesis. Surface materials at Yucca Mountain contain pedogenic calcite ($CaCO_3$) and opal (BSC 2004 [DIRS 169734], Section 3.3.5). The predominance of silicon dioxide (SiO_2) cements at Yucca Mountain is documented in the study by Taylor (1986 [DIRS 102864], Figure 9); which indicates that the accumulation rate of calcite, while occurring, is significantly less than that for SiO_2, as $CaCO_3$ is primarily derived from airborne dust (BSC 2004 [DIRS 169734], Sections 7.1.3.3 and 5.2.2.2.1), while the opaline SiO_2 originates from in-place weathering of the parent material (BSC 2004 [DIRS 169734], Sections 3.3.2 and 3.3.5.1). Therefore, cementation by opaline SiO_2 is common in the study area, and its accumulation in the soils is favored over that of $CaCO_3$ (Taylor 1986 [DIRS 102864], pp. 31 to 33). The more soluble $CaCO_3$ tends to translocate to the base of the wetting zone where it tends to form lenses (Taylor 1986 [DIRS 102864]). The net effects of shallow diagenesis and associated cementation on infiltration in an arid environment are to stabilize the surface environment and decrease the net vertical infiltration rate (Reeves 1976 [DIRS 104303], p. 110; BSC 2004 [DIRS 169734], Section 5.2.1.1, pp. 5-3, and 5-4).

Subsurface bacteria have the potential to influence sediments and fractured rocks. Cementation in the presence of microorganisms may be enhanced by sorption of minerals to microbial cells or through microbially mediated redox reactions that form insoluble precipitates. Alternatively, microorganisms may accelerate the transport minerals by chelation, by pH changes that increase radionuclide solubilities, or by redox reactions that generate soluble species, and by affecting colloid transport. Plate count, direct count, and phospholipid fatty-acid data indicate a low abundance of microorganisms in Yucca Mountain tuff (Kieft et al. 1997 [DIRS 100767], p. 3,130). According to the study by Kieft et al. (1997 [DIRS 100767]), "the low numbers of culturable aerobic heterotrophs in Yucca Mountain samples is consistent with previous findings for unsaturated tuff," and, "water appears to be the primary factor limiting microbial growth and activity in the unsaturated volcanic tuff." Likewise, the low levels of active bacterial and fungal biomass (0 to 16 micrograms of carbon per gram of soil; CRWMS M&O 1999 [DIRS 105031], Figure 14) in the shallow soils above Yucca Mountain are not expected to contribute appreciably to diagenesis in the next 10,000 years. Excluded FEPs 2.2.09.01.0A (Microbial Activity in the SZ) and 2.2.09.01.0B (Microbial Activity in the UZ) address the effects of microbial activity in the saturated zone and unsaturated zone. These FEPs are excluded on the basis of low consequence. In view of these findings, it may be inferred that microbial activity does not play a major role in the development of diagenesis at Yucca Mountain.

The effect of variability in rates and location of infiltration is already addressed in TSPA by varying the infiltration rates associated with varying climatic conditions. The net effect of past diagenesis in the host rocks is included implicitly in the TSPA through the assignment of models and parameters for flow and transport in the unsaturated zone and saturated zone. The potential for future climate change to affect shallow diagenesis is minimal in comparison, as discussed below. Taylor (1986 [DIRS 102864], Chapter 5) indicates that silts that formed in alluvium and eolian fines of Holocene to early Pleistocene or late Pliocene age (times associated with wetter climatic conditions) near Yucca Mountain are characterized by distinctive trends in the accumulation of secondary clay, $CaCO_3$, and opaline SiO_2 that correspond with the ages of the surficial deposits. Notwithstanding, Taylor (1986 [DIRS 102864]) states that accumulation rates of these materials during the Holocene can be attributed to several possible climatic scenarios associated with the Holocene-Pleistocene climate change, but suggests that precipitation has not been a limiting factor and that climatic change was not sufficient to greatly decrease rates of accumulation. Although Taylor (1986 [DIRS 102864]) suggests that increased precipitation in the future may transfer $CaCO_3$ accumulations to greater depths in those areas where precipitation is greater, this process over the next 10,000 years is expected to be insignificant compared to the variability that has resulted since deposition of the host rock.

The rocks within the unsaturated zone below the repository and along the saturated zone flowpath to the RMEI exhibit diagenetic features that have been established over millions of years (Whelan 2004 [DIRS 170697], Figures 3 and 5). These changes tend to transform minerals in rock to more stable forms in equilibrium with their surroundings (Press and Siever 1978 [DIRS 167965], p. 484). A principal effect of deeper diagenesis at Yucca Mountain is the infilling and coating of open fractures and lithophysal cavities by calcite and silica (Whelan 2004 [DIRS 170697], p. 3). Although these coatings may dissolve and reprecipitate, the net effect is a reduction of pore space and permeability in the rock. The effects of fracture infilling is considered in the assignment of flow parameters in TSPA modeling through in situ testing (BSC 2004 [DIRS 170014]). Faults and fractures are addressed in included FEPs 1.2.02.01.0A (Fractures), 1.2.02.02.0A (Faults), 2.2.03.02.0A (Rock Properties), and 2.2.07.08.0A (Fracture flow in the UZ).

Based on the previous discussion, omission of FEP 1.2.08.00.0A (Diagenesis) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.09.00.0A

FEP NAME:

Salt Diapirism and Dissolution

FEP DESCRIPTION:

This FEP addresses geologic processes that are primarily relevant to repositories located in salt deposits. Salt diapirism refers to the tendency of salt to flow under lithostatic loading when density and viscosity contrasts with surrounding strata are favorable. Such a process would modify the groundwater flow regime and affect radionuclide transport. Salt domes are the best-known example of salt diapirism. Dissolution can occur when any soluble mineral within the formation is removed by flowing water. Large scale dissolution is a potentially important process in rocks that are composed predominantly of water-soluble evaporite minerals, such as salt.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Yucca Mountain is located in the southwestern Nevada volcanic field and consists of tilted fault blocks composed of layered sequences of ash flow, ashfall, carbonates, and bedded tuffs of Miocene age (BSC 2004 [DIRS 170029], Sections 6, 6.5, and Table 6-2; SNL 2007 [DIRS 174109], Sections 6.3, 6.4, and Table 6-2; BSC 2004 [DIRS 169734], Section 3.3.4; Day et al. 1998 [DIRS 100027]). Evaporite deposits of sufficient volume to result in significant salt diapirism and dissolution have not been reported to exist near Yucca Mountain (DTN: GS010908314221.001 [DIRS 162874], file: *i-2755_map.pdf*). Any sizable deposit would be evident in well logs or high sodium or chloride measurements in groundwater. Measured sodium levels at the saturated zone site scale flow model ranges from 46 to 130 mg/L (SNL 2007 [DIRS 177391], Section A6.3.4.9) and measured chloride ranges from 3 to 125 mg/L (SNL 2007 [DIRS 177391], Section A6.3.4.2). By comparison, at the Waste Isolation Pilot Plant site in Carlsbad, NM, sodium concentrations in the Rustler/Culebra dolomite (non-sodium) formation, range from 54 to 63,000 mg/L with most wells more then 10,000 mg/L (Siegel et al. 1991 [DIRS 183944], Figure 1-8), reflecting dissolution of the underlying Salado (halite) formation and contamination of wells throughout the area. Thus, the presence of any sizable salt formation would be noticed in well logs or high sodium or chloride concentrations in wells.

The repository is not planned to be developed in a salt dome or cavern, and the related process of lithologic flow is therefore not relevant to the geologic setting for Yucca Mountain. Any salt formations in the area would necessarily be either too small or so far away as to not be of significance to flow and transport in the repository area. Based on the above discussion, omission of FEP 1.2.09.00.0A (Salt Diapirism and Dissolution) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321

(70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

Large-scale dissolution of minerals other than salt is discussed in excluded FEP 1.2.09.02.0A (Large-scale Dissolution) and diapir formation in non-salt deposits is discussed in excluded FEP 1.2.09.01.0A (Diapirism).

FEP: 1.2.09.01.0A

FEP NAME:

Diapirism

FEP DESCRIPTION:

Diapirism is the process by which plastic, low density rocks (most commonly evaporites) may flow under lithostatic loading when density and viscosity contrasts with the surrounding strata are favorable. Such a process would modify the groundwater flow regime and affect radionuclide transport.

SCREENING DECISION:

Excuded – low consequence

SCREENING JUSTIFICATION:

In the broadest sense, diapirism encompasses "the piercing or rupturing of domed or uplifted rocks by mobile core material, by tectonic stresses as in anticlinal folds, by the effect of geostatic load in sedimentary strata as in salt domes or shale diapirs, or by igneous intrusions, forming diapiric structures such as plugs" (Bates and Jackson 1984 [DIRS 128109], p. 138). The concept of diapirism is usually applied to salt structures resulting from geostatic loading (see excluded FEP 1.2.09.00.0A (Salt Diapirism and Dissolution)) but can also be applied to the doming effects associated with igneous intrusion.

Current tectonic stresses in the region are extensional (BSC 2004 [DIRS 168030], Section 6.3.1), and such a stress regime is not conducive to the compression-related anticlinal folding and doming associated with diapirism. The geologic materials at Yucca Mountain are brittle (particularly the welded tuffs), and exhibit deformation by faulting and jointing, with the formation of breccias, rather than folding and doming. The volcanic rocks present at the site are not capable of ductile flow under the stresses and at the temperatures expected due to geostatic loading and waste emplacement. In general, ductile behavior is associated with increased temperatures and hydrostatic pressures and is only expected at deep levels of the Earth's crust and in the mantle. Yucca Mountain is located in an area of moderate heat flow in the Southern Great Basin, south of any regions of relatively high crustal heat flow that might be more conducive to diapirism (Lachenbruch and Sass 1978 [DIRS 142990], pp. 212 and 246). Thus, diapirism related to tectonic stresses and geostatic loading is precluded because the necessary geologic materials and stress environment conducive to diapirism do not occur at Yucca Mountain.

Diapirism related to igneous intrusion is relevant to the disruptive event scenario in FEP 1.2.04.03.0A (Igneous Intrusion into Repository). Because of the stress regime at Yucca Mountain, an igneous event is expected to be in the form of a dike (BSC 2004 [DIRS 169989], Section 6.1). By way of corroboration, Smith et al. (1998 [DIRS 118967], p. 155) point out that extension is generally accommodated in the upper crust by intrusion of vertical dikes perpendicular to the extension direction, with surface deformation possibly including open

fissures, monoclines, normal faults, and grabens, and with surface uplift being approximately a few meters (Smith et al. 1998 [DIRS 118967], Figure 2). Thus, dike formation would tend to be oriented parallel to the existing faults and fractures and therefore would have minimal effect on groundwater flow systems because the possible associated diapirism would be of small scale compared to the volume over which flow and transport occurs. The potential for hydrologic response to igneous intrusion is more fully evaluated in excluded FEP 1.2.10.02.0A (Hydrologic Response to Igneous Activity). In particular, for the case of a 10 km-long, 5 km-deep, and 100 m-wide disc-shaped dike initially intruded into the saturated zone, the maximum rise in the water table due to heat effects would be on the order of 25 m (Kuiper (1991 [DIRS 163417], p. 121), not a sufficiently large increase to impact flow pathways or saturate the repository horizon (see included FEP 1.3.07.02.0A (Water Table Rise Affects SZ), and included FEP 1.3.07.02.0B (Water Table Rise Affects UZ)). Furthermore, the estimated size distributions for any potential future dikes at Yucca Mountain (SNL 2007 [DIRS 174260], Table 7-1) show that the dike analyzed by Kuiper (1991 [DIRS 163417]) is much larger than those potentially relevant to the repository. Because igneous-related diapirism from such a dike would be on the same scale, igneous-related diapirism is excluded based on low consequence.

Based on the preceding discussion, omission of FEP 1.2.09.01.0A (Diapirism) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with the proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.09.02.0A

FEP NAME:

Large-Scale Dissolution

FEP DESCRIPTION:

Dissolution can occur when any soluble mineral is removed by flowing water. Large-scale dissolution is a potentially important process in rocks that are composed predominantly of water-soluble evaporite minerals, such as salt.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Large-scale dissolution is a process principally affecting highly soluble evaporite rocks such as halite or carbonates. The unsaturated zone at Yucca Mountain has only a trace abundance of evaporitic minerals, as demonstrated by very low salt content in leachates from leaching numerous unsaturated zone rock samples (DTNs: LL030408023121.027 [DIRS 162949], GS030608312272.005 [DIRS 163745], LA0305RR831222.001 [DIRS 163422], and LA0307RR831222.002 [DIRS 164090]), and is primarily composed of high-silica minerals such as quartz, feldspar, and glass (BSC 2004 [DIRS 170031], Appendices C and E). Solubilities of these minerals are too low to produce large dissolution cavities, breccia pipes, or solution chimneys over the time scales of interest and expected water flow rates. Local dissolution processes are discussed in excluded FEP 2.2.08.03.0B (Geochemical Interaction and Evolution in the UZ).

The volcanic rocks present in the saturated zone are not readily soluble in water and their solubility is low enough that large-scale dissolution does not occur. Volcanic rocks tend to weather to clay minerals with only a relatively small amount of silica going into solution. The volcanic units in the saturated zone in the vicinity of Yucca Mountain are primarily comprised of silica (quartz and cristobalite), alkali feldspars, and zeolites (SNL 2008 [DIRS 184806], Section A2). The solubility of quartz, for example, is 12 mg/L at 1 bar pressure and pH 7 at 25°C (Freeze and Cherry 1979 [DIRS 101173], p. 106), which is relatively low compared to evaporite and carbonate solubilities. Large-scale dissolution of evaporites such as halite, with a solubility of 360,000 mg/L at 1 bar pressure and pH 7 at 25°C (Freeze and Cherry 1979 [DIRS 101173], p. 106), can be excluded from the saturated zone flow and transport models because evaporites are present in only trace amounts in any of the formations along the saturated zone transport pathways from underneath the repository to the accessible environment. This low abundance is apparent not only from the quantitative mineralogy of the rocks, but also from relatively low halide concentrations and generally low total dissolved solids concentrations in saturated zone water samples taken from the entire saturated zone flow model domain (SNL 2007 [DIRS 177391], Appendix A), which precludes a significant presence of evaporites.

Of all the hydrogeologic units in the Yucca Mountain hydrogeologic framework model (Belcher 2004 [DIRS 173179]; SNL 2007 [DIRS 174109], Figures 6-5 to 6-7), those containing carbonates are the most soluble in groundwater (solubility of 90 mg/L to 500 mg/L, depending on the pCO_2, at 1 bar pressure and pH 7 at 25°C (Freeze and Cherry 1979 [DIRS 101173], p. 106)). The permeability of these units is typically quite high, primarily due to solution channels and fractures (SNL 2007 [DIRS 177391], Section 6.3.1.1). Carbonates in the vicinity of Yucca Mountain exist only in the saturated zone at depths of 500 m or more below the water table (SNL 2007 [DIRS 174109], Figure 6-5). New extensive carbonate dissolution cavities are not expected to develop because such dissolution is not typically observed in carbonates at such depths below the water table (Freeze and Cherry 1979 [DIRS 101173], pp. 514 to 515).

Under unusually drier climatic conditions than at present, which is not expected within the next 10,000 years (BSC 2004 [DIRS 170002], Section 7.1), the water table may drop from its current potentiometric surface to lower levels. While not expected, there is mineralogical evidence to suggest that the maximum drop could be as much as 300 m (see excluded FEP 1.3.07.01.0A (Water Table Decline)). Even given this unexpected drop, the water table would still remain several hundreds of meters above the carbonate aquifer along the saturated zone transport paths (SNL 2007 [DIRS 174109], Figure 6-5), and significant dissolution of the carbonates would not occur.

Even if dissolution did occur in the carbonate aquifer, its depth below the water table, combined with the upward vertical hydraulic gradient throughout the saturated zone flow model domain (SNL 2007 [DIRS 177391], Section 6.3.1.5), preclude the possibility that radionuclides will reach the carbonate aquifer. In addition to head and borehole flow/pressure measurements that indicate an upward vertical hydraulic gradient in the saturated zone, the lack of a volcanic aquifer geochemical signature in the carbonate aquifer and vice-versa (SNL 2007 [DIRS 177391], Appendix A) suggests a lack of hydraulic communication between the two aquifers. Thus, large-scale dissolution in the carbonate aquifer can be excluded on the basis of low consequence because, even if dissolution cavities form in the carbonates, radionuclides are not expected to reach them.

Based on the previous discussion, omission of FEP 1.2.09.02.0A (Large-Scale Dissolution) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.10.01.0A

FEP NAME:

Hydrologic Response to Seismic Activity

FEP DESCRIPTION:

Seismic activity, associated with fault movement, may create new or enhanced flow pathways and/or connections between stratigraphic units, or it may change the stress (and therefore fluid pressure) within the rock. These responses have the potential to significantly change the surface and groundwater flow directions, water level, water chemistry, and temperature.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The extent and significance of water table rise in response to seismic activity and changes in the large hydraulic gradient that exists to the north of the repository are assessed. The effects of seismic activity on groundwater chemistry are also considered.

Hydrologic responses to seismic activity, either modeled or measured at analogue sites are documented here. Indirect causes of such behavior due to changes in the hydrologic properties of the rock matrix, faults or fracture network are discussed in excluded FEPs 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock), 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults) and 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures). Changes in the porosity and permeability of the regional geology (and hence, in flow and transport properties of the unsaturated zone, saturated zone, and potentially through the emplacement drifts) can be brought about by vibratory ground motion and alteration of the local stress fields (which may lead to the formation of new faults and/or fractures or in some cases the closing of existing fractures). A change in flow through the drifts has the potential to increase degradation of EBS components and waste packages, leading to radionuclide release. Aspects of flow change through the repository drift are addressed separately in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology). The effect of seismic activity on radionuclide transport is addressed in a sensitivity study that is detailed in excluded FEPs 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults) and 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures).

A hypothesis has been proposed that long-term changes in water table elevations are associated with seismic-induced permanent changes in regional permeability (Davies and Archambeau 1997 [DIRS 103180]). A transient change in water table elevations is associated with seismically induced changes to the local stress fields, which can lead to processes such as “seismic pumping.” Seismic pumping (Szymanski 1989 [DIRS 106963], pp. 3 to 22) is defined here as the temporary increase in height of the water table caused by fault movement. This movement of the water table is caused by the opening and closing of fractures during an earthquake cycle.

Longer-term changes are not expected to result from such permanent changes in stress because the existing data do not show any relationship between the long-term state of stress and water table elevation (Stock et al. 1985 [DIRS 101027]; Stock and Healy 1988 [DIRS 101022]). Water table elevations can change from a few centimeters to several tens of meters in response to seismic activity (National Research Council 1992 [DIRS 105162], Chapter 5). The change in water table elevation can also affect: (1) saturated zone flow and pathways, if the change in water table elevations are extensive enough to change the regional potentiometric surfaces, and (2) groundwater geochemistry, as the displaced water is moved into, and interacts with, rocks composed of different mineralogy. Because seismic activity is closely associated with tectonic activity, a decline in tectonic activity coincides with a decline in the frequency and intensity of seismic activity.

Investigations of analogue sites and numerical studies indicate that hydrologic response to seismic activity at the Yucca Mountain repository will be of low consequence. A brief summary of these investigations is given below.

Earthquakes can cause changes in groundwater levels, sometimes at distances far removed from the epicenter. The hydrologic effects of three seismic events in 1992 that were observed in groundwater monitoring wells at Yucca Mountain provide estimates of water-level fluctuations occurring in response to earthquakes. A magnitude 7.5 earthquake occurred at Landers, California, on June 28, 1992, followed a few hours later by a magnitude 6.6 earthquake at Big Bear Lake, California (O'Brien 1993 [DIRS 101276], Table 1). These earthquakes were regional, located about 293 and 296 km away from Yucca Mountain, respectively. A magnitude 5.6 earthquake occurred June 29, 1992, about 23 km from Yucca Mountain at Little Skull Mountain.

The 1992 data from the groundwater monitoring wells are listed in DTN: GS930108312312.003 [DIRS 171974] and document the earthquake-induced fluctuations in water level. Based on the data in DTN: GS930108312312.003 [DIRS 171974], the three earthquakes produced mostly short-term water level fluctuations on the order of tens of centimeters. The Landers earthquake caused about a 90-cm water-level fluctuation at well USW H-5. The following Big Bear Lake earthquake caused a 20-cm water-level fluctuation. The response of well USW H-3 to the Landers earthquake involved a brief water-level spike followed by a 20-cm decrease, returning to near normal levels within several hours. The response of wells USW H-5 and USW H-6 to the magnitude 5.6 Little Skull Mountain earthquake were 40 and 20 cm, respectively. The water level decreased about 50 cm at well UE-25 P#1 over three days following the earthquake, but the recovery of the water table in this well required about six months. Many other wells showed no response or smaller fluctuations over short time periods (on the order of hours) (O'Brien 1993 [DIRS 101276], Table 1). For perspective, it is noted that the repository would be located approximately 300 m above the current water table so that future water-level fluctuations of the magnitude of those observed in 1992 would not affect the repository horizon.

Several modeling investigations have been conducted to estimate the hydrologic response (i.e., change in water table elevations) given predicted fault displacements in the Yucca Mountain region. One investigation was performed by the National Research Council (1992 [DIRS 105162], Chapter 5). This group estimated the maximum changes in water table elevations over a 10,000-year period in response to seismic activity, which presumes some

degree of fault displacement. They estimated fault displacement using two modeling approaches: (1) a dislocation approach, where zones of extension on one side of a fault are balanced by compression across the fault; and (2) the more realistic "changes in the regional stress" approach caused by normal fault slippage in regions of extension. The regional stress approach evaluated the effect of stress on pore pressure, which is dependent on the elastic properties of the bulk rock and the mineral grains. Both models resulted in a transient change in water table elevation given a seismic event in the Yucca Mountain region. However, the extent of the rise differed for both models. Adopting the dislocation model, the maximum rise in the water table is approximately 17 m (Carrigan et al. 1991 [DIRS 100967], p. 1,159) (discussed below). Results from the regional stress approach resulted in a maximum water table rise of 50 m (National Research Council 1992 [DIRS 105162], Chapter 5, p. 116). The latter approach was developed by determining a realistic parameter range for the ratio of rock to mineral compressibility and then computing a result using the extreme value from this range that produced the highest water table rise. The durations of the changes were not specifically evaluted; however, the panel concluded that the increase in water level would gradually dissipate. The panel concluded that regardless of the approach, the maximum water table rise given a seismic event would be less than 50 m. Given the National Research Council study, it is inferred that a 13-m slip along Solitario Canyon fault (the approximate mean displacement for the Solitario Canyon fault based on an annual exceedance probability of 10^{-8}), which could implicitly impose the maximum change in volume stress strain changes on pore pressure, would result in no more than a 50-m rise in the water table.

By way of corroboration, Gauthier et al. (1996 [DIRS 100447], pp. 163 to 164) analyzed the potential effects of seismic activity as a result of three different types of fault displacements (normal, listric, and strike-slip faulting) on contaminant transport in the saturated zone due to changes in water table elevation. For all three fault types, a 1-m displacement with a 30-km rupture length was considered. Their simulations for the TSPA used in the viability assessment of the timing, amplitude, and duration of water table rise indicated a maximum rise of 50 m within an hour of a simulated strike-slip seismic event, with a smaller rise for the other types of events. The simulated system returned to steady-state conditions within six months. Gauthier et al. (1996 [DIRS 100447], pp. 163 to 164) conclude that:

> In general, seismically induced water-table excursions caused by poroelastic coupling would not influence the models presently being used to determine long-term performance of a repository at Yucca Mountain; therefore, we excluded them from the total-system simulations.

Investigations focusing on the potentiometric hydrologic response, given changes in rock properties adjacent to a fault, demonstrate that the changes in water table elevation are transient and local in nature. Numerical simulations by Carrigan et al. (1991 [DIRS 100967]) of seismic pumping involving earthquakes typical of the Basin and Range province (approximately 1-m fault slip) produced 2- to 3-m excursions of a water table 500 m below the ground surface. Extrapolation to an event of about 4-m slip would result in a transient rise of 17 m near the fault (Carrigan et al. 1991 [DIRS 100967], p. 1,159). Carrigan et al. (1991 [DIRS 100967]) modeled a 100-m-wide fracture zone centered on a vertical fault, with vertical permeability increased by a factor of 1,000. Water-level excursions in the fracture zone were twice as great as in the

adjacent block. For a fault-fracture zone with 1-m slip, transient excursions of about 12 m were modeled by Carrigan et al. (1991 [DIRS 100967]).

The significance of a rise in the water table is that it reduces the contribution to the barrier capability of the unsaturated zone by shortening the flow path from the repository to the saturated zone. Regardless, data and modeling results indicate that changes in water table elevation at Yucca Mountain are not expected to exceed 50 m and are expected to be transient. It is therefore expected that the water table excursions caused by earthquakes will not cause sufficient water table level fluctuations to threaten, even temporarily, the repository horizon, which in the current design is approximately 300 m above the water table. The water table could rise by up to about 120 m in the vicinity of the repository under wetter climates expected in the future (see included FEP 1.3.07.02.0A (Water Table Rise Affects SZ)), but seismic events are still unlikely to affect hydrologic conditions at the repository horizon.

Another aspect of the water table rise issue concerns the large hydraulic gradient of up to 0.13 just to the north of the repository (SNL 2007 [DIRS 177391], Section 6.3.1.4). The water table elevation rises as one moves from south to north away from the repository. If this gradient were to migrate southward, the resulting water table below the repository could be much higher than present-day conditions.

The work of Davies and Archambeau (1997 [DIRS 103180], p. 28) presents a hypothesis that the large hydraulic gradient is a result of residual stress effects in the rock induced by the Timber Mountain caldera. Furthermore, the authors suggest that moderate earthquakes in this area could induce a sufficient change in geomechanical strain downstream of the current large hydraulic gradient to induce a similar gradient downstream of the repository. This would result in a large (150 m to 250 m) rise in the water table beneath the repository. However, the hypothesis regarding the residual stress effects of the 10 Ma Timber Mountain caldera contradicts extensive previous experience in the region of the Nevada Test Site (Stock et al. 1985 [DIRS 101027]). This composite experience is compiled from 14 sources reporting results from diverse methods, including hydraulic fracturing, overcoring stress measurements, earthquake focal mechanisms, borehole breakouts, orientations of explosion-produced fractures, and study of Quaternary faults and cinder-cone alignments. These studies show a reasonably uniform direction of extension between northwest and west, with a mixed potential-slip regime of normal faulting (mainly for shallow indicators) and strike-slip faulting (mainly for deep indicators). The Davies and Archambeau discussion is also inconsistent with stress measurements in borehole G-2 as reported by Stock and Healy (1988 [DIRS 101022]). Stock and Healy (1988 [DIRS 101022]) characterize G-2 as being within the same ("combined normal and strike-slip") faulting regime as that indicated by the results from the three holes that they tested south of the large gradient. Based on the stress measurements in the four holes, the tendency for strike-slip faulting is greatest in the southeastern hole, UE-25p#1, not in the northern Yucca Mountain area where G-2 is located, as Davies and Archambeau (1997 [DIRS 103180]) propose.

Stress measurements are also available from the ESF. Results from hydraulic fracturing experiments in two boreholes in the Thermal Test Facility alcove and one borehole in the Northern Ghost Dance Fault alcove indicate a west-northwest extensional stress regime. The relative magnitudes of the principal stresses are consistent with potential normal faulting (SNL 1996 [DIRS 163645]; DTNs: SN308F3710195.003 [DIRS 166458] and

SN37100195002.001 [DIRS 131356]). Principal stress orientations inferred from earthquake focal mechanism studies also indicate a west-northwesterly directed least principal stress. Observed focal mechanisms exhibit a mixture of normal and strike-slip faulting. The overall data suggest a uniform stress regime in the vicinity of Yucca Mountain (von Seggern et al. 2001 [DIRS 156297], Section 9).

Available data do not support a residual stress effect from the Timber Mountain caldera, do not support a modern stress field changing from strike-slip in northern Yucca Mountain to normal south of the large hydraulic gradient, and do not support a southward decrease of the least principal stress. Based on these findings, any changes in stress resulting from seismic activity would be expected to have a negligible effect on the location of the large hydraulic gradient. Therefore, migration of the large hydraulic gradient as a result of seismic activity is excluded from TSPA on the basis of low consequence.

Finally, the effect of a seismic-induced hydrologic response on saturated zone groundwater chemistry will be insignificant. Groundwater isotopic and geochemical signatures within the Yucca Mountain region are indicative of groundwater flow directions and flow paths that have existed over the past 10,000 years. Uncorrected groundwater ages determined from ^{14}C (percent modern carbon) data (SNL 2007 [DIRS 177391], Table A6-7 and Section B7) and an exponential decay relationship (SNL 2007 [DIRS 177391], Equation A6-3) range from about 12,000 to 18,000 years old in the vicinity of Yucca Mountain. The analysis of the geochemistry supports the conclusion that the bulk of the groundwater beneath Yucca Mountain is derived from local recharge (SNL 2007 [DIRS 177391], Sections A6.3.6.3 and A6.3.6.4). Therefore, the saturated zone groundwater under the repository and along the saturated zone transport path is primarily paleoclimate recharge water with a small component (2% to 15%) of young water less than 1,000 years old (SNL 2007 [DIRS 177391], Table A6-8). Given that the saturated zone groundwater below the repository comes from local recharge through the unsaturated zone, any saturated zone water that is temporarily forced less than 50 m into the unsaturated zone by seismic activity would be expected to have a negligible effect on chemical composition or temperature relative to natural variations.

For the unsaturated zone, the range of water compositions that is used to define radionuclide sorption coefficients is taken from the range of water compositions found in the unsaturated zone and saturated zone (SNL 2007 [DIRS 177396], Appendix A, Section A4). Therefore, any alteration of composition through mixing of unsaturated zone and saturated zone waters as a result of water table rise is expected to lie within the range of uncertainty for groundwater composition already included in the TSPA. For the unsaturated zone, any effects of water table rise are expected to have a negligible effect on temperature in comparison with the effects of repository heating, which is excluded in terms of unsaturated zone flow and transport in excluded FEPs 2.2.10.01.0A (Repository-Induced Thermal Effects on Flow in the UZ) and 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation_Dissolution)).

In summary, the direct effects of seismic activity on the water table are transient and are negligible considering the height of the repository above the water table (the maximum projected water table rise due to seismic activity is 50 m and the projected repository height is at least 300 m above the current water table over the majority of the repository area). Even taking into

account an increase in the water table elevation associated with wetter climates expected in the future (up to 120 m), seismic events are still unlikely to affect hydrologic conditions at the repository horizon. As a result, groundwater flow and radionuclide transport would not be significantly affected by the hydrologic effects of future seismic activity, and therefore the hydrologic response to seismic activity is excluded from the TSPA on the basis of low consequence. The effects of seismic activity on groundwater chemistry and temperature are also excluded from the TSPA on the basis of low consequence, because the changes in temperature caused by seismicity will be negligible compared to changes resulting from other natural variations in temperature or through repository heating. Changes in geochemical conditions will also be negligible in terms of the uncertainties in water chemsitry already included in the unsaturated zone and saturated zone models used in TSPA. Southward migration of the large hydraulic gradient, which currently lies to the north of the repository, is excluded from the TSPA on the basis of low consequence.

Based on the previous discussion, omission of FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.2.10.02.0A

FEP NAME:

Hydrologic Response to Igneous Activity

FEP DESCRIPTION:

Igneous activity includes magmatic intrusions, which may alter groundwater flow pathways, and thermal effects that may heat up groundwater and rock. Igneous activity may change the groundwater flow directions, water level, water chemistry, and temperature. Eruptive and extrusive phases may change the topography, surface drainage patterns, and surface soil conditions. This may affect infiltration rates and locations.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Any future igneous activity in the Yucca Mountain region is expected to be basaltic (BSC 2004 [DIRS 169989], Section 6.2). The intrusion of a basalt dike at or near the repository block could locally alter the hydrological properties of the host rock and thereby affect flow-and-transport characteristics and radionuclide release to the accessible environment. The mean probability for the occurrence of a volcanic intrusion at Yucca Mountain is 1.7×10^{-8} per year (BSC 2004 [DIRS 169989], Table 7-1), which is not sufficiently low for exclusion from the TSPA on the basis of low probability (10 CFR 63.342 [DIRS 180319]). However, changes in hydrological properties caused by igneous activity are not expected to affect repository performance significantly, as discussed below.

The technical basis for exclusion from the TSPA of the hydrologic response to igneous activity relies on a variety of information including phenomena observed at analogue sites (such as thermal and geochemical effects on rock properties), analysis of effects of igneous activity on groundwater flow pathways, analysis of the potential for the development of a hydrothermal system, and analysis of the potential effects of eruptions on surface topography. These topics are discussed in the following paragraphs. Not all of the studies discussed here were performed for the purpose of assessing igneous impacts on hydrology, nevertheless, they still have considerable relevance to this subject and inferences from these studies may be drawn.

Observed Phenomena at Analogue Sites—Observations of mineral alterations around igneous intrusions at natural analogue sites show that alteration is limited to a zone that extends less than 10 m away from the intrusion/host rock contact (CRWMS M&O 1998 [DIRS 105347], pp. 5-41 to 5-71; Valentine et al. 1998 [DIRS 119132], p. 5-74). An appropriate analogue for understanding the characteristics of a volcanic event at Yucca Mountain is the Paiute Ridge intrusive/extrusive center (Byers and Barnes 1967 [DIRS 101859]) on the northeastern margin of the Nevada Test Site. The Paiute Ridge center is a small-volume Miocene volcanic center comparable in volume and composition to Quaternary volcanoes near Yucca Mountain (BSC 2004 [DIRS 169989], Section 6.3.2.1). Paleomagnetic, geochronologic, and geochemical

data indicate that the entire intrusive/extrusive complex formed during a brief magmatic pulse and thus represents a single volcanic event. The vents and associated dike system formed within a north-northwest-trending extensional graben, and there are excellent exposures of a variety of system depths. This includes remnants of surface lava flows, volcanic conduits, and dikes and sills intruded into tuff country rock at depths of up to 300 m. There is evidence of shallow structural control of dike emplacement at Paiute Ridge, including dike emplacement along fault planes (Byers and Barnes 1967 [DIRS 101859]). Dike lengths at Paiute Ridge range from less than 1 km to 5 km, comparable to the range estimated for post-Miocene volcanism near Yucca Mountain.

The margins of the Paiute Ridge dike complex are described in detail by Carter Krogh and Valentine (1996 [DIRS 160928], pp. 7 and 8) and are also discussed in the analysis of excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties). In the region of an intrusion, zones of change in host-rock properties occur. Alterations include formation of vitrophyres and/or various degrees of contact welding of the host rock, vesicle formation, and formation of fiamme, which are flattened glassy inclusions. Carter Krogh and Valentine (1996 [DIRS 160928]) report that "Visible thermal effects on the wall rocks disappear within 1 m of the dike margin." The spatial extent of the alteration caused by dikes was also confirmed using x-ray diffraction, x-ray fluorescence, and ion chromatograph analytical methods to detect changes in mineralogical content and volatiles gained or lost during contact metamorphism (Valentine et al. 1998 [DIRS 119132], p. 5-44). Alteration effects were found to be limited to within 5 to 10 m of the dike margin (Valentine et al. 1998 [DIRS 119132], p. 5-41). Hydrologic changes are therefore also expected to be confined to within a few meters of the dike margin. As discussed in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties), dike orientations are expected to be subparallel to the major flow directions in the unsaturated zone and saturated zone, resulting in a negligible effect on unsaturated zone and saturated zone flow. A detailed discussion of the expected configuration of igneous intrusions and their effects on flow patterns and perched water is presented in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties).

There is no indication in the unsaturated zone of extensive hydrothermal circulation and alteration, brecciation, deformation related to magmatic intrusion, or vapor-phase recrystallization during the magmatic intrusions into the vitric and zeolitized tuffs (CRWMS M&O 1998 [DIRS 105347], p. 5-42). Further discussion concerning the effects of igneous intrusions on mineralogy is given in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties). Given the limited area of alteration around the intrusion, the impact of any geochemical changes are minimal in the unsaturated zone. Because saturated zone water chemistry is dominated by the chemical and atmospheric conditions and the large volume of paleoclimate recharge waters, the small volume of igneous-altered rock would have little impact on the characteristics of saturated zone water chemistry along groundwater flow paths as discussed in included FEP 2.2.08.01.0A (Chemical Characteristics of Groundwater in the Saturated Zone) and excluded FEP 2.2.08.03.0A (Geochemical Interactions and Evolution in the Saturated Zone). Thus, the regional saturated zone geochemistry in the Yucca Mountain vicinity will not be significantly affected by igneous activity.

Interaction with Repository Drifts—A dike intersecting a repository drift would result in magma entering the drift. A simple conduction-only cooling model indicates that if a drift is

instantaneously and entirely filled with basaltic magma at 1,150°C, it (and the surrounding rock) will cool to sub-boiling in less than three years, with boiling temperatures extending no more than 10 m from the drift (SNL 2007 [DIRS 177430], Figures 6-98 and 6-99; DTN: MO0408EG831811.008 [DIRS 173078]). Contact metamorphism caused by dikes appears to be confined to distances of less than 5 m from the dike (BSC 2004 [DIRS 169734], Section 4.2.3.5). With significant thermal perturbations limited to less than 100 years and alteration limited to zones of a few meters around the dike, the thermal and chemical effects of basaltic magmatism on unsaturatede zone processes in the vicinity of an intersected repository drift would be negligible.

Several configurations are possible as a result of post-intrusion in-drift conditions. One possible scenario is that the drift will be filled with cooled but fractured magma that will maintain the capillary barrier and flow diversion potential at the interface. A second scenario is that the magma may drain out of the interior, leaving an air space that would also maintain the capillary barrier. The third scenario is for the magma to encapsulate the waste, but with few cooling joints, thereby providing no capillary barrier. In the TSPA model, only the third scenario is invoked and is justified as an approximation that does not underestimate the impact of the event on system performance. After post-intrusive magma cooling, seepage water is expected to flow through the contact metamorphic aureole and react with the basalt in the intruded emplacement drifts. The geochemical interactions of the seepage water and rock and the resulting hydrochemistry are addressed in included FEP 1.2.04.04.0B (Chemical Effects of Magma and Magmatic Volatiles).

Potential for Development of a Hydrothermal System—Findings from the Paiute Ridge analogue site indicate that "the occurrence of low-temperature clinoptilolite and opal also suggests that thermal transfer into the adjacent country rock was minimal" (CRWMS M&O 1998 [DIRS 105347], p. 5-57). Findings from the Grants Ridge analogue site in New Mexico suggest the absence of a hydrothermal system at that location (CRWMS M&O 1998 [DIRS 105347], p. 5-74). Further, the study concluded that, "an intrusion at Yucca Mountain would not result in large amounts of hydrothermally driven mass transfer" (CRWMS M&O 1998 [DIRS 105347], p. 5-74). Consequently, the development of hydrothermal systems from igneous activity is excluded from the TSPA based on low consequence due to their limited size relative to the repository footprint. Hydrothermal activity is also discussed in excluded FEP 1.2.06.00.0A (Hydrothermal Activity).

Effects on the Water Table—Kuiper (1991 [DIRS 163417], p. 121) suggested that if a 10-km-long, 5-km-deep, and 100-m-wide disc-shaped dike initially intruded into the saturated zone, the maximum rise in the water table due to heat effects would be on the order of 25 m; not a sufficiently large increase to impact flow pathways or saturate the repository horizon (see included FEPs 1.3.07.02.0A (Water Table Rise Affects SZ) and 1.3.07.02.0B (Water Table Rise Affects UZ)). Furthermore, the dike analyzed by Kuiper (1991 [DIRS 163417]]) is much larger than the estimated size distributions for any potential future dikes at Yucca Mountain (SNL 2007 [DIRS 174260], Table 7-1).

Potential Topographic and Surface Effects Following an Eruption—There is a potential for igneous activity (primarily via eruption or effusive flow) to change surface topography, and subsequently affect drainage and infiltration. The effects could hypothetically result in

temporary obstruction of a drainage system by a lava flow at the surface or as a result of the sloughing of ash or soil materials from hill slopes into drainages. The steep topographic gradients at Yucca Mountain above the repository and the limited extent of effusive flow from small-scale volcanoes such as Lathrop Wells (SNL 2007 [DIRS 174260], Section C.9) would limit the consequences of any such topographic changes. Lava flows along the northern edge of the northeast lava field of the Lathrop Wells volcano did block a drainage channel resulting in a temporary, and possibly ephemeral, impoundment of water (SNL 2007 [DIRS 174260], Appendix C). Subsequent erosion produced new channels, allowing any drainage water to flow around the blockage. The formation of the impoundment was a result of the (1) relatively flat topography in the vicinity of the the Lathrop Wells volcano, (2) the geometry of the fault-block bounded valley where the volcano resides, and (3) the relatively large drainage area associated with the blocked channel. Even if a lava dam were to form in one of the washes that drain the repository block at Yucca Mountain, it would not produce a large surface-water impoundment relative to the repository emplacement area because of the steeper topography, narrower widths, and smaller drainage areas of these washes as compared with the Lathrop Wells case. Consequently, significant ponding and consequent increased infiltration are not anticipated. Included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport) discusses assumptions regarding infiltration of radionuclides into underlying soil following ash flow and subsequent redistribution.

Another potential effect of igneous activity would be the deposition of an ash cover on the repository block. The range of mean particle size erupted during violent Strombolian eruptions is described by a log-triangular distribution with a minimum of 0.01 mm, a mode of 0.1 mm, and a maximum of 1.0 mm (SNL 2007 [DIRS 174260], Table 7-1). These values are typical of median grain sizes in silt, fine sand, and coarse sand, which typically have porosities of 40%, 35%, and 30%, respectively (Bear 1972 [DIRS 156269], pp. 40 and 46). Using these porosity and grain size ranges and the modified Kozeny-Carman equation for permeability (Bear 1972 [DIRS 156269], p. 166):

$$k = \frac{d_m^2}{180} \frac{n^3}{(1-n)^2}$$

where k is permeability, d_m is grain size, and n is porosity, the estimated permeability of the ash deposit ranges from 4×10^{-14} to 2×10^{-10} m^2. Mean bedrock saturated hydraulic conductivity in the infiltration model ranges from 6×10^{-7} to 3×10^{-5} m/s, corresponding to a permeability range of 7×10^{-14} to 3×10^{-12} m^2, and soil saturated hydraulic conductivity ranges from 7×10^{-7} to 11×10^{-7} m/s, corresponding to a permeability range of 7×10^{-14} to 1×10^{-13} m^2 (SNL 2008 [DIRS 182145], Tables 6.5.2.3-1 and 6.5.2.6-1). Therefore, an ash deposit is expected to have a permeability similar to or higher than that of the underlying bedrock and soil. Vertical flow will be limited by the lowest permeability units (the soil and bedrock in this case), and therefore the ash deposit would not cause a significant increase in infiltration rates. Based on the analyses in the net infiltration model report (SNL 2008 [DIRS 182145]), infiltration decreased as the soil thickness increased. The porous ash would behave hydraulically as an increase in soil thickness, and thus the deposited ash would be expected to decrease net infiltration, after vegetation is reestablished. The establishment of vegetation is important

because the increased soil thickness (or added ash) allows infiltrated water to be stored within the root zone of the plants, which then transpire the water back to the atmosphere.

Summary—Igneous intrusions that might occur in the time frame of 10,000 years after closure would affect a relatively small volume of the host rock and are expected to be oriented subparallel to existing flow directions. Consequently, future intrusions would not have a significant effect on groundwater flow patterns or water levels. Given the limited area of any thermal or geochemical alteration, and the consequent change of rock properties around an intrusion, any geochemical effects would be minimal. The potential development of a hydrothermal system from igneous activity is not expected based on analogue studies and would be of low consequence due to its limited size relative to the repository footprint. Any possible changes to topography and soils from extrusive activity are also of low consequence.

Based on the previous discussion, omission of FEP 1.2.10.02.0A (Hydrologic Response to Igneous Activity) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.3.01.00.0A

FEP NAME:

Climate Change

FEP DESCRIPTION:

Climate change may affect the long-term performance of the repository. This includes the effects of long-term change in global climate (e.g., glacial/interglacial cycles) and shorter-term change in regional and local climate. Climate is typically characterized by temporal variations in precipitation and temperature.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Global climate change is addressed in TSPA, using a climate analysis based on paleoclimate information. That is, the record of climate changes in the past is used to predict the expected changes in climate for the future. Future climates are described in terms of discrete climate states that are used to approximate continuous variations in climate. The discussion in this FEP is limited to natural processes. The effects of human activity on climate change are addressed in excluded FEP 1.4.01.00.0A (Human Influences on Climate).

Future climate forecasts (BSC 2004 [DIRS 170002]) indicate that the climate at Yucca Mountain is predicted to evolve to the cooler, wetter conditions of a glacial-transition climate within the first 10,000 years after disposal. Within that period of time, the present-day climate is predicted to last for 400 to 600 years after present; a monsoon climate is predicted to last from the end of the present-day climate to between 900 and 1,400 years after present; and a glacial-transition (intermediate) climate state is predicted to last for the remainder of the 10,000-year period (BSC 2004 [DIRS 170002], Table 6-1). A fourth climate state is based on regulation (proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394) and continues from 10,000 years to 1,000,000 years postclosure. To simplify how the climate change is implemented in the TSPA model for the first 10,000 years postclosure, only the maximum durations were used (i.e., 600 years for the present-day climate, 1,400 years for the monsoon climate, and 8,000 years for the glacial-transition climate) (SNL 2008 [DIRS 183478], Section 6.3.1.2). Proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]) requires that the DOE vary factors related to climate based on cautious but reasonable assumptions. At the same time, changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology should not be projected (10 CFR 63.305(b) [DIRS 180319]). The climate change FEP was evaluated and addressed from the perspective of natural processes and from the perspective of the factors that are related to human activity. In accordance with the proposed rule (70 FR 53313 [DIRS 178394], pp. 53315 and 53316), the effects of climate change after 10,000 years, but within the period of geologic stability, are assumed to be limited to the results of increased percolation of water through the repository, with percolation rates reflecting climate conditions that are wetter and cooler than present-day conditions.

Climate change is addressed in the unsaturated zone model and incorporated into TSPA through the use of unsaturated zone flow fields that have different surface water infiltration rates as a result of the four different climate states. For the pre-10,000-year climate states, climate conditions are addressed in the infiltration model (SNL 2008 [DIRS 182145], Section 6.5.1.1[a]) through the selection of analogues at other locations with present-day climates that are representative of the range of future climate conditions projected at Yucca Mountain (BSC 2004 [DIRS 170002], Section 6.6). The meteorological data from these analogues are then used for modeling infiltration under these future climate conditions at Yucca Mountain. A description of the modeling methods used for infiltration, and of how it is affected by climate, is given in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5).

For the post-10,000-year period, the climate change analysis is limited to the effects of increased water flow through the repository as a result of climate change, and the resulting transport and release of radionuclides to the accessible environment, in accordance with proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394]), which defines the deep percolation rates for that period as based on a log-uniform probability distribution from 13 to 64 mm/yr. Unsaturated zone flow weighting factors were used to calibrate the unsaturated zone model using input from four infiltration maps representing the 10th, 30th, 50th, and 90th percentile infiltration scenarios for the present-day climate. The weighting factors were calculated to be 0.62, 0.16, 0.16, and 0.06 for the 10th, 30th, 50th, and 90th percentile infiltration scenarios. The midpoints of these probability ranges for a cumulative probability distribution are at 0.31, 0.70, 0.86, and 0.97, respectively. These midpoints were applied to the log-uniform proposed percolation flux range of 13 to 64 mm/yr resulting in targets of 21.29, 39.52, 51.05, and 61.03 mm/yr for the 10th, 30th, 50th, and 90th percentile infiltration scenarios, respectively. These midpoints were compared to the average infiltration calculated (over the repository footprint) for the 12 infiltration maps. Four maps were selected that most closely matched the midpoint values. The four infiltration maps that were selected and scaled are: the present-day 90th percentile, the glacial-transition 50th percentile, the glacial-transition 90th percentile, and the monsoon 90th percentile infiltration maps. These maps were scaled so that the average water flux rates through the repository footprint exactly matched the target values at the repository horizon. Once the infiltration boundary condition was determined, the methods used to generate the post-10,000-year flow fields were the same as used to generate the pre-10,000-year flow fields (SNL 2007 [DIRS 184614], Section 6.1.4).

The results of the infiltration model are then used for computing unsaturated zone flow throughout the UZ flow model domain, which includes the repository waste emplacement zone. The UZ flow model uses the infiltration results as top boundary conditions for unsaturated zone flow calculations (SNL 2007 [DIRS 184614], Section 6.1.4). The UZ flow fields are used directly in TSPA (SNL 2007 [DIRS 184614], Section 6.2.5). The output flow fields are in DTNs: LB0612PDFEHMFF.001 [DIRS 179296]; LB0701MOFEHMFF.001 [DIRS 179297]; LB0701GTFEHMFF.001 [DIRS 179160]; and LB0702PAFEM10K.002 [DIRS 179507], developed for use in performance assessment (SNL 2008 [DIRS 183478]).

Changes in net infiltration resulting from future climate change is also implicitly included in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], which predicts the expected range in the thermal-hydrologic parameters including: temperature and relative humidity. This

model uses the unsaturated zone flow fields as one of its inputs and therefore model results are affected by climate change.

Climate change is included in the treatment of radionuclide transport for the TSPA as discussed in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.8). The effect of climate change on repository performance was studied by using pre-generated flow fields under different climates (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]). For the TSPA, the pregenerated flow fields are used by the finite element heat and mass (FEHM) model as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.9).

The effects of climate change are also included in the model for seepage water chemistry through changes in the percolation flux rates. The percolation flux values used in the model are based on fluxes at the PTn/TSw boundary predicted by the UZ flow model, given in the following four DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332] representing each climate state. The approach used is a plug flow model that has a transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4). The effects of flow on the water chemistry are evaluated in terms of the amount of feldspar dissolution that occurs during flow through the TSw (SNL 2007 [DIRS 177412], Sections 6.3.2.4.5). This is a function of the ambient feldspar dissolution rate, the dissolution rate temperature dependence, the model for the thermal field, and the plug flow model for transport through the TSw (SNL 2007 [DIRS 177412], Section 6.3.2.4.5). The starting point for evaluating potential water compositions in the near field is the composition of ambient pore waters in the TSw. The available pore water data from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and grouped into four compositional groups (SNL 2007 [DIRS 177412], Section 6.3.2.3). The amount of feldspar dissolution is passed to TSPA in a lookup table, as the water–rock interaction parameter, or WRIP (SNL 2007 [DIRS 177412], Section 6.3.2.4.5; DTN: SN0703PAEBSPCE.006 [DIRS 181571]).

Potential effects of climate change on the amount of infiltration and percolation are similarly taken into account in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.6.5). Seepage is calculated in the TSPA using percolation flux distributions based on results from the UZ flow and transport model (SNL 2007 [DIRS 184614], Section 6.4[a]) given in DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332] representing each climate state. Condensation of water along the drift wall is affected by changes in climate and associated unsaturated zone flow as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]), since percolation is used as an input to the drift wall condensation model.

The effects of climate change on radionuclide transport in the saturated zone are incorporated into the SZ flow and transport abstraction model and the SZ one-dimensional transport model as implemented in the TSPA by assuming instantaneous change from one steady-state flow

condition to another steady-state condition in the saturated zone. Changes in climate state are assumed to affect the magnitude of groundwater flux through the saturated zone system but have a negligible impact on flow paths. The effect of changes in groundwater flux is incorporated into the SZ flow and transport abstraction model by scaling the timing of radionuclide mass breakthrough curves proportionally to the change in SZ-specific discharge (SNL 2008 [DIRS 183750], Section 6.5).

In the biosphere model, the effect of climate change on the BDCFs for the groundwater exposure scenario must be weighed against two requirements. One requirement is not to project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology (10 CFR 63.305(b) [DIRS 180319]). The other requirement is to vary factors related to climate based on cautious but reasonable assumptions consistent with present knowledge (proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394])). Because BDCFs are a function of climate factors that depend on human activities and those that do not, the effect of climate change on BDCFs needed to be evaluated from the perspective of these two requirements. It was concluded that human activities, which should not be projected to change, have the largest effect on the BDCFs, and that the BDCFs are relatively insensitive to climate change effects on those parameters that are independent of human activities (SNL 2007 [DIRS 177399], Section 6.11.3). Therefore, consistent with the requirement not to project changes in human knowledge or technology, present-day climate BDCFs for the groundwater exposure scenario are used for both the pre-10,000-year and the post-10,000-year performance assessment calculations. This represents an appropriate balance between these two requirements, meets the requirements of 10 CFR 63.305(b) [DIRS 180319] and proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]), and is appropriate for the assessment of doses to the RMEI for 10,000 years following disposal as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3).

BDCFs for the volcanic ash exposure scenario were relatively insensitive to the effects of the climate change on the model parameters. Therefore, the present-day climate BDCFs for the volcanic ash exposure scenario were used in the TSPA for the 10,000-year period following repository closure and beyond 10,000 years, within the period of geologic stability, as prescribed by proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394]) (SNL 2007 [DIRS 177399], Section 6.12.3).

The biosphere component of the climate change FEP is implemented in the TSPA through the groundwater and volcanic BDCFs. The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples the BDCFs to propagate uncertainty from the biosphere model into TSPA dose calculations.

In summary, climate change is included in the TSPA model of the geosphere and biosphere transport for the performance assessments that demonstrate compliance with the individual protection standards in proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]). For the human intrusion event (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), only the post-10,000-year climate is used, because the human intrusion event is not expected to occur before 10,000 years following disposal. For the performance assessment that demonstrates compliance with the groundwater protection standards (10 CFR 63.331

[DIRS 180319]), only those components of this FEP that address the geosphere transport are included.

FEP: 1.3.04.00.0A

FEP NAME:

Periglacial Effects

FEP DESCRIPTION:

This FEP addresses the physical processes and associated landforms in cold but ice-sheet-free environments. Permafrost and seasonal freeze/thaw cycles are characteristic of periglacial environments. These effects could include erosion and deposition.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP refers to climate conditions that could produce a cold, but ice-sheet-free, environment at Yucca Mountain. The consequences of such a climate could include permafrost (permanently frozen ground), although paleoclimate records indicate that the climate conditions necessary to form permafrost are not expected at Yucca Mountain over the next 10,000 years (BSC 2004 [DIRS 170002], Section 6.6.2). This analysis forecasts that during the next 10,000 years the climate will evolve from the present interglacial climate through the monsoon to glacial-transition climate (BSC 2004 [DIRS 170002], Section 7.1). The glacial-transition climate (identified as "intermediate" in Sharpe 2003 [DIRS 161591], Table 6-6) has the lowest predicted mean annual temperatures for the 10,000-year period following repository closure (BSC 2004 [DIRS 170002], Section 6.6.2; Sharpe 2003 [DIRS 161591], Section 6.3.2). For the glacial-transition climate, analogue sites provide a basis for the conclusion that the estimated range of mean annual temperatures is 8.3°C to 10.1°C (DTN: UN0201SPA021SS.007 [DIRS 161588], file: *table 6-3.doc*; Sharpe 2003 [DIRS 161591], Table 6-3), which is too warm to sustain permafrost. Only the coldest scenario for the full glacial climate (Oxygen Isotope Stage 6/16) is expected to have a mean annual temperature of 0°C (Sharpe 2003 [DIRS 161591], Figure 6-4). The expected return to such a climate is 200,000 years after present (Sharpe 2003 [DIRS 161591], Table 6-5), although, even during the last glacial maximum, the mean annual temperature at Yucca Mountain exceeded 0°C (Thompson et al. 1999 [DIRS 109470], Figures 17 and 18).

The consequence of permafrost at Yucca Mountain can be evaluated using the risk-informed approach by considering the joint outcome of the probability of this process and its consequences. Considering the zero probability of the mean annual temperature in the Yucca Mountain region being 0°C or less during the 10,000-year period following repository closure (see excluded FEP 1.3.05.00.0A (Glacial and Ice Sheet Effects)), and the low consequence of permafrost (because the agriculture for the cooler and wetter conditions would rely less on irrigation than under the present-day climatic conditions), the impact of omitting this FEP from the TSPA would be insignificant.

Another process included in this FEP are the seasonal freeze/thaw cycles, which could influence soil erosion and deposition. Freeze/thaw mechanical erosion is expected to increase as the climate cools. However, the degree of erosion is expected to be insignificant even during the cooler climate condition. The time-averaged erosion at Yucca Mountain over a 10,000-year period is expected to be less than 10 cm (YMP 1993 [DIRS 100520], Section 3.4). This is based on estimates for erosion rates at Yucca Mountain over the last 12 million years (YMP 1993 [DIRS 100520], Section 3.4) and therefore includes the effects of cooler climates, including full glacial periods.

The erosion rate is an input parameter for the biosphere model. It is one of the parameters that influence the radionuclide concentration in surface soils (SNL 2007 [DIRS 177399], Sections 6.4.1.1 and 6.4.1.4). The value of this parameter, as used in the biosphere model, is characteristic of agricultural soils, unlike the erosion rate caused by natural processes discussed in the previous paragraph, including those in the Amargosa Valley area. The erosion rate is in the range from 0.2 to 1.1 $kg/m^2/yr$, which corresponds to 1.3×10^{-4} to 7.3×10^{-4} m/yr, when a soil bulk density of 1,500 kg/m^3 is used (DTN: MO0609SPASRPBM.004 [DIRS 179988], Sections 1 and 3). Over 10,000 years, this erosion rate would result in the removal/replacement of 1.3 to 7.3 m of cultivated soil. The erosion rate on noncultivated cropland and on pastureland is much lower than that for the cultivated cropland, even in the areas located farther north than southern Nevada that would experience freeze/thaw cycles (USDA 2000 [DIRS 160548], Tables 10 and 11). Therefore, the additional effect of the seasonal freeze/thaw cycles, if these occurred, would be insignificant on the erosion rate in comparison with the erosion caused by agricultural activities. Consequently, periglacial effects will not have a significant impact on the output of the biosphere model.

The effects of seasonal freeze/thaw cycles on deposition are expected to increase when the climate evolves from the present-day climate to a cooler and wetter climate. The compliance point is located within the depositional basin on the Fortymile Wash alluvial fan. The evolution of Fortymile Wash indicates that the overall process in this system during the Quaternary has been aggradation (i.e., the accumulation of deposits) (YMP 1993 [DIRS 100520], Section 3.4). The influx of uncontaminated material into the compliance location would lower the radionuclide concentration in the soil (and thus the dose to the RMEI) due to dilution.

Based on the preceding discussion, omission of FEP 1.3.04.00.0A (Periglacial Effects) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.3.05.00.0A

FEP NAME:

Glacial and Ice Sheet Effect

FEP DESCRIPTION:

This FEP addresses the effects of glaciers and ice sheets occurring within the region of the repository, including direct geomorphologic effects and hydrologic effects. These effects include changes in topography (due to glaciation and melt water), changes in flow fields, and isostatic depression and rebound. These effects could include erosion and deposition.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP refers to the local effects of glaciers and ice sheets. Based on the paleoclimate records, the existence of glaciers or ice sheets at Yucca Mountain is not expected during the 10,000 years postclosure (BSC 2004 [DIRS 170002], Section 6.6). The analysis forecasts that during the next 10,000 years the climate will evolve from the present interglacial climate through the monsoon to glacial-transition climate (BSC 2004 [DIRS 170002], Section 7.1). The glacial-transition climate (identified as "intermediate" in Sharpe 2003 [DIRS 161591], Table 6-6) has the lowest predicted mean annual temperatures for the 10,000-year period following repository closure (BSC 2004 [DIRS 170002], Section 6.6.2; Sharpe 2003 [DIRS 161591], Section 6.3.2). For the glacial-transition climate, analogue sites provide a basis for the conclusion that the estimated range of mean annual temperatures is 8.3°C to 10.1°C (DTN: UN0201SPA021SS.007 [DIRS 161588], file: *table 6-3.doc*; Sharpe 2003 [DIRS 161591], Table 6-3), which is too warm to sustain glaciers or ice-sheets. Only the coldest scenario for the full glacial climate (Oxygen Isotope Stage 6/16) is expected to have a mean annual temperature of 0°C (Sharpe 2003 [DIRS 161591], Figure 6-4). The expected return for such a climate is 200,000 years-after-present (Sharpe 2003 [DIRS 161591], Table 6-5), although, even during the last glacial maximum, the mean annual temperature at Yucca Mountain exceeded 0°C (Thompson et al. 1999 [DIRS 109470], Figures 17 and 18).

The closest alpine glaciers to Yucca Mountain during the Pleistocene were in the White Mountains in California and possibly the Spring Range near Las Vegas (BSC 2004 [DIRS 169734], Section 6.4.1.4), both too far from Yucca Mountain to have any effect on site geomorphology or hydrology. Given the relatively low elevation of Yucca Mountain, there is no reasonable mechanism by which an alpine glacier could form at the site over the next 10,000 years. The geomorphologic and hydrological effects associated with glaciers, such as changes in topography resulting from erosion, deposition, and glacial transport, changes in flow fields, and isostatic depression and rebound, are therefore not expected to occur at Yucca Mountain.

An evaluation was made to demonstrate that this FEP is very unlikely to occur during the 10,000-year period following repository closure. As previously noted, the expected return of the maximum full glacial climate, when the mean annual temperature is at or below freezing, is approximately 200,000 years after present. This forecast is based on celestial mechanics involving earth-orbital cycles, which are corroborated by Devil's Hole and Owens Lake paleoclimatological records (BSC 2004 [DIRS 170002], Section 1; Sharpe 2003 [DIRS 161591], Section 1). The earth-orbital cycles result from the precession of the earth axis, variations in earth orbit eccentricity, and obliquity (i.e., changes in the Earth axis of rotation) (BSC 2004 [DIRS 170002], Section 6.4). The changes in these orbital parameters affect the total radiation received at the top of earth's atmosphere and thus the climate. Based on analysis of the timing of past climate changes associated with the Earth-orbital cycles it is very unlikely that an anomaly in the Earth's orbit would develop during the 10,000-year period following repository closure causing the full glacial climate. Because the climatic changes induced by changes in the Earth's orbit are not random, and the next maximum full glacial climate is not expected for approximately 200,000 years from present, the probability of glaciers and ice sheets forming at Yucca Mountain during the 10,000-year period following repository closure is considered to be zero.

Based on the preceding discussion, FEP 1.3.05.00.0A (Glacial and Ice Sheet Effects) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 1.3.07.01.0A

FEP NAME:

Water Table Decline

FEP DESCRIPTION:

Climate change could produce decreased infiltration (e.g., an extended drought), leading to a decline in the water table in the saturated zone, which would affect the release and exposure pathways from the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The Yucca Mountain region is a desert environment and future climate predictions indicate only increased precipitation (BSC 2004 [DIRS 170002], Sections 6.6 and 7.1; DTNs: GS000308315121.003 [DIRS 151139] and UN0201SPA021SS.007 [DIRS 161588]). Moreover, paleoclimate records indicate that arid conditions are short compared to wetter conditions while climatic conditions during the past two million years were wetter than current conditions 70% to 80% of the time (Forester et al. 1996 [DIRS 100148], p. 52). Analysis of Searles Lake deposits indicate that extremely dry conditions (resulting in lake desiccation) have occurred only twice within the past 600,000 years: once about 290,000 years ago and again in the past 10,000 years (Jannik et al. 1991 [DIRS 109434], p. 1,146 and Figure 10). This FEP examines the effects of a climate change over the next 10,000 years that lead to much drier conditions resulting in desertification of the surface environment, decreased infiltration, and declining water table elevation. It should be noted that the water table has been modeled to be higher for the post-10,000-year period because of the higher rate of deep infiltration required in 10 CFR 63.342(c) (70 FR 53313 [DIRS 178394]).

Present groundwater elevations in the Basin and Range province (which includes the Yucca Mountain region) reflect the current arid climatic conditions and the decrease in infiltration (i.e., decreased recharge) over the course of the present-day climate. The present-day climate extends for 600 years beyond the present in the TSPA. After the present-day climate, warmer and wetter monsoonal climatic conditions extend an additional 1,400 years. A cooler and wetter glacial-transition climatic condition will follow the brief monsoonal period and will persist for the remainder of the 10,000 years after repository closure (BSC 2004 [DIRS 170002], Section 7). *Future Climate Analysis* (BSC 2004 [DIRS 170002]) only predicts the average expected climate; however, this FEP addresses variability of future climates that could yield short-term, arid conditions that cause the current water table elevation to fall. However, these anomalously dry conditions are not expected to lower the water table elevation by more than a few meters (Luckey et al. 1996 [DIRS 100465], p. 29; Ervin et al. 1994 [DIRS 100633], pp. 11 to 13). Such small decreases to the water table elevation are well within the uncertainties included in both the unsaturated and saturated zone models and are therefore of low consequence.

Decreases in water table elevation would not degrade the performance of either the unsaturated or saturated zones. Specifically, a decreased water table elevation increases the unsaturated zone thickness. Decreases in the elevation of the water table result in a decrease in specific discharge because of the expected decrease in hydraulic gradient. Moreover, based on the saturated zone flow calculations, the transport pathways under current and expected wetter climatic conditions are confined to the following hydrostratigraphic units: the Crater Flat-Prow Pass, Crater Flat-Bullfrog, and Crater Flat-Tram, the Paintbrush Volcanic Aquifer, the Volcanic and Sedimentary Unit, and the Alluvium. Of these six units, most transport pathways pass through the Crater Flat-Bullfrog hydrostratigraphic unit (SNL 2007 [DIRS 177391], Figures 6-17 and 6-22). The Crater Flat-Prow Pass and -Bullfrog units are the most permeable volcanic units in the flowpath (SNL 2007 [DIRS 177391], Section 6.5.1.3 and Table 6-10; SNL 2007 [DIRS 177394], Section 6.2). Lowering the water table elevation in these volcanic units would result in a transport path increasingly in the Crater Flat-Tram unit and potentially in the Volcanic and Sedimentary unit. The permeabilities of these units are lower than the Crater Flat-Bullfrog. Therefore, if the water table elevation were lowered, transport times would increase because of the decreased permeabilities through which radionuclides would travel and the performance of the saturated zone would improve.

Based on the previous discussion, omission of FEP 1.3.07.01.0A (Water Table Decline) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.3.07.02.0A

FEP NAME:

Water Table Rise Affects SZ

FEP DESCRIPTION:

Climate change could produce increased infiltration, leading to a rise in the regional water table, possibly affecting radionuclide release from the repository by altering flow and transport pathways in the SZ. A regionally higher water table and change in SZ flow patterns might move discharge points closer to the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Water table rise is possible for the predicted future climates. The predicted future climates (monsoon and glacial transition) are wetter than present day and are expected to produce greater infiltration than the present day climate (SNL 2008 [DIRS 182145], Section 6.5.7[a]). Increased infiltration produces increased recharge to the groundwater system. The increased recharge will have two impacts on the groundwater system: (1) water levels will rise (D'Agnese et al. 1999 [DIRS 120425], p. 21), and (2) the amount of groundwater flowing past any location per unit time will increase (SNL 2008 [DIRS 183750], Section 6.5[a]). The groundwater flux, defined as the amount of groundwater flowing past any location per unit time per unit cross-sectional area, will also increase with the increase in recharge. As described later, the rise in water table leads to increases in radionuclide travel times in the saturated zone, while the increased groundwater fluxes lead to decreases in travel times.

The TSPA simulations of the saturated zone account for wetter climatic conditions with the use of a multiplicative factor that is the ratio of predicted groundwater flux under future climate conditions to the groundwater flux under present-day conditions while keeping the water table position at the present-day levels. An alternative conceptual model that included simulations with a higher water table elevation is described in later paragraphs. The multiplicative factor is called the saturated zone groundwater flux ratio (SNL 2008 [DIRS 183750], Section 6.5[a], Table 6-4[a]). The saturated zone groundwater multiplier scales the saturated zone radionuclide breakthrough curves, effectively modeling the impacts of increased groundwater flow that will exist for a higher water table condition (SNL 2008 [DIRS 183750], Section 5).

The TSPA simulations are performed for present-day, monsoon, and glacial-transition climates as well as the regulatory-based post-10,000-year case (proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394])). For the early time when the present-day and monsoon climate dominate, the saturated zone groundwater multiplier will be used to scale the saturated zone radionuclide breakthrough curves from the glacial-transition results to the early climates. Three groundwater flux multipliers are used to characterize changes in the groundwater flow system reflective of future climatic conditions. For a monsoon climate, the groundwater flux is

1.9 times greater than that of the present-day climate. For a glacial-transition climate, the groundwater flux is 3.9 times greater than that of the present-day climate (SNL 2008 [DIRS 183750], Table 6-4[a]). For the post-10,000-year period, the saturated zone groundwater flux is maintained at 3.9 times greater than present day. This increased flux is a realistic representation of the assumed wetter and cooler climate conditions that are expected to exist during nearly two-thirds of the time after 10,000 years (Sharpe 2003 [DIRS 161591], Figure 6-8). The rationale for the use of the flux multiplier approach is provided in the following discussion.

Saturated zone transport times at the 18-km boundary using the flux multiplier method have been compared to transport times performed on an alternative model domain to corroborate the SZ flow model. The alternative model domain method allows the water table to be higher than present conditions (SNL 2007 [DIRS 177391], Section 6.6.4). The simulated water table rise varied from 20 m south of Highway 95 to 100 m north of the repository. The rise at the location of the Paleosprings at the southern end of Crater Flat was 30 m and beneath the repository was 50 m. Sorbing and nonsorbing radionuclide breakthrough curves show initial tracer breakthrough times (the leading edge of the radionuclide breakthrough curve) that are a factor of two to four times greater for the alternative model method compared with breakthrough times using the flux multiplier method. At the median (50%) breakthrough, the time is about a factor of 6 longer for the alternative model method. Additionally, radionuclide breakthrough curve trailing-edge times for the alternative model domain are well over an order of magnitude greater compared to those derived using a flux multiplier (SNL 2008 [DIRS 184806], Appendix E, Figures E-1 and E-2). Another simulation where the water table was assumed to rise 120 m beneath the repository produced similar results (BSC 2004 [DIRS 170036], Appendix E). The longer transport times using the alternative model are a function of several factors. The higher water table incorporated in the alternative model domain enables both sorbing and nonsorbing radionuclides to pass through less permeable upper volcanic confining units (that are above the water table in the present climate case), resulting in longer path lengths and transport times. Additionally, a higher water table promotes longer flow paths through the porous alluvium, equating to longer alluvium transport times.

Based on the comparison with results from the alternative model that simulates a higher water table, it is concluded that the simplified, flux multiplier method results in more rapid radionuclide transport to the 18-km boundary. That is, the flux multiplier method that accounts for the effect of climate change on water table elevations provides a conservative estimate of groundwater transport times in the saturated zone under wetter climate conditions compared to the case where the higher water table is simulated.

In summary, the saturated zone aspect of this FEP is included in TSPA by accounting for the effects of a higher water table on radionuclide transport in the saturated zone through the use of groundwater flux multipliers.

Water table rise associated with future climates is included in the radionuclide transport simulations for the unsaturated zone, and is discussed in included FEP 1.3.07.02.0B (Water Table Rise Affects UZ). To include this water table rise in TSPA calculations, the water table elevation is instantaneously increased by 120 m in the UZ model domain when the climate changes from present-day to monsoon climate. The same water table elevation is also used for

the glacial-transition climate. This approach uses the reasonable upper bound (120 m rise) from several estimates of the water table elevation under the repository in the past (SNL 2007 [DIRS 177391], Section 6.6.4). The water table rise of 120 m is maintained in the UZ model domain for the post-10,000-year period as a conservative representation of the effects of wetter and cooler climate conditions.

Water table rise could alter the location of groundwater discharge points, which could alter groundwater exposure pathways. Current natural groundwater discharge points along the saturated zone flow paths are several kilometers downstream from the 18-km accessible environment boundary. Also, modeling results indicate that, under the future climate states considered in the TSPA, the water table would not rise sufficiently to cause the formation of springs and the contamination of soils downgradient of the repository within the 18-km boundary (SNL 2007 [DIRS 177391], Section 6.6.4). The water table could rise to within 5 m of the ground surface at the location of paleospring deposits located southwest of the Yucca Mountain repository (SNL 2007 [DIRS 177391], Figure 6-21 as indicated by the blue shaded regions), but the Solitario Canyon and Windy Wash faults (SNL 2007 [DIRS 177391], Figure 6-12) serve as barriers between these paleosprings and potential flow paths from the repository (SNL 2007 [DIRS 177391], Figures 6-15 and 6-17). Therefore, even if springs were to develop in the shallow water table southwest of the repository, it is not expected that radionuclides released from the repository would be consituents of the spring water. Exposure via such pathways is insignificant compared to the exposure pathways considered in the biosphere model (see excluded FEP 2.2.08.11.0A (Groundwater Discharge to Surface Within the Reference Biosphere)).

However, given the depth to groundwater shown in *Information and Analyses to Support Selection of Critical Groups and Reference Biospheres for Yucca Mountain Exposure Scenarios* (LaPlante and Poor 1997 [DIRS 101079], Figure 2-2) and the possible paleodischarge locations identified in *Simulated Effects of Climate Change on the Death Valley Regional Ground-Water Flow System, Nevada and California* (D'Agnese et al. 1999 [DIRS 120425], p. 6), the possible effects of changes in groundwater level under future climate conditions are included in the biosphere model consistent with proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]), which requires that the DOE vary factors related to hydrology and climate based on cautious but reasonable assumptions consistent with present knowledge. In addition, the use of such water needs to be included, consistent with 10 CFR 63.312(c) [DIRS 180319], which specifies the constraints for the radionuclide concentration in the groundwater used by the RMEI.

The biosphere model for the groundwater exposure scenario includes the effects of water table rise because the model calculates BDCFs for a unit activity concentration in the water, regardless of the origin of the water. If the groundwater entering the biosphere through a spring or other discharge point were an additional source of radionuclides in the biosphere, it would be treated in a manner similar to groundwater from a well. Therefore, water table rise is considered in the model, analogous to included FEP 1.4.07.02.0A (Wells), in the soil, air, plant, animal, fish, ^{14}C, and ingestion submodels (SNL 2007 [DIRS 177399], Sections 6.4.1 to 6.4.6 and 6.4.9).

The biosphere aspect of the water table rise is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007

[DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). For the performance assessment that demonstrates compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]), only those components of this FEP that address the geosphere transport are included.

FEP: 1.3.07.02.0B

FEP NAME:

Water Table Rise Affects UZ

FEP DESCRIPTION:

Climate change could produce increased infiltration, leading to a rise in the regional water table, possibly affecting radionuclide release from the repository by altering flow and transport pathways in the UZ. A regionally higher water table and change in UZ flow patterns might flood the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The water table will be higher in future climate states that have greater infiltration rates; these are discussed in included FEP 1.3.01.00.0A (Climate Change). To include this predicted water table rise in the TSPA calculations, the water table elevation is instantaneously increased by up to 120 m when the climate changes from present-day to monsoon climate. In the UZ flow model area, the present-day water table varies from less than 730 m to greater than 940 m above mean sea level (BSC 2004 [DIRS 169855], Figure 6.2). Within the repository footprint, the present-day water table varies from around 730 to 850 m above mean sea level (BSC 2004 [DIRS 169855], Figure 6.2). Note that the bottom boundary for the flow models of all climate states is the present-day water table. For use in conjunction with FEHM's multispecies particle tracking model the flow-field files for the monsoon, glacial-transition, and post-10,000-year climate flow fields from the UZ flow model abstraction are postprocessed to approximate the affects of a rising water table. The rising water table is approximated by constraining the water table to a minimum elevation of 850 m above mean sea level (SNL 2008 [DIRS 184748], Section 6.4.8). That is for future climates, any locations where the present-day water table is below 850 m it is set to 850 m and any locations where the present-day water table is above 850 m, the water table is not adjusted from the present-day level (BSC 2004 [DIRS 169855]). The same water table elevation is also used for the glacial-transition climate state.

Water table changes are implemented in the TSPA by allowing the water table to change elevation instantaneously upon change in climate, concurrent with changes in infiltration (implemented by the postprocessor software WTRISE (V2.0 2003 [DIRS 163453], STN: 105372.000) for radionuclide transport), thus affecting the unsaturated flow and pathways in the unsaturated zone. The original flow fields that are part of the UZ flow model abstraction are postprocessed with WTRISE, allowing the user to specify new water table locations in the flow field files. FEHM utilizes the updated flow fields and, as a result, particles will exit the unsaturated zone at the new water table (SNL 2008 [DIRS 184748], Section 6.4.8). At a time step where the water table rises, FEHM removes all the particles in the gridblocks between the old water table and the new water table (SNL 2007 [DIRS 184614], Section 6.6.2.2).

The particles removed from the volume between the old and new water tables immediately enter the saturated zone.

Paleoclimate data indicate that the historical water table has never risen to the level of the repository (Forester et al. 1999 [DIRS 109425], pp. 46 to 56). Based on analysis of mineralogic alteration (zeolitization and tridymite distribution) and strontium isotope ratios, and groundwater flow modeling, the water table for future climates (both monsoon and glacial transition) is specified in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.8). Future climate flow fields, implemented in the UZ flow model (SNL 2007 [DIRS 184614], Section 6.6.2.2), have been postprocessed using WTRISE.

In accordance with proposed 10 CFR 63.342(c) (70 FR 53313 [DIRS 178394]), the effects of climate change after 10,000 years, but within the period of geologic stability, are represented by the NRC-prescribed distribution of percolation rates at repository depth. The TSPA model simulations use four flow fields to represent this distribution (SNL 2007 [DIRS 184614], Section 6.6.2.2). The water table rise assumed in the TSPA for the post-10,000-year period is the same as that assumed for future climates in the pre-10,000-year period.

The effect of water table rise on the thermal regime is not included in the TSPA because the exact boundary condition values for temperature, gas pressure, and saturation are not important for thermal-hydrologic seepage model results. The temperature and gas pressure values that define the initial temperature and pressure fields, respectively, are significantly altered in the near-field rock early in the simulations once the drifts heat up.

FEP: 1.4.01.00.0A

FEP NAME:

Human Influences on Climate

FEP DESCRIPTION:

Future human actions, either intentional or accidental, could influence global, regional, or local climate.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The description of present-day climate, as discussed in included FEP 1.3.01.00.0A (Climate Change), is based on climate records that implicitly include effects of modern society over the duration of the historical record. Future changes in human influences on climate are excluded from postclosure assessment on the basis of requirements contained in 10 CFR 63.305(b) [DIRS 180319] and 10 CFR 63.305(c) [DIRS 178394], which provide as follows: "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application" (10 CFR 63.305(b) [DIRS 180319]); and "DOE must vary factors related to the geology, hydrology, and climate based upon cautious, but reasonable assumptions consistent with present knowledge of factors that could affect the Yucca Mountain disposal system during the period of geologic stability and consistent with the requirements for performance assessment specified at § 63.342" (10 CFR 63.305(c) [DIRS 178394]).

The supplementary information portion of the preamble to 10 CFR Part 63 (66 FR 55732 [DIRS 156671]) provides rationale for the requirements in 10 CFR 63.305(b) and (c) and indicates that natural evolution of the geosphere and biosphere is to be included in the performance assessment but any impacts caused by future changes in human behaviors are not to be included. In response to comments made in the rulemaking proceeding associated with climate change (66 FR 55732 [DIRS 156671], p. 55757), the NRC emphasized the importance of including "climate change in both the geosphere and biosphere performance assessment calculations to ensure that the conceptual model of the environment is consistent with our scientific understanding of reasonably anticipated natural events." Similarly, in 67 FR 62628 [DIRS 162317], the NRC stated "DOE's performance assessments are required to consider the naturally occurring features, events and processes that could affect the performance of a geologic repository" (67 FR 62628 [DIRS 162317], p. 62629). In further response to comments, the NRC also stated that considering future economic growth trends and human behaviors would add inappropriate speculation into the requirements and would lead to problems deciding which alternative futures are credible and which are unrealistic (66 FR 55732 [DIRS 156671], p. 55757).

Prediction of human-induced climate changes would not only involve speculations about the local population, but also introduce inherently large uncertainties in prediction of the future global population behaviors and resulting consequences. In its discussion of the consideration of future economic growth trends, the NRC found that inclusion of such future predictions would not only add inappropriate speculation, but also "would not enhance public safety, and is likely inconsistent with the EPA standards" (66 FR 55732 [DIRS 156671], p. 55757).

Based on these requirements, the FEPs related to changes in or predictions of future human activities are excluded. Future climate analysis does not include potential changes that may occur as a result of future changes in human actions. Accordingly, this FEP is excluded from the TSPA by regulation.

FEP: 1.4.01.01.0A

FEP NAME:

Climate Modification Increases Recharge

FEP DESCRIPTION:

Climate modification causes an increase in recharge in the Yucca Mountain region. Increased recharge might lead to increased flux through the repository, perched water, or water table rise.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Future climate forecasts (BSC 2004 [DIRS 170002]) indicate that the climate at Yucca Mountain is predicted to evolve to the cooler, wetter conditions of a glacial-transition climate within the assessment timeframe. Monsoon and glacial-transition (intermediate) climate states are predicted to last about 38,000 years after waste emplacement (Sharpe 2003 [DIRS 161591]). Climate modification in the period up to 10,000 years is included in the TSPA through the use of three discrete climate states: present-day, monsoon, and glacial-transition. The effects of climate change after 10,000 years, but within the period of geologic stability, are assumed to be limited to the results of increased water flowing through the repository and the resulting transport and release of radionuclides to the accessible environment in accordance with proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394], pp. 53315 to 53316). Increased deep percolation is reflective of wetter and cooler climate conditions than present-day conditions.

The effects of climate modification and increased recharge are considered by a number of processes represented by TSPA. The primary effect is to the calculation of net infiltration and associated percolation fluxes through the unsaturated zone. Percolation fluxes are used to calculate seepage fluxes into the repository and radionuclide transport from the repository to the saturated zone. Percolation fluxes also provide inputs to the calculation of drift-wall condensation and the evolution of thermal-hydrologic conditions in the unsaturated zone and repository, which affect chemical processes associated with radionuclide transport.

Spatially distributed net infiltration calculations provide inputs to the calculation of the spatial distribution of percolation fluxes in the unsaturated zone, otherwise know as UZ flow fields. A total of sixteen UZ flow fields are used in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478], Section 5.2). The flow conditions at the top boundary of the UZ flow model are provided from twelve net infiltration maps, four maps for the present-day, monsoon, and glacial-transition climate states that correspond to the 10th, 30th, 50th, and 90th infiltration percentiles for each of these climate states. For the post-10,000-year climate state, the development of the four utililized flow fields is described below. These infiltration maps are developed in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5.7[a]), and are used to propogate infiltration uncertainty through to the TSPA results. The probability weights for UZ flow fields

are calculated using the initial infiltration percentiles (monsoon and glacial transition climates) and UZ flow model calibration results (present-day climate) as described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.8). For the period from 10,000 years postclosure to the time of geologic stability, an additional four uncertainty cases are developed based on the prescribed percolation flux distribution through the repository footprint given in proposed 10 CFR 63.342(c) (70 FR 53313 [DIRS 178394]). The output flow fields are in DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507], which were developed for use in performance assessment (SNL 2008 [DIRS 183478]).

For the post-10,000–year period, the climate change analysis is limited to the effects of increased water flow through the repository as a result of climate change, and the resulting transport and release of radionuclides to the accessible environment, in accordance with proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394]). The proposed rule defines the deep percolation rates for that period as based on a log-uniform probability distribution from 13 to 64 mm/yr. This distribution was divided into four quantiles to develop four flow fields that most closely matched target rates based on proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394]). The midpoint of each quantile was used to represent the average flux for the given flow field. The four midpoint values are 21.29, 39.52, 51.05, and 61.03 mm/yr (SNL 2007 [DIRS 184614], Section 6.1.4, Table 6.1-3). Four corresponding net infiltration maps representing present-day 90th percentile, glacial-transition 50th percentile, glacial-transition 90th percentile, and monsoon 90th percentile, respectively, are used to represent these quantiles. Net infiltration for these four cases was scaled so that the average water flux through the repository footprint matched the target values (quantile midpoints) at the repository horizon. Once the infiltration boundary condition was determined, the method used to generate the post-10,000-year flow fields was the same as that used to generate the pre-10,000-year flow fields (SNL 2007 [DIRS 184614], Section 6.1.4).

Calculations of seepage flux (flow into the repository drifts) are affected by increases in recharge caused by future climate changes because the drift seepage model uses unsaturated zone flow fields as input (SNL 2007 [DIRS 181244], Section 6.6.5). Seepage is calculated in the TSPA using percolation flux distributions based on results from the UZ flow model (SNL 2007 [DIRS 181244], Section 6.4[a]) given in DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332] representing the three three climate states and the post-10,000-year fluxes, respectively.

The effect of future climate changes in the form of increased recharge is included in the UZ transport model for TSPA through the use of unsaturated zone flow fields as input to the model (SNL 2008 [DIRS 184748], Section 6.5.1; DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]).

Increased recharge from future climate change is included in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]), which predicts the expected range in the thermal-hydrologic parameters, including temperature and relative humidity (SNL 2008 [DIRS 184433]). This

model uses the unsaturated zone flow fields as one of its inputs, and therefore model results are affected by increases in recharge caused by future climate modifications.

In addition, condensation of water along the drift wall is affected by changes in recharge as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]) as percolation is used as an input to the drift wall condensation model.

The effects of climate modification on the amount of percolation are also included in the model for seepage water chemistry through changes in the percolation flux (SNL 2007 [DIRS 177412]). The percolation flux values used in this model are based on fluxes at the PTn/TSw boundary predicted by the UZ flow model given in the following four DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332], representing the three climate states and the post-10,000-year fluxes, respectively. The system is modeled assuming plug-flow with transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4). The effects of feldspar dissolution on the water chemistry are evaluated in terms of the amount of feldspar dissolution that occurs during flow through the TSw (SNL 2007 [DIRS 177412], Sections 6.3.2.4.4 and 6.3.2.4.5). The amount of feldspar dissolved is a primary parameter in determining the composition of potential seepage waters. This is a function of the ambient feldspar dissolution rate, the dissolution rate temperature dependence, the model for the thermal field, and the plug-flow model for transport through the TSw (SNL 2007 [DIRS 177412], Section 6.3.2.4.5). The starting point for evaluating potential water compositions in the near field is the composition of ambient pore waters in the TSw. The available pore-water data from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and grouped into four compositional groups (SNL 2007 [DIRS 177412], Section 6.3.2.3). The uncertainty in the amount of feldspar dissolution is propogated through to TSPA using a lookup table, as the water–rock interaction parameter, or WRIP (SNL 2007 [DIRS 177412], Section 6.3.2.4.5).

Perched water has not been observed in observation wells in the unsaturated zone above the repository horizon (BSC 2004 [DIRS 169734], Section 7.4.2). The potential effect of perched water above the repository is indirectly related to lateral diversion of percolation flux in the PTn unit above the repository. PTn effects on the flow fields are discussed in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.2). The potential for water table rise caused by climate modification is included in TSPA calculations by adjusting the flow fields to the higher water tables, as implemented by the WTRISE software (LBNL 2003 [DIRS 163453]) and as modeled by *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.6.4).

The effect of climate modification in the form of increased recharge is discussed in included FEPs 1.3.07.02.0A (Water Table Rise Affects SZ) and 1.3.07.02.0B (Water Table Rise Affects UZ).

FEP: 1.4.01.02.0A

FEP NAME:

Greenhouse Gas Effects

FEP DESCRIPTION:

The Greenhouse Effect is the result of so-called 'greenhouse gases' allowing incoming solar radiation to pass through the Earth's atmosphere, but preventing much of the outgoing infrared radiation from the surface and lower atmosphere from escaping into outer space. Greenhouse gases include water vapor, carbon dioxide (CO_2), methane (CH_4), nitrous oxide (N_2O), halogenated fluorocarbons (HCFCs), ozone (O_3), perfluorinated carbons (PFCs), and hydrofluorocarbons (HFCs). Many of these gases are generated through various natural and physical processes, and have been responsible for maintaining habitable conditions on the planet. Human activities, such as burning fossil fuels, clearing forests (thereby increasing the oxidation of soil organic matter with the concurrent release of CO_2 as a decay product), most motorized transport and industrial processes have the potential to increase the levels of greenhouse gases, which could lead to changes in climate.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The description of the present-day climate, as discussed in included FEP 1.3.01.00.0A (Climate Change), is based on climate records that implicitly include effects of modern society over the duration of the historical record as well as the greenhouse gas effects. Future changes in human influences on the concentrations of atmospheric gases are excluded from postclosure assessment on the basis of the requirements contained in 10 CFR 63.305(b) [DIRS 180319] and in proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]), which provide as follows: "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application" (10 CFR 63.305(b) [DIRS 180319]); and "DOE must vary factors related to the geology, hydrology, and climate based upon cautious, but reasonable assumptions consistent with present knowledge of factors that could affect the Yucca Mountain disposal system during the period of geologic stability and consistent with the requirements for performance assessment specified at § 63.342." (proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394])).

The supplementary information portion of the preamble to 10 CFR Part 63 (66 FR 55732 [DIRS 156671]) provides a rationale for the requirements in proposed 10 CFR 63.305(b) [DIRS 180319] and (c) (70 FR 53313 [DIRS 178394]) and indicates that natural evolution of the geosphere and biosphere is to be included in the performance assessment but any impactss caused by future changes in human behaviors are not to be included. In response to comments made in the rulemaking proceeding associated with climate change (66 FR 55732

[DIRS 156671], p. 55757), the NRC emphasized the importance of including "climate change in both the geosphere and the biosphere performance assessment calculations to ensure that the conceptual model of the environment is consistent with our scientific understanding of reasonably anticipated natural events." Similarly, in 67 FR 62628 ([DIRS 162317], p. 62629) the NRC states, "DOE's performance assessments are required to consider the naturally occurring features, events and processes that could affect the performance of a geologic repository." In further response to comments, the NRC stated that considering future economic growth trends and human behaviors would add inappropriate speculation into the requirements and would lead to problems deciding which alternative futures are credible and which are unrealistic (66 FR 55732 [DIRS 156671], p. 55757).

Prediction of the future human-induced emissions of greenhouse gases and their potential to effect climate change would not only involve speculation about the local population but also introduce inherently large uncertainties in prediction of the future global population behavior and resulting consequences. In their discussion of consideration of future economic growth trends, the NRC found that inclusion of such future predictions would not only add inappropriate speculation, but also "would not enhance public safety, and is likely inconsistent with the EPA standards" (66 FR 55732 [DIRS 156671], p. 55757).

Based on these requirements, the FEPs related to changes in or predictions of future human activities are excluded. Future climate analysis does not incorporate potential changes, including variations in greenhouse gas effects, that may occur as a result of changes in future human actions. Accordingly, this FEP is excluded from the TSPA by regulation.

FEP: 1.4.01.03.0A

FEP NAME:

Acid Rain

FEP DESCRIPTION:

Acid rain refers to precipitation on a local to regional scale containing higher than normal amounts of nitric and sulfuric acids. This can result from man-made sources such as emissions produced from the burning of fossil fuels. Acid rain can detrimentally affect aquatic and terrestrial life by interfering with the growth, reproduction, and thus survival of affected organisms. It can influence the behavior and transport of contaminants in the biosphere, particularly by affecting surface water and soil chemistry and may also cause societal change due to contamination of water sources.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The description of present-day climate, as discussed in included FEP 1.3.01.00.0A (Climate Change), includes the effects of acid rain and is based on climate records that implicitly include effects of modern society over the duration of the historical record. Future human influences on climate and other components of the reference biosphere are excluded on the basis of requirements contained in 10 CFR 63.305(b) [DIRS 180319] and proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]), which provide as follows: "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application" (10 CFR 63.305(b) [DIRS 180319]); and "DOE must vary factors related to the geology, hydrology, and climate based upon cautious, but reasonable assumptions consistent with present knowledge of factors that could affect the Yucca Mountain disposal system during the period of geologic stability and consistent with the requirements for performance assessments specified at § 63.342" (proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394])).

The supplementary information portion of the preamble to 10 CFR Part 63 (66 FR 55732 [DIRS 156671]) provides rationale for the requirements in 10 CFR 63.305(b) [DIRS 180319] and (c) (70 FR 53313 [DIRS 178394]) and indicates that only natural evolution of the geosphere and biosphere is to be included in the performance assessment but any impacts caused by the future changes in human behaviors are not to be included. In 67 FR 62628 [DIRS 162317], the NRC states, "DOE's performance assessments are required to consider the naturally occurring features, events and processes that could affect the performance of a geologic repository" (67 FR 62628 [DIRS 162317], p. 62629). In response to comments made in the rulemaking proceeding, the NRC stated that considering future economic growth trends and human behaviors would add inappropriate speculation into the requirements and would lead to problems

deciding which alternative futures are credible and which are unrealistic (66 FR 55732 [DIRS 156671], p. 55757).

The NRC stated further that the natural systems of the biosphere should be allowed to vary consistent with the geologic record, which provides the basis for predicting future biosphere changes (66 FR 55732 [DIRS 156671], p. 55757). The present knowledge of the factors related to climate does not allow prediction of the climate changes caused by future human behavior. The climate change predictions are based on the geologic record and concern the natural evolution of the reference biosphere.

Prediction of future human actions resulting in acid rain would not only involve speculations about the local population, but also introduce inherently large uncertainties in prediction of the future global population behaviors and resulting consequences. In the discussion of consideration of future economic growth trends, the NRC found that inclusion of such future predictions would not only add inappropriate speculation, but also "would not enhance public safety, and is likely inconsistent with the EPA standards" (66 FR 55732 [DIRS 156671], p. 55757).

Based on these requirements, the FEPs related to changes in the prediction of future human activities are excluded. Future climate analysis does not incorporate potential changes, including effects of acid rain, that may occur as a result of future changes in human actions. Therefore, acid rain as a consequence of future changes in human activities is excluded from consideration in the TSPA by regulation.

There also exists another potential source of acid rain. A volcanic eruption can, under certain conditions, lead to acid rain, although such conditions are not expected to occur at Yucca Mountain. When SO_2, initially dissolved in magma, escapes during a volcanic eruption, it interacts with moisture in air producing atmospheric aerosols in form of small sulfuric acid droplets (by atmospheric oxidation of sulfur dioxide in the presence of water). When atmospheric moisture is abundant, these fine sulfate aerosols combine and precipitate as acid rain. Other volcanic gases, such as hydrogen sulfide, hydrogen chloride, and hydrogen fluoride, can also contribute, although the most significant impact comes from SO_2.

The consequence of an acid rain event on radionuclide releases from the repository and radiological exposures to the RMEI can be evaluated by using a risk-informed approach. The risk-informed evaluation considers the joint outcome of the probability and the consequence of acid rain of volcanic origin. For the acid rain to influence the repository or the reference biosphere, the following conditions would have to occur: (1) an eruptive volcanic event would have to take place in the vicinity of Yucca Mountain, followed by (2) the atmospheric transport of aerosols containing sulfuric acid from the point of emission to Yucca Mountain or the reference biosphere, followed by (3) the wet deposition of these aerosols in form of acid rain at those locations. These events are independent, so the probability of the sequence of events is the product of their probabilities. Considering a low probability of a volcanic eruption in the Yucca Mountain region (BSC 2004 [DIRS 169989], Section 6.2), a relatively short eruption duration and small value (SNL 2007 [DIRS 174260], Table 7-1), a random location relative to Yucca Mountain and the reference biosphere, and a low humidity associated with arid and semi-arid climate, acid rain is not expected at Yucca Mountain or in the reference biosphere.

However, if acid rain occurred, any effects would be localized and of short duration. The effects of acid rain on the chemistry of precipitation that could reach the repository would be negligible considering the relative volumes of precipitation that would be affected by acid rain and that unaffected by acid rain over the period of repository performance. The effects of acid rain on the soil conditions and on subsequent radionuclide transport are implicitly included in the biosphere model through the distributions of soil-to-plant transfer factors. The uncertainty in these parameters accounts for the possible changes in soil conditions (e.g., due to addition of soil amendments), and is also appropriate for the volcanic conditions (BSC 2004 [DIRS 169672], Sections 6.2.1). An acid rain event would thus not significantly affect the radionuclide transport in the biosphere and the resulting exposures to the RMEI. Therefore, acid rain of volcanic origin would have a negligible effect on the results of performance assessment and, therefore, can be excluded.

Based on the regulatory requirements, the FEPs related to changes in, or the prediction of, future human activities are excluded. Future climate analysis does not incorproate potential changes including acid rain that may occur as a result of future changes in human actions. Accordingly, this FEP is excluded from the TSPA by regulation.

FEP: 1.4.01.04.0A

FEP NAME:

Ozone Layer Failure

FEP DESCRIPTION:

Human actions (i.e., the use of certain industrial chemicals) may lead to destruction or damage to the earth's ozone layer. This may lead to significant changes to the climate locally and globally, affecting properties of the geosphere such as groundwater flow patterns.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The description of present-day climate, as discussed in included FEP 1.3.01.00.0A (Climate Change), is based on climate records that implicitly include effects of modern society over the duration of the historical record. Future changes in human influences on climate are excluded from postclosure assessment on the basis of requirements contained in 10 CFR 63.305(b) [DIRS 180319] and proposed 10 CFR 63.305 (c) (70 FR 53313 [DIRS 178394]), which provide as follows: "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application" (10 CFR 63.305(b) [DIRS 180319]); and "DOE must vary factors related to the geology, hydrology, and climate based upon cautious, but reasonable assumptions consistent with present knowledge of factors that could affect the Yucca Mountain disposal system during the period of geologic stability and consistent with the requirements for performance assessment specified at § 63.342" (proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394])).

The supplementary information portion of the preamble to 10 CFR Part 63 (66 FR 55732 [DIRS 156671]) provides rationale for the requirements in 10 CFR 63.305(b) [DIRS 180319] and (c) (70 FR 53313 [DIRS 178394])) and indicates that only natural evolution of the geosphere and biosphere is to be included in the performance assessment but any impacts caused by future changes in human behaviors are not to be included. In response to comments made in the rulemaking proceeding associated with climate change (66 FR 55732 [DIRS 156671], p. 55,757), the NRC emphasized the importance of including "climate change in both the geosphere and the biosphere performance assessment calculations to ensure that the conceptual model of the environment is consistent with our scientific understanding of reasonably anticipated natural events." Similarly, in 67 FR 62628 [DIRS 162317] the NRC states, "DOE's performance assessments are required to consider the naturally occurring features, events and processes that could affect the performance of a geologic repository…" (67 FR 62628 [DIRS 162317], p. 62629). In further response to comments, the NRC stated that considering future economic growth trends and human behaviors would add inappropriate speculation into

the requirements and would lead to problems deciding which alternative futures are credible and which are unrealistic (66 FR 55732 [DIRS 156671], p. 55757).

Prediction of ozone layer failure due to future human actions would not only involve speculation about the local population, but also introduce inherently large uncertainties in prediction of the future global population behavior and resulting consequences. In its discussion of consideration of future economic growth trends, the NRC found that inclusion of such future predictions would not only add inappropriate speculation, but also "would not enhance public safety, and is likely inconsistent with the EPA standards" (66 FR 55732 [DIRS 156671], p. 55757).

Based on these requirements, the FEPs related to changes in or predictions of future human activities are excluded. Future climate analysis does not incorporate potential changes, including ozone layer failure, that may occur as a result of future changes in human actions. Accordingly, this FEP is excluded from the TSPA by regulation.

FEP: 1.4.02.01.0A

FEP NAME:

Deliberate Human Intrusion

FEP DESCRIPTION:

Humans could deliberately intrude into the repository, although without appropriate precautions, intruders could experience high radiation exposures. In addition, waste packages and other containment may be damaged during intrusion, thereby potentially increasing radionuclide release rates to the biosphere. Motivation for deliberate human intrusion includes mining for waste retrieval, site remediation/improvement activities, archaeological investigation, facility sabotage, and acts of war.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Regulations indicate that deliberate human intrusion into the Yucca Mountain repository may be excluded from consideration in the TSPA. The approach to addressing potential future human intrusion into the repository is discussed in Subpart E of 10 CFR Part 63 ([DIRS 180319]). In particular, in discussing institutional controls, 10 CFR 63.102(k) [DIRS 180319] provides, in part, that:

> …because it is not possible to make scientifically sound forecasts of the long-term reliability of institutional controls, it is not appropriate to include consideration of human intrusion into a fully risk-based performance assessment for purposes of evaluating the ability of the geologic repository to achieve the performance objective at § 63.113(b). Hence, human intrusion is addressed in a stylized manner….

Further, in discussing the human intrusion analysis, 10 CFR 63.102(l) [DIRS 180319] provides, in part, that:

> Although the consequences of an assumed intrusion event would be a separate analysis, the analysis is similar to the performance assessment required by § 63.113(b) but subject to specific requirements for evaluation of human intrusion specified at §§ 63.321, 63.322 and 63.342.

Therefore, an assessment of human intrusion is required to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), but human intrusion does not require consideration within the demonstration of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])).

Future human intrusion may be intentional and deliberate or may be inadvertent and accidental. Supplementary discussion in the preamble to 40 CFR Part 197 [DIRS 155216] clarifies the point that consideration of deliberate human intrusion in the TSPA is not intended. In the supplementary information to 40 CFR Part 197 (66 FR 32074 [DIRS 155216], p. 32105, Item 3), the EPA, in response to comments regarding the human intrusion stylized analysis, states:

> Comments we received proposing alternative drilling frequencies and intentions, such as deliberately drilling into the repository, did not provide a sufficient rationale to abandon the NAS [National Academy of Science] recommendations and we therefore retained our original framing for the scenario.

The EPA amplifies on this point in 66 FR 32074 ([DIRS 155216], p. 32,127, Item 10). The EPA explicitly states that:

> Some comments suggested that there is a strong possibility for deliberate intrusion into the repository to access its content as possible resources. We believe that there is no useful purpose to assessing the consequences of deliberate intrusions because in that case the intruders would be aware of the risks and consequences and would have decided to assume the risks. This is consistent with NAS's [the National Academy of Science] conclusion regarding intentional intrusion (NAS Report, p. 14).

Further clarification that deliberate human intrusion may be excluded from the TSPA is provided in the requirements for the analysis of the human intrusion scenario (10 CFR 63.322 [DIRS 180319]). According to 10 CFR 63.322(a) [DIRS 180319], the DOE must assume that there is a single human intrusion as a result of exploratory drilling for groundwater. Therefore, deliberate human intrusion such as mining for waste retrieval, site remediation/improvement activities, archaeological investigation, facility sabotage, and acts of war may be may be excluded from the TSPA.

In summary, FEP 1.4.02.01.0A (Deliberate Human Intrusion) may be excluded from the TSPA based on regulation. Inadvertent human intrusion is discussed in included FEP 1.4.02.02.0A (Inadvertent Human Intrusion) and is included in the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 1.4.02.02.0A

FEP NAME:

Inadvertent Human Intrusion

FEP DESCRIPTION:

Humans could accidentally intrude into the repository. Without appropriate precautions, intruders could experience high radiation exposures. Moreover, containment may be left damaged, which could increase radionuclide release rates to the biosphere. Inadvertent human intrusion might occur during scientific, mineral or geothermal exploration.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The approach to addressing potential future human intrusion into the Yucca Mountain repository is discussed in Subpart E of 10 CFR Part 63 [DIRS 180319]. In particular, in discussing institutional controls, 10 CFR 63.102(k) [DIRS 180319] provides, in part, that:

> …because it is not possible to make scientifically sound forecasts of the long-term reliability of institutional controls, it is not appropriate to include consideration of human intrusion into a fully risk-based performance assessment for purposes of evaluating the ability of the geologic repository to achieve the performance objective at § 63.113(b). Hence, human intrusion is addressed in a stylized manner….

Further, in discussing the human intrusion analysis, 10 CFR 63.102(l) [DIRS 180319] provides, in part, that:

> Although the consequences of an assumed intrusion event would be a separate analysis, the analysis is similar to the performance assessment required by § 63.113(b) but subject to specific requirements for evaluation of human intrusion specified at §§ 63.321, 63.322 and 63.342….

Therefore, an assessment of human intrusion is required to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), but human intrusion does not require consideration within the demonstration of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR [DIRS 178394])) or within the demonstration of compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]).

The approach to assessing human intrusion is set out in Subpart L of 10 CFR Part 63 [DIRS 180319] and proposed 10 CFR Part 63 (70 FR 53313 [DIRS 178394]). A definition of human intrusion is provided in 10 CFR 63.302 [DIRS 180319], the individual protection

standard for human intrusion is provided in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and the approach to evaluating a human intrusion scenario is specified in 10 CFR 63.322 [DIRS 180319], as discussed below.

Human intrusion is defined as follows:

> Human intrusion means breaching of any portion of the Yucca Mountain disposal system, within the repository footprint, by any human activity.

Future human intrusion may be intentional and deliberate or may be inadvertent and accidental. The supplementary discussion in the preamble to 66 FR 32074 (40 CFR Part 197 [DIRS 155216]) clarifies the point that consideration of deliberate human intrusion in the TSPA is not intended, as discussed in detail in excluded FEP 1.4.02.01.0A (Deliberate Human Intrusion). Consideration of human intrusion into the repository is limited to inadvertent intrusion.

Inadvertent human intrusions are considered within the context of the regulatory requirements to demonstrate compliance with the human intrusion standard. Proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) states the following:

> (a) DOE must determine the earliest time after disposal that the waste package would degrade sufficiently that a human intrusion (see § 63.322) could occur without recognition by the drillers.
>
> (b) DOE must demonstrate that there is a reasonable expectation that the reasonably maximally exposed individual receives, as a result of human intrusion, no more than the following annual dose:
>
> (1) 0.15 mSv (15 mrem) for 10,000 years following disposal; and
>
> (2) 3.5 mSv (350 mrem) after 10,000 years, but within the period of geologic stability.
>
> (c) DOE's analysis must include all potential environmental pathways of radionuclide transport and exposure, subject to the requirements at § 63.322.

The assessment of inadvertent human intrusion is based on an evaluation of the dose resulting from a stylized human intrusion drilling scenario. This approach is documented in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478], Section 6.7) to demonstrate that the repository design will exhibit a measure of resilience against a typical human intrusion scenario. The scenario is not intended to represent all forms of human intrusion that could affect the repository. The stylized scenario for human intrusion makes use of the following assumptions (10 CFR 63.322 [DIRS 180319]):

> (a) There is a single human intrusion as a result of exploratory drilling for groundwater;

(b) The intruders drill a borehole directly through a degraded waste package into the uppermost aquifer underlying the Yucca Mountain repository;

(c) The drillers use the common techniques and practices that are currently employed in exploratory drilling for groundwater in the region surrounding Yucca Mountain;

(d) Careful sealing of the borehole does not occur, instead natural degradation processes gradually modify the borehole;

(e) No particulate waste material falls into the borehole;

(f) The exposure scenario includes only those radionuclides transported to the saturated zone by water (e.g., water enters the waste package, releases radionuclides, and transports radionuclides by way of the borehole to the saturated zone); and

(g) No releases are included which are caused by unlikely natural processes and events.

In particular, TSPA evaluation of the earliest time at which a waste package is expected to be breached is discussed in Section 6.7.2 of *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]); Section 6.7.2.1 of that report (SNL 2008 [DIRS 183478]) describes the analysis of drip shield and waste package degradation for this scenario; Section 6.7.2.2 describes unlikely events-related damage mechanisms; and Section 6.7.2.3 (describes the potential for waste package penetration by a drilling event. Implementation and the process for estimating the mean annual dose for the human intrusion scenario is discussed in Section 6.7.3 of *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]).

The requirement in 10 CFR 63.322(f) [DIRS 180319], that only radionuclides transported to the saturated zone need be considered, precludes consideration of exposure of the public, drillers, or other human intruders to radionuclides in cuttings, circulated materials, or tailings. The supplementary information in the preamble to 10 CFR Part 63 (66 FR 55732 [DIRS 156671], p. 55761, Supplementary Information, 3.10 Human Intrusion Standard) is clear regarding the intent of the NRC on this point:

> Human intrusion has the potential for releasing particulate HLW to the surface with drill cuttings or providing a fast pathway for radionuclides to be transported to the saturated zone by water (e.g., water enters the waste package, releases radionuclides, and transports radionuclides by way of the borehole to the saturated zone). NAS [The National Academy of Science] concluded, and the Commission agrees, that analysis of the risk to the public or the intruders (i.e., drilling crew) from radioactive drill cuttings left unattended at the surface for subsequent dispersal into the biosphere would not fulfill the purpose of the human intrusion calculation because it would not show how well a particular repository site and design would protect the public at large. Rather, an analysis of the hazard of particulate HLW left on the surface would be dominated by assumptions subject

> to significant speculation and uncertainty regardless of the particular site or design under evaluation. Additionally, the release to the surface represents a one-time release with no long-term effect on the repository barriers.

Therefore, consideration of the exposure of intruders to radioactive waste is specifically excluded. Exposure as a consequence of human intrusion is limited to the transport of radionuclides by water flowing through a borehole that intrudes through a waste package, which is sufficiently degraded that it goes undetected by the drill operators, directly into the saturated zone.

In summary, inadvertent human intrusion is included in the demonstration of compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), but does not require consideration within the demonstration of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) or within the demonstration of compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). The assessment of inadvertent human intrusion is based on an evaluation of the dose resulting from a stylized scenario, which is discussed in included FEPs 1.4.04.00.0A (Drilling Activities – Human Intrusion) and 1.4.04.01.0A (Effects of Drilling Intrusion).

FEP: 1.4.02.03.0A

FEP NAME:

Igneous Event Precedes Human Intrusion

FEP DESCRIPTION:

An igneous event, such as a dike, could intersect the repository and significantly alter the material and structural properties of a drip shield and/or waste package. Because of the change in properties of these materials resulting from an igneous intrusion, an intruder, using groundwater exploration drilling techniques, may not be able to recognize that something other than naturally-occurring material has been encountered.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

The probability of a dike intruding the repository has been determined to have a mean annualized probability of 1.7×10^{-8} (BSC 2004 [DIRS 169989], Table 7-1). An igneous event is therefore a "not expected event," as defined in proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]). This FEP is applicable only to the performance assessment used to demonstrate compliance with the individual protection standard for human intrusion in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]). The human intrusion scenario is defined by 10 CFR 63.322 [DIRS 180319] as a single stylized scenario where a driller bores a single borehole into the repository. 10 CFR 63.322(g) [DIRS 180319] states, "no releases are included which are caused by unlikely natural processes and events." Proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]) further states: "DOE's assessments for the human-intrusion and ground-water protection standards shall not include consideration of unlikely features, events, and processes, or sequences of events and processes, i.e., those that are estimated to have less than one chance in 10 and at least one chance in 10,000 of occurring within 10,000 years of disposal."

In conclusion, FEP 1.4.02.03.0A (Igneous Event Precedes Human Intrusion) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 1.4.02.04.0A

FEP NAME:

Seismic Event Precedes Human Intrusion

FEP DESCRIPTION:

A seismic event of sufficient magnitude to significantly alter the material and structural properties of a drip shield and/or waste package could occur in the vicinity of the repository. Because of the change in properties, an intruder, using groundwater exploration drilling techniques, may not be able to recognize that something other than naturally-occurring material has been encountered.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Human intrusion is not considered in the performance assessment used to demonstrate compliance with the individual protection standard of proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) or the groundwater protection standard of 10 CFR 63.331 [DIRS 180319], but is addressed separately in a stylized performance assessment used to demonstrate compliance with the human intrusion individual protection standard of proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]). The stylized human intrusion performance assessment that is conducted to demonstrate compliance with proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) must include events with at least a 1 in 10 chance in 10,000 years of occurring (i.e., an approximate annual probability of 10^{-5} or greater) (proposed 10 CFR 63.342(b) (70 FR 53313 [DIRS 178394]), if these events are found to have a significant effect on the results of the performance assessment (proposed 10 CFR 63.342(a) and (c) (70 FR 53313 [DIRS 178394])). Lower probability events need not be considered (proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394])).

A seismic event may produce damage to drip shields or waste packages through effects from: (1) fault displacement along faults that intersect the repository, (2) damage induced by rockfall, and 3) mechanical damage induced by seismic ground motion.

The number of drip shields/waste packages estimated to lie on generic faults is 214 (SNL 2007 [DIRS 176828], Table 6-71) out of a total of 11,162 drip shields/waste packages (SNL 2007 [DIRS 176828], Table 6-62), to be stored in the repository. Waste package and drip shield failure due to fault displacement along faults intersecting the repository footprint has an annual probability of exceedance less than 2.2×10^{-7} [per year] for waste packages containing a TAD canister and less than 2.5×10^{-7} [per year] for codisposal waste packages (SNL 2007 [DIRS 176828], Table 6-67). Thus, failure of drip shields or waste packages from fault displacement is not relevant to the performance assessments conducted for proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), because the probability is lower than the regulatory threshold (see paragraph 1). For the same reason, waste package and drip shield

damage due to either rockfall or seismic ground motion associated with seismic events with probability less than 10^{-5} are not relevant.

Seismic events with an annual probability of 10^{-5} or above are associated with the potential for seismic-related damage to the drip shields and waste packages (SNL 2007 [DIRS 176828], Sections 5, 6.3, 6.4, and 6.5). For this magnitude of seismic event, corresponding to a response of 1.05 m/s PGV (SNL 2007 [DIRS 176828], Section 6.1.7), there is no possibility of rupture for 23-mm OCB TAD (SNL 2007 [DIRS 176828], Section 6.5.1.1) or codisposal (SNL 2007 [DIRS 176828], Section 6.6.1.1) waste packages with intact internals. The rupture probability for a 23-mm OCB TAD canister waste package with degraded internals is zero for single impacts (SNL 2007 [DIRS 176828], Section 6.5.1.1). Internals are degraded by multiple seismic events. The probability of failure for a drip shield depends on its plate thickness which slowly decreases with time because of general corrosion (modeled mean corrosion rate = 5 nm/yr ; SNL 2007 [DIRS 180778], Section 7.2.2) and on the rockfall loading factor for the 1.05 m/s PGV range. For a 15-mm plate thickness, which approximately corresponds to the plate thickness at 10,000 years, the probability of failure due to 100% rockfall loading (worst case) is zero (SNL 2007 [DIRS 176828], Table 6-36) and is only 0.001 when the drip shield thickness is reduced to 10 mm, which occurs on average at about 97,000 years. Thus, a seismic event only affects the timing or radiological exposure to the RMEI if a damaged drip shield or waste package is intersected by drilling.

For a 1.05 m/s PGV magnitude seismic event, the probability of damage to a 23 mm OCB TAD with intact internals is zero (SNL 2007 [DIRS 176828], Table 6-4) at a 90% residual stress threshold. The 90% residual stress threshold is the lower bound for the residual tensile stress threshold for potential crack initiation. The probability of damage to a codisposal waste package with a 23-mm OCB and intact internals is 0.559 (SNL 2007 [DIRS 176828], Tables 6-14 and 6-16). The mean and standard deviation of the damage at the 1.05 m/s PGV level is 0.120 and 0.144 m^2 (SNL 2007 [DIRS 176828], Section 6.5.4), which is a relatively small part of the total surface area of the TAD canister, 33.64 m^2 (SNL 2007 [DIRS 176828], Section 6.5.4), and as such the material properties (such as compressive strength), or the structural strength of the features will not have been significantly altered in terms of their ability to be recognized during drilling (SNL 2008 [DIRS 183478], Section 6.7.2.2). Figure 6-102 of *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478] gives a nonconditional nonzero damaged area of approximately 0.15 m^2 for 15-mm drip shield plates, again corresponding to a small area compared to the total area of the drip shield.

Thus, the material properties (such as compressive strength), or the structural strength of the features will not have been significantly altered in terms of their ability to be recognized during drilling (SNL 2008 [DIRS 183478], Section 6.7.2.2). Since the materials retain their basic physical characteristics (compressive strength in particular), the drilling assembly will respond to material changes in a recognizable way. As the emplacement drift is penetrated, a loss of drilling fluid will alert the driller to a change of conditions (SNL 2008 [DIRS 183478], Section 6.7.2.3.2). Damage in the drift produced by seismic activity may produce rubble which would tend to cause uneven loading of the drill bit (SNL 2008 [DIRS 183478], Section 6.7.2.3.2). As an undamaged EBS component (drip shield or waste package) is encountered, the drill bit will tend to bounce or slide and would tend to slip off unless the drill bit were aligned on the apex of the drip shield, further signaling a response by the driller (SNL 2008

[DIRS 183478], Section 6.7.2.3.3). Encountering a damaged feature, the drill bit will catch on fractures or cracks in the surface of the material. In extreme cases, contact will prevent the drill bit from rotating as it becomes entangled with the metals and alloys of the various engineered features. Under these conditions, the significant differences in shear strength and modulus of elasticity between naturally occurring and engineered feature materials will be important factors in the recognition by the driller that metal has been contacted by the bit (SNL 2008 [DIRS 183478], Section 6.7.2.3.4). A more complete discussion on driller recognition of EBS components within the host rock is given in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478], Section 6.7.2.3.4).

DOE must determine the earliest time after disposal that a waste package would degrade sufficiently that a human intrusion could occur without recognition by the drillers (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). The time until such degradation will depend most significantly on the rate of general corrosion of the drip shield and waste package materials. There is little expectation that a seismic event with an annual probability of 10^{-5} or more would affect this degradation time significantly. Based on the preceding discussion, seismic events with an annual probability of 10^{-5} or above would not induce significant changes in the material properties of the host rock or the engineered feature materials, or significantly affect the rate of degradation of engineered feature materials. These events are of low consequence because the magnitude and time of the resulting radiological exposures to the RMEI, or radionuclide releases to the accessible environment, would not be significantly adversely changed by their omission. Other seismic events of greater magnitude, which may occur with probability less than 10^{-5}, are not relevant as per proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]).

Based on the previous discussion, omission of FEP 1.4.02.04.0A (Seismic Event Precedes Human Intrusion) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.4.03.00.0A

FEP NAME:

Unintrusive Site Investigation

FEP DESCRIPTION:

This FEP concerns airborne, geophysical, or other surface-based investigations of a repository site area after its closure.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Unintrusive activities have the potential to affect the repository. Activities that might produce deep excavation in the area of the repository are covered by excluded FEPs 1.4.05.00.0A (Mining and other Underground Activities) and 1.4.02.01.0A (Deliberate Human Intrusion), and in included FEPs 1.4.02.02.0A (Inadvertent Human Intrusion), 1.4.04.00.0A (Drilling activities), and 1.4.04.01.0A (Effects of Drilling Intrusion). Intrusive activities, whether deliberate or not, are considered human intrusion. Human intrusion is defined as (10 CFR 63.302 [DIRS 180319]):

> Human intrusion means breaching any portion of the Yucca Mountain disposal system, within the repository footprint, by any human activity.

This is an important concept in that any human activity that breaches the disposal system is included within the regulatory definition of human intrusion. Any human or human-induced activity (including surface-based site investigations, digs, grading, etc.) that breaches the natural barrier system is, by definition, a human intrusion. However, 10 CFR 63.113(d) [DIRS 180319] and 40 CFR 197.26 [DIRS 175755] stipulate that human intrusion shall be assessed only through the consideration of the human intrusion stylized analysis, which deals with the use of drilling techniques related to water well drilling.

There are a number of possible human activities with the potential to affect the repository that do not physically breach the Yucca Mountain disposal system. These might include surveys, mapping activities, and investigations using electromagnetic waves (sound, infrared, electromagnetic pulse events, lasers). Because the repository is located at least 200 m (656 ft) below the surface (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06), these technologies in their present state do not produce sufficient energy to have a noticeable effect on the repository.

Based on the above discussion, omission of FEP 1.4.03.00.0A (Unintrusive Site Investigation) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with the proposed 10 CFR 63.311 and

63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.4.04.00.0A

FEP NAME:

Drilling Activities (Human Intrusion)

FEP DESCRIPTION:

This FEP addresses any type of drilling activity in the repository environment. These activities may be taken with or without awareness of the presence of the repository and with or without consent of the repository licensee. Drilling activities may be associated with natural resource exploration (water, oil and gas, minerals, geothermal energy), waste disposal (liquid), fluid storage (hydrocarbon, gas), or reopening existing boreholes.

SCREENING DECISION:

Included

TSPA DISPOSITION:

An assessment of human intrusion is required as part of the Yucca Mountain repository license application to demonstrate compliance with the stylized human intrusion scenario based on exploratory drilling for groundwater in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]). The assessment of human intrusion is discussed in included FEP 1.4.02.02.0A (Inadvertent Human Intrusion). Compliance with the human intrusion standard involves evaluation of the dose resulting from a stylized inadvertent human intrusion analysis. Other drilling activities associated with natural resource exploration (oil and gas, minerals, geothermal energy), waste disposal (liquid), fluid storage (hydrocarbon, gas), or reopening existing boreholes are excluded by regulation.

The stylized human intrusion scenario is implemented to demonstrate that the repository design will exhibit a measure of resilience against a typical human intrusion scenario. The scenario is not intended to represent all forms of human intrusion that could affect the repository. The scope of the stylized scenario is set out in 10 CFR 63.322 [DIRS 180319], which requires that the analysis must assume the intrusion is the result of exploratory drilling for groundwater. Specifically, according to 10 CFR 63.322(a) [DIRS 180319], it should be assumed that:

> There is a single human intrusion as a result of exploratory drilling for ground water.

And according to 10 CFR 63.322(c) [DIRS 180319] it should be assumed that:

> The drillers use the common techniques and practices that are currently employed in exploratory drilling for ground water in the region surrounding Yucca Mountain.

In summary, FEP 1.4.04.00.0A (Drilling Activities (Human Intrusion)) is included in the demonstration of compliance with the individual protection standard for human intrusion

(proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), but does not require consideration within the demonstration of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) or within the demonstration of compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). The analysis conducted to demonstrate compliance with the individual protection standard for human intrusion is discussed in detail in included FEP 1.4.02.02.0A (Inadvertent Human Intrusion).

FEP: 1.4.04.01.0A

FEP NAME:

Effects of Drilling Intrusion

FEP DESCRIPTION:

Drilling activities that intrude into the repository may create new release pathways to the biosphere and alter existing pathways. Possible effects of a drilling intrusion include interaction with waste packages, increased saturation in the repository leading to enhanced radionuclide transport to the SZ, changes to groundwater and EBS chemistry, and waste brought to the surface.

SCREENING DECISION:

Included

TSPA DISPOSITION:

An assessment of human intrusion is required as part of the Yucca Mountain repository license application. The effects of drilling intrusion are included in the demonstration of compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), but do not require consideration within the demonstration of compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) or within the demonstration of compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). The analysis conducted to demonstrate compliance with the individual protection standard for human intrusion is discussed in detail in included FEP 1.4.02.02.0A (Inadvertent Human Intrusion). Compliance with the human intrusion standard involves evaluation of the dose resulting from a stylized inadvertent human intrusion scenario.

The stylized human intrusion scenario is implemented to demonstrate that the repository design will exhibit a measure of resilience against a typical human intrusion scenario. The scenario is not intended to represent all forms of human intrusion that could affect the repository. The scope of the stylized scenario is set out in 10 CFR 63.322 [DIRS 180319], which requires that the analysis must assume the intrusion is the result of exploratory drilling for groundwater, as discussed in included FEP 1.4.04.00.0A (Drilling Activities (Human Intrusion)). 10 CFR 63.322 [DIRS 180319] also specifies how the effects of drilling intrusion should be evaluated. In particular, according to 10 CFR 63.322 [DIRS 180319], it should be assumed that:

> (b) The intruders drill a borehole directly through a degraded waste package into the uppermost aquifer underlying the Yucca Mountain repository

and that:

> (d) Careful sealing of the borehole does not occur, instead natural degradation processes gradually modify the borehole;

> (e) No particulate waste material falls into the borehole;
>
> (f) The exposure scenario includes only those radionuclides transported to the saturated zone by water (e.g., water enters the waste package, releases radionuclides, and transports radionuclides by way of the borehole to the saturated zone); and
>
> (g) No releases are included which are caused by unlikely natural processes and events.

As part of the evaluation of the effects of drilling intrusion to demonstrate compliance with the human intrusion standard in proposed 10 CFR 63.321(a) (70 FR 53313 [DIRS 178394]) the NRC specifies that:

> DOE must determine the earliest time after disposal that the waste package would degrade sufficiently that a human intrusion could occur without recognition by the drillers.

As discussed in FEP 1.4.02.02.0A (Inadvertent Human Intrusion), inadvertent human intrusion is not considered to be possible while the drip shield and waste package remain intact. The rationale for this approach is given in *System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478], Section 6.7). Specifically, Section 6.7.2.3.4 of that report (SNL 2008 [DIRS 183478]) states:

> Selection of a bit for drilling involves knowledge of the characteristics of the rock. …there are significant differences between the tensile strengths and other material properties of the geologic units at Yucca Mountain and the materials for the drip shield and waste package. Because the materials used in the drip shield and waste packages have high tensile strengths, yield strengths and increased modulus of elasticity compared to the host rock properties, the tooth of a roller bit [typically used in drilling water wells due to their low cost and wide range of operational flexibility] cannot penetrate enough to cause sufficient strain for chipping to occur. Rather, if contact with the drip shield occurs, the rotation of the bit would result in a tearing or shearing action with associated and recognizable high torque values. Consequently, the ductility of the metals makes them nearly impenetrable by techniques used in drilling rock. Boring in metals typically utilizes a milling technique. The downhole milling tools needed to penetrate the drip shield and waste package are not typically used in groundwater exploration, and use of such tools would be a clear indicator of recognition of penetration of some type of metallic, anthropogenic structure.

Consequently, penetration of the drip shield or waste package without recognition by the driller prior to general corrosion failure of the engineered barriers is not feasible.

General corrosion failure of the drip shields is not expected to occur prior to 230,000 years (SNL 2008 [DIRS 183478], Section 6.7.2). Based on this analysis, unrecognized human intrusion is modeled conservatively to not occur prior to 200,000 years.

In conclusion, the effects of drilling intrusion are included in the TSPA for the stylized human intrusion scenario (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]); and 63.322 [DIRS 180319]). However, the assessment of human intrusion does not form part of the TSPA analyses for individual protection (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) or groundwater protection (10 CFR 63.331 [DIRS 180319]). The human intrusion standard is discussed in detail in included FEP 1.4.02.02.0A (Inadvertent Human Intrusion).

FEP: 1.4.05.00.0A

FEP NAME:

Mining and Other Underground Activities (Human Intrusion)

FEP DESCRIPTION:

Mining and other underground human activities (e.g., tunneling, underground construction, quarrying) could disrupt the disposal system and affect predicted repository performance.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Mining, tunneling, underground construction, and quarrying and any other human activity of this type intersecting the repository footprint is defined as a human intrusion as per 10 CFR 63.302 [DIRS 180319]:

> Human intrusion means breaching any portion of the Yucca Mountain disposal system, within the repository footprint, by any human activity.

This is an important concept in that any human activity that breaches the disposal system is included within the regulatory definition of human intrusion.

10 CFR 63.102(k) [DIRS 180319] states that "it is not appropriate to include consideration of human intrusion into a fully risk-based performance assessment for purposes of evaluating the ability of the geologic repository to achieve the performance objective at § 63.113(b). Hence, human intrusion is addressed in a stylized manner." The performance objectives for this stylized analysis are given in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]). In addition, the regulation specifies that the stylized analysis assume the intrusion is the result of exploration for groundwater. This is emphasized in 10 CFR 63.322 [DIRS 180319]. Therefore, all other types of intrusion of the repository footprint (including mining, tunneling, underground construction, and quarrying) are, by default, excluded due to the regulation.

Mining and other underground human activities outside the repository footprint are excluded on the grounds that they do not occur in the region today and 10 CFR 63.305(b) [DIRS 180319] specifies that "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology." Two related FEPs are included FEP 2.4.10.00.0A (Urban and Industrial Land and Water Use), which states that urban and industrial activities are included in the biosphere model to the extent that they occur today in the Amargosa Valley, and excluded FEP 1.4.08.00.0A (Social and Institutional Development), which excludes social and institutional development (activities, communities, and cities) in the vicinity of Yucca Mountain on the basis of regulation.

In summary FEP 1.4.05.00.0A (Mining and Other Underground Activities (Human Intrusion) is excluded from the performance assessments conducted to demonstrate compliance with the proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of regulation.

FEP: 1.4.06.01.0A

FEP NAME:

Altered Soil or Surface Water Chemistry

FEP DESCRIPTION:

Human activities (e.g., those resulting in industrial pollution or those involving the use of agricultural chemicals) may produce local changes to the soil chemistry and, therefore, to the chemistry of water infiltrating Yucca Mountain. This could result in a contaminant plume of unspecified nature interacting with the repository and possibly with waste packages.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Human activities may affect soil and surface water chemistry because of the use of chemicals in agricultural activities or the effects of pollution from industrial activities. Such effects on soil and surface water chemistry may impact the chemistry of infiltrating water. To the extent that agricultural and industrial activities currently practiced in the Yucca Mountain region (e.g., in Amargosa Valley) may affect repository performance, they are already included in the characterization of the natural barrier system and the biosphere. Future changes in these activities, including extensions of agricultural and industrial activities to Yucca Mountain itself, where they do not occur today, are excluded based on regulatory requirements. Specifically, 10 CFR 63.305(b) [DIRS 180319] states that "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology. In all analyses done to demonstrate compliance with this part, the DOE must assume that all of those factors remain constant as they are at the time of submission of the license application."

Industrial activities at the surface associated with the construction, operation, and closure of a repository at Yucca Mountain also have a potential to affect soil or water chemistry at the site. However, such activities will be designed and conducted in such a way to ensure that there are no significant adverse impacts on repository performance. As discussed in excluded FEPs 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design) and 1.1.12.01.0A (Accidents and Unplanned Events during Construction and Operation), accidents and deviations from plans, designs, and accidents will be evaluated for potential impacts, and significant deviations will be corrected as needed. Impacts of industrial activities associated with the repository itself on soil and water chemistry will be minor and will have no significant adverse impacts on long-term repository performance. Potential effects of subsurface industrial activities associated with repository construction, operation, and closure are addressed separately (e.g., in excluded FEP 1.1.02.00.0A (Chemical Effects of Excavation and Construction in EBS)).

Consistent with the above discussion, omission of FEP 1.4.06.01.0A (Altered Soil or Surface Water Chemistry) will not result in a significant adverse change in the magnitude or time of

radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], based on low consequence.

FEP: 1.4.07.01.0A

FEP NAME:

Water Management Activities

FEP DESCRIPTION:

Water management is accomplished through a combination of dams, reservoirs, canals, pipelines, and collection and storage facilities. Water management activities could have a major influence on the behavior and transport of contaminants in the biosphere.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The living style (called the lifestyle hereafter) and behaviors of the current residents of the Town of Amargosa Valley (called Amargosa Valley hereafter) explicitly include certain water management activities, such as irrigation and fish farming, and implicitly include the use of the associated infrastructure such as pipelines, storage and collection facilities, and ponds, as well as groundwater pumping wells.

10 CFR 63.305(a) [DIRS 180319] requires that the reference biosphere be consistent with present knowledge of the conditions in the region, and 10 CFR 63.305(b) [DIRS 180319] requires that the DOE "not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology." Therefore, future water management activities in Amargosa Valley are assumed to be the same as the current activities.

The physical infrastructure for water management in Amargosa Valley, such as pipelines, storage and collection facilities, ponds and pumping wells, is considered under included FEP 1.4.07.02.0A (Wells). Climate change aspects are discussed in included FEP 1.3.01.00.0A (Climate Change). Fluctuations in the water table, which may affect water management, are discussed in excluded FEP 1.3.07.01.0A (Water Table Decline) and included FEPs 1.3.07.02.0B (Water Table Rise Affects UZ) and 1.3.07.02.0A (Water Table Rise Affects SZ). Water management activities related to irrigation are jointly addressed in this FEP and in included FEP 2.4.09.01.0B (Agricultural Land Use and Irrigation).

The effects of existing water management activities are implicitly included in the current potentiometric surface for Yucca Mountain and the surrounding vicinity. The potentiometric surface is based on the analysis of the current water-level data documented in *Water-Level Data Analysis for the Saturated Zone Site-Scale Flow and Transport Model* (BSC 2004 [DIRS 170009], Section 6.4). Future water management activities are presumed to be those currently in practice. Consequently, *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]) assumes that the saturated zone flow domain is a steady-state system (SNL 2008 [DIRS 183750], Section 6.3.1[a]), thus implicitly accounting for the impact of future water management activities on the predicted flow and transport paths. This is consistent with

the statement above that future water management activities are assumed to be the same as the current activities. Water usage in Amargosa Valley varies seasonally, with the largest groundwater pumping occurring in the summer when the water needs of crops is largest. These seasonal fluctuations do not cause groundwater levels to fluctuate in the vicinity of the Yucca Mountain repository (BSC 2004 [DIRS 170009], Sections 6.2.1 and 6.3, Table 6-3). The future water use of the RMEI is assumed to be consistent with the current practices in Amargosa Valley. As the present groundwater levels account for the long term average impact of irrigation pumpage, and as seasonal irrigation pumpage does not impact water levels elsewhere in the groundwater model area, the impact of future water management activities is included in the simulation of the groundwater system.

Within the biosphere model, this FEP is included in the air, plant, and fish submodels of the groundwater exposure scenario through incorporation of parameters dealing with the fraction of overhead irrigation (BSC 2004 [DIRS 169673], Section 6.3) and the irrigation intensity (BSC 2004 [DIRS 169673], Section 6.6); of parameters related to the evaporative cooler use, such as the airflow rate, water use rate, and water transfer fraction (BSC 2004 [DIRS 169672], Section 6.5.2); and of the water concentration-modifying factor (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.5), which is used in the fish submodel. Parameter distributions were developed based in part on the types of water distribution and storage systems currently in use in Amargosa Valley for crop irrigation (BSC 2004 [DIRS 169673], Sections 6.3 and 6.6), evaporative cooler use, and fish farming (BSC 2004 [DIRS 169672], Section 6.4).

Groundwater exposure scenario BDCFs are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3).

All aspects of the water management activities FEP described above are included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). For the performance assessment that demonstrates compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]), only those components of this FEP that address the geosphere transport are included.

FEP: 1.4.07.02.0A

FEP NAME:

Wells

FEP DESCRIPTION:

One or more wells drilled for human use (e.g., drinking water, bathing) or agricultural use (e.g., irrigation, animal watering) may intersect the contaminant plume.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Two postclosure quantitative requirements, the individual protection standard given in proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) and the individual protection standard for human intrusion given in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), provide a limit the dose that may be received by the RMEI. Further guidance given in 10 CFR 63.312(c) [DIRS 180319] specifies that the RMEI uses well water with an average concentration of radionuclides based on an annual water demand of 3,000 acre-feet (3.7×10^6 m^3), which includes use of wells for both domestic and agricultural purposes. Therefore, the use of well water for domestic and agricultural purposes is included in the performance assessments for these two requirements. This FEP is also considered in the calculation of conversion factors for evaluating compliance with the dose portion of the groundwater protection standards of 10 CFR 63.331 [DIRS 180319] (SNL 2007 [DIRS 177399], Section 6.15.1).

Groundwater wells are the initial source of radionuclides entering the reference biosphere for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Tables 6.2-1 and 6.7-1 and Section 6.3.1). Radionuclide concentration in groundwater is the corresponding parameter in the mathematical model used in the soil, air, plant, animal, fish, ^{14}C, and ingestion sub-models of the biosphere model (SNL 2007 [DIRS 177399], Sections 6.4.1 to 6.4.6, and 6.4.9).

The effects of wells on the dose to the RMEI are included by assuming that all of the radionuclide mass that reaches the accessible environment is contained in the annual water demand of 3,000 acre-feet, from which the RMEI obtains all required water (SNL 2008 [DIRS 183750], Section 6.3.3). As wells are the most common means of extracting groundwater, the approach used in *Saturated Zone Flow and Transport Abstraction Model* (SNL 2008 [DIRS 183750]) simulates the effect of one or more wells, located such that the wells completely intercept the radionuclide plume, but does not speculate about details of the wells such as discharge rates, diameter, screened intervals, etc. This approach accounts for wells used for domestic or agricultural purposes that may intersect the contaminant plume.

The effect of pumping wells on the groundwater flow system has been incorporated in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]) via the configuration of the water table (BSC 2004 [DIRS 170009]) used as an upper boundary for the flow model and the amount of

flow crossing the model boundaries as provided by the *Death Valley Regional Groundwater Flow System Model* (Belcher 2005 [DIRS 173179]). The regional model specifically incorporated the irrigation wells located south of Yucca Mountain in the community of Amargosa Valley. The water table configuration used to define the top of the SZ flow model and the wells used to provide target water levels for calibration reflect average water levels near the community of Amargosa Valley, which includes the effect of pumping. Thus, *Saturated Zone Flow and Transport Abstraction Model* (SNL 2008 [DIRS 183750]) includes the effect of wells used to withdraw groundwater.

The assessment of annual doses is carried out in the TSPA model using the biosphere dose conversion factors (BDCFs) generated in the biosphere model as TSPA input parameters (SNL 2007 [DIRS 177399], Section 6.11 and 6.12). The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. For the TSPA scenario classes involving groundwater withdrawn from a well as a source of radionuclides, the annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. Such an approach is possible because quantities calculated in the groundwater exposure scenario sub-models of the biosphere model, including radionuclide concentrations in the environmental media and the annual dose from various exposure pathways, are proportional to the radionuclide concentration in the groundwater (SNL 2007 [DIRS 177399], Section 6.4.10.2). Thus, for this exposure scenario, the biosphere model contribution to the dose assessment (i.e., BDCFs) can be separated from the source (i.e., radionuclide concentration in the groundwater). The BDCF for a radionuclide is numerically equal to the annual dose to the RMEI for a unit activity concentration of the radionuclide in the water (SNL 2007 [DIRS 177399], Section 6.4.10.2). To support the assessment of doses in TSPA for the scenario classes involving radionuclide release to the groundwater, the present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3).

Climate change, including treatment of long-term infiltration rates, is discussed in included FEP 1.3.01.00.0A (Climate Change). Fluctuations in the water table, which may affect well drilling, are discussed in excluded FEP 1.3.07.01.0A (Water Table Decline) and included FEPs 1.3.07.02.0B (Water Table Rise Affects UZ) and 1.3.07.02.0A (Water Table Rise Affects SZ).

All aspects of this FEP described above are included in the performance assessments that demonstrate compliance with the individual protection standards in proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]) and with the groundwater protection standards in 10 CFR 63.331 [DIRS 180319].

FEP: 1.4.07.03.0A

FEP NAME:

Recycling of Accumulated Radionuclides from Soils to Groundwater

FEP DESCRIPTION:

Radionuclides that have accumulated in soils (e.g., from deposition of contaminated irrigation water) may leach out of the soil and be recycled back into the groundwater as a result of recharge (either from natural or agriculturally induced infiltration). The recycled radionuclides may lead to enhanced radionuclide exposure at the receptor.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The estimated increase in the mean dose to the RMEI as a consequence of radionuclide recycling, averaged over the period of simulation, is calculated to be less than 11%, which is not significant compared with the range of uncertainty simulated by the TSPA model. Recycling of radionuclides accumulated in soils encompasses two pathways, irrigation recycling and capture of deep percolation from septic systems. The irrigation recycling pathway includes the leaching of radionuclides from agricultural soil irrigated with contaminated water, transport of the radionuclides by deep percolation to the water table, and recapture of the radionuclides by the water supply well. The potential recapture of deep percolation from septic systems is also included as a pathway to recycle radionuclides to the water where they are recaptured by the water supply well. The hypothetical community in which the RMEI resides is located in the accessible environment above the highest concentration of radionuclides in the plume of contamination, which is approximately 18 km from the repository. Such a community is assumed to practice irrigated agriculture, consistent with the regulatory construct that a rural community could be located at such a location; that the members of this community could grow some food using well water; and that other gardening, farming, and raising of domestic animals could occur (66 FR 32093 [DIRS 155216], p. 32093). Radionuclide recycling is a phenomenon that could reasonably result from irrigated farming, as inferred from observations of deep percolation beneath irrigated fields in Amargosa Valley (Stonestrom et al. 2003 [DIRS 165862]).

To consider the consequence of radionuclide recycling, an analysis was conducted based on a stylized agricultural and residential water use scenario for calculating the potential impact on dose to the RMEI as a result of radionuclide recycling at the location of the hypothetical community of which the RMEI is part. The analysis of the radionuclide recycling process consists of a quantitative process model that considers radionuclide recycling as a process that is coupled to the stylized biosphere model as applied in TSPA. The recycling model is developed in accordance with current and proposed regulatory requirements governing the RMEI (10 CFR 63.312 [DIRS 180319]) and the reference biosphere (10 CFR 63.305 [DIRS 180319] and 10 CFR 63.305c (70 FR 53313 [DIRS 178394])). The output of the recycling model, when coupled with the biosphere model in the TSPA, is the mean annual dose to the RMEI.

Recycling Process Model

The documentation of the recycling model, presented in *Irrigation Recycling Model* (SNL 2007 [DIRS 182130]), describes the conceptual model that was developed as its basis, model parameters (many of which are treated as probabilistic), the modeling assumptions that were made in the process of constructing the conceptual and mathematical models, and the numerical implementation with results.

The recycling model evaluates the potential impact of recycling of radionuclides contained within irrigation and residential water on the concentration of radionuclides in the groundwater at the location of the RMEI, based upon the current water use practices of individuals residing in the town of Amargosa Valley. The biosphere-based recycling process model was coupled with the biosphere model in the TSPA to conduct a sensitivity analysis of the impact of radionuclide recycling on the dose to the RMEI (SNL 2007 [DIRS 182130], Section 6.7).

Model Description—The conceptual recycling model assumes the existence of a single hypothetical water supply well located approximately 18 km from the repository at the location of the RMEI, which is at the point above of the highest concentration of radionuclides in the plume of contamination (10 CFR 63.312(a) [DIRS 180319]). The well is assumed to continuously withdraw groundwater at a constant rate equal to the annual rate of 3,000 acre-ft per year, consistent with the definition of the RMEI (10 CFR 63.312(c) [DIRS 180319]) and all of the radionuclide mass crossing the location of the RMEI is assumed to be captured in the 3,000 acre-ft per year of water withdrawn by the well. Of the water that is withdrawn by the well, at least 85% is used for irrigation and at least 4% is used for residential purposes (66 FR 32074 [DIRS 155216], p. 32112); the remaining 11% of withdrawn water is assumed to be distributed between irrigation and residential uses.

The portion of the well water that is applied to irrigated fields is simulated to move downward in the unsaturated zone using a piston-flow approach. This is a simplified representation that does not incorporate the relationships between the pressure, saturation, and hydraulic conductivity under unsaturated conditions. The piston flow rate is equal to the percolation rate in the unsaturated zone. These assumptions are reasonable because they lead to realistic transport velocities through the unsaturated zone (SNL 2007 [DIRS 182130], Section 7.2). The percolation rate in the unsaturated zone beneath the irrigated fields is estimated in the biosphere model (BSC 2004 [DIRS 169673], Table 6.9-1). This percolation rate is the result of all the processes occurring at the soil–atmosphere interface, such as crop evapo-transpiration, soil evaporation, irrigation, precipitation, and other processes. Because the percolation rate is available, the recycling model uses this rate directly and does not simulate the soil–atmosphere interface to estimate percolation rate. Advection, sorption, dispersion, and colloid transport processes are simulated in the unsaturated zone.

The residential portion of the withdrawn water is assumed to be recycled via septic leach fields. Transport from these leach fields to the water table is conservatively assumed to be instantaneous to simplify the analysis. This is reasonable because residential water volumes are much smaller than irrigation water volumes (as noted above, at least 85% of the withdrawn water is used for irrigated agriculture).

The residential and irrigation water use locations do not necessarily coincide with the location of the withdrawal well because residences and fields do not co-exist at the same location, and because the 3,000 acre-ft per year of groundwater withdrawn is sufficient to irrigate approximately four fields (SNL 2007 [DIRS 182130], Section 6.5.3.2.5), all of which occupy different locations within the farming community. The water that is withdrawn is assumed to be applied to irrigated fields and supplied to residences located at various distances from the pumping well. Probability distributions representing the distance from a pumping well to irrigated fields and to residences were developed from aerial photographs of the town of Amargosa Valley (SNL 2007 [DIRS 182130], Figures 6.5-3 and 6.5-5). The analysis implicitly assumes that contaminated well water is distributed to distant locations for use. The fields and residences are randomly located around the pumping well (i.e., no directional preference) and the distances are determined by sampling the distances from the probability distributions of distance.

Radionuclides in water that is applied to an irrigated field or used at a residence is recycled back to the pumping well if the field or residence lies above the capture zone of the well. The edges of the capture zone are defined by analytic solutions (SNL 2007 [DIRS 182130], Sections 6.5.3.3.1 and 6.5.3.3.2) based on the aquifer thickness, a uniform ambient specific discharge, and a parameter that represents the difference in the saturated thickness of the aquifer upgradient and downgradient of the well. These parameters are uncertain and are described by probability distributions. The simulations of the location of irrigated fields and the size of the capture zone are used to generate two parameters, the well recapture fraction cumulative distribution and the residential fraction cumulative distribution. These two parameters identify the fraction of irrigation or residential water that is recycled back to the pumping well (SNL 2007 [DIRS 182130], Sections 6.5.3.4.3 and 6.5.3.5.1).

To simplify the analyses, radionuclides that reach the water table and are within the well capture zone are returned to the well volume without accounting for transport within the saturated zone. This is a bounding assumption because the radionuclides from the distant irrigation locations will have to travel through the saturated zone to reach the pumping well.

To calculate the dose, the concentrations of radionuclides in the well water are supplied to the biosphere component (SNL 2007 [DIRS 177399]) in the TSPA model to determine the dose to the RMEI.

Three mechanisms of removing radionuclides from the recycling process were considered, leading to open-system behavior and placing limits on the long-term increase in concentrations within the aquifer. Some portion of the radionuclides will be permanently removed from the recycling process because:

(1) The fraction of the irrigation water that is used on fields located outside the capture zone of the water supply well will not be pumped back to the land surface. This will affect sorbing and nonsorbing radionuclides.

(2) The fraction of the residential water used outdoors and the fraction of residential water used indoors outside the well capture zone will not be pumped back to the land surface. This will affect sorbing and nonsorbing radionuclides.

(3) Erosion of soil from irrigated fields will transport the radionuclide mass sorbed to the soil out of the recycling system. This process will mostly affect sorbing radionuclides.

Parameters for the Recycling Model

The radionuclide recycling analysis utilizes parameters from a number of project sources. These include the alfalfa irrigation and overwatering rates (BSC 2004 [DIRS 169673], Tables 6.9-1 and 6.5-2), supporting parameters for the biosphere model analysis (SNL 2007 [DIRS 177399]), numerous flow and transport parameters related to transport in alluvium were obtained from the saturated zone flow and transport abstraction model (SNL 2008 [DIRS 183750]) and its output DTNs, and site specific parameters obtained from measurements in the vicinity of the RMEI location were used in the capture zone analysis (SNL 2007 [DIRS 182130], Section 6.5.3.3.3). For example, the specific discharge estimates were obtained from testing at wells NC-EWDP-19D and 22S. The aquifer thickness is based on observed stratigraphy at wells NC-EWDP-10SA, -23P, -2DB, -19D, and -22S (SNL 2007 [DIRS 182130], Section 6.5.3.3.3.1). The difference in saturated thickness (part of the capture zone analysis) comes from observed water levels and stratigraphy at wells NC-EWDP-19D and -22S.

The depth to the water table at the location of the RMEI, which also represents the length of the unsaturated zone flow path, was determined for the future glacial-transition climate state using predicted water table rise beneath the repository of 120 m and the simulated location and elevation of surface discharge downgradient of the RMEI (SNL 2007 [DIRS 182130], Section 6.5.3.7).

The parameters noted above, and others, are treated as uncertain and described by probability distributions (SNL 2007 [DIRS 182130], Section 6.5).

The radionuclides from the irrigation and residential pathways recaptured by the regulatory well are used in calculating groundwater concentrations at the RMEI location. These concentrations are passed to the biosphere component model in the TSPA sensitivity analysis using both the seismic ground motion and igneous intrusion scenarios to estimate the impacts of the increase in radionuclide concentrations in groundwater on mean annual doses (SNL 2007 [DIRS 182130], Sections 6.6 and 6.7). Transient effects in the calculations due to the radionuclide recycling process do not impact the results after a simulation time of about 5,000 years (SNL 2007 [DIRS 182130], Section 6.6). At early time, radionuclides recycled along the residential pathway arrive at the withdrawal well before radionuclides from the irrigation pathway. As the residential pathway accounts for less than 15% of the total water, the impact of radionuclide recycling at early time is very small. As time passes, radionuclides from the irrigation pathway arrive and the full effect of radionuclide recycling becomes apparent (SNL 2007 [DIRS 182130], Figures 6.6-4 to 6.6-6). The impact of radionuclide recycling is based on the later time results to incorporate both the residential and irrigation pathways.

The assumption of immediate transport to the well in the saturated zone is expected to have a similar impact. The transport processes in the saturated zone would be expected to delay the onset of recycling, but not significantly alter the long-term increase in concentrations.

Consequence—The simulations result in approximately an 11% average increase in mean dose for both the seismic ground motion and igneous intrusion scenarios over the 10,000-year period (SNL 2008 [DIRS 182130], Section 6.7, pp. 6-60 and 6-62).

Based on the previous discussion, omission of FEP 1.4.07.03.0A (Recycling of Accumulated Radionuclides from Soils to Groundwater) will not significantly change the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment when considered with respect to the uncertainty already incorporated in the TSPA model. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 ([DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.4.08.00.0A

FEP NAME:

Social and Institutional Developments

FEP DESCRIPTION:

Social and institutional developments could affect the long-term performance of the repository. The most likely is social and institutional development resulting in new activities, communities, or cities in the vicinity of Yucca Mountain.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

10 CFR 63.305(b) [DIRS 180319] states, "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology. In all analyses done to demonstrate compliance with this part, the DOE must assume that all of those factors remain constant as they are at the time of submission of the license application." Therefore, speculation concerning potential changes in society, including social and institutional development, are excluded on the basis of regulatory requirements in 10 CFR 63.305(b) [DIRS 180319].

INPUTS:

FEP: 1.4.09.00.0A

FEP NAME:

Technological Developments

FEP DESCRIPTION:

Technological developments may affect the long-term performance of the repository. These include changes in the ability of humans to intrude the site, and changes that might affect contaminant exposure and its health implications.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

10 CFR 63.305(b) [DIRS 180319] specifically states, "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology. In all analyses done to demonstrate compliance with this part, the DOE must assume that all of those factors remain constant as they are at the time of submission of the license application." Therefore, speculation concerning technological development is excluded on the basis of the regulatory requirements in 10 CFR 63.305(b) [DIRS 180319].

FEP: 1.4.11.00.0A

FEP NAME:

Explosions and Crashes (Human Activities)

FEP DESCRIPTION:

Explosions or crashes resulting from future human activities may affect the long-term performance of the repository. Explosions may result from nuclear war, underground nuclear testing, or resource exploitation.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Explosions or crashes that result from human activities are considered a form of human intrusion. Per 10 CFR 63.102(l) [DIRS 180319], human-intrusion related events are subject to specific requirements for evaluation of human intrusion, specified in proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) and in 10 CFR 63.322 [DIRS 180319]. These quantitative postclosure requirements specify that the consequences of human intrusion are to be evaluated via a stylized analysis. This stylized analysis includes the effect of a borehole that penetrates a single waste package, and does not include the effects of explosions and crashes. Nuclear or conventional wars and underground nuclear testing are excluded by 10 CFR 63.305(b) [DIRS 180319], which states, "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases of human knowledge or technology. In all analyses done to demonstrate compliance with this part, DOE must assume that all of those factors remain constant as they are at the time of submission of the license application." For these reasons, this FEP is excluded on the basis of regulation.

FEP: 1.5.01.01.0A

FEP NAME:

Meteorite Impact

FEP DESCRIPTION:

Meteorite impact close to the repository site might disturb or remove rock to such an extent that radionuclide transport to the surface is accelerated. Possible effects include alteration of flow patterns (by re-activation or formation of faults and fractures), changes in rock stress, cratering, and exhumation of waste.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Possible effects of a large meteorite impact near the repository include penetration of the repository and exhumation of waste. A meteorite associated with an impact crater not deep enough to exhume waste could reactivate or form faults and fractures, change the rock stress, and the associated shock wave could possibly cause damage to drifts and waste packages, or initiate an earthquake. Of particular interest for smaller meteorite impacts is the possibility of increased infiltration to the repository through damage to the geologic layers that limit infiltration. Analysis of a meteorite impact depends on the probability of occurrence of variously sized impact craters, the area and relative dimensions of the repository footprint, and the depth of the repository below the ground surface. The probability of an impact crater of a given size being formed directly above or adjacent to the repository depends on the total flux of meteors that penetrate the earth's atmosphere and impact the surface (hence becoming meteorites) and the area of the repository footprint (the target area). Two crater sizes of interest in the analysis are: (1) craters that are deep enough to exhume waste from the repository, and (2) craters that are deep enough to fracture or damage the Paintbrush nonwelded (PTn) tuff layer above the repository. Potential fracturing or damage to the overlying Tiva Canyon units is not of concern because of the damping effect of the PTn (SNL 2007 [DIRS 184614], Section 6.9[a]). The size of these craters is determined by the depth from ground surface to the top of the repository, as well as the depth to the Paintbrush nonwelded tuff. Detailed probability calculations and a discussion of meteorite impact probability and cratering information that provide the technical basis for exclusion are given in Appendix D.

The overburden thickness from the repository emplacement area to the topographic surface is specified to be a minimum of 200 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06). Also of interest are the minimum depth to and thickness of the PTn. The PTn primarily consists of nonwelded to partially welded tuffs and extends from the base of the densely to moderately welded Tiva Canyon welded tuff (TCw) to the top of the TSw, which is densely welded (SNL 2007 [DIRS 184614], Section 6.2.2). With its high porosity and low fracture intensity, the PTn rock matrix has a large capacity for storing groundwater and effectively damps percolation transients at the base of the TCw unit. Water imbibing into the

PTn rock matrix, from rapid fracture flow in the TCw above, results in a more uniform distribution of groundwater flux at the base of the PTn such that unsaturated zone groundwater flow below the PTn is essentially steady (SNL 2007 [DIRS 184614], Section 6.9[a]). Geologic data indicate that the PTn ranges in thickness from greater than 125_m beneath northern Yucca Mountain to about 20 m in the south (Figure D-3), with breaks in area coverage along the Solitario Canyon, Iron Ridge, and Dune Wash fault systems. Within the repository area, the thickness of the PTn unit ranges from approximately 30 to 60 m (Appendix D). The depth to the PTn unit also varies from 0 where it outcrops in gullies in the northernmost portion of the repository to more than 120 m in the southern portion of the repository (Figure D-2).

Groundwater movement through specific rock units depends on the hydrogeologic properties of the rock units (SNL 2007 [DIRS 184614], Sections 6.1.2 and 6.2.2). Water that infiltrates into the Tiva Canyon welded unit can be transported rapidly through existing fractures as far as the underlying Paintbrush nonwelded unit, which limits flow transients, making flow through the unsaturated zone below this unit to the repository steady-state in character due to high porosity and low fracture density of this unit. The possibility of increased fracturing in the Paintbrush nonwelded unit due to a meteorite impact has the potential to increase transient flow through this unit and through the repository.

An evaluation (Appendix D) indicates that only small cratering effects needed to be considered, due to the low probability of large crater diameters being associated with complex cratering (Grieve et al. 1995 [DIRS 135260], p. 194; Wuschke et al. 1995 [DIRS 129326], p. 3). The information was translated from the the initial meteor radius to a resulting crater radius and other effects to produce a distribution of crater diameters based on meteorite flux to the earth. For impact probability calculation, a rectangular target area was designed that enclosed the repository footprint and was extended one-half crater diameter on each side to include near-miss impacts (Appendix D).

Appendix D provides cratering probability curves (based on two sources) in Figure D-5 and Figure D-6 for the frequency of cratering for the target area. The maximum crater diameter that corresponds to the 10^{-8} annualized exceedance probability over the target area is less than 60 m (Appendix D).

For a crater diameter of 60 m, the exhumation depth is 6 to 20 m, with a 0.1 to 0.33 ratio of exhumation depth to crater diameter (Appendix D). Because the overburden is at least 200 m, this crater size is insufficient to cause waste exhumation (Appendix D). The exhumation of waste from the repository can therefore be excluded based on low probability because the probability of a cratering event sufficiently large to cause waste exhumation is less than 10^{-8} per year.

In addition, given a fracturing depth to crater diameter ratio of 0.33 to 0.76, the maximum depth of induced fractures from a 60-m diameter cratering event (i.e., an estimate of the largest crater likely at the threshold probability of 10^{-8} events per year) would be no greater than 45 m based on a fracture depth to crater diameter ratio of 0.76 (Appendix D). Depths of less than 45 m would not affect infiltration into the repository because they are too shallow to reach the top of the PTn over most of the repository area. Figure D-1 shows that with the exception of the northwestern- and northern-most tip of the repository where the PTn outcrops, the distance to the

top of the PTn is at least 60 m. In these northern areas with a lesser distance between the ground surface and the PTn, the PTn itself is more than 90-m thick (Appendix D). Therefore, the PTn unit would maintain its original thickness even after the impact of a maximum-penetration cratering event that corresponds to the 10^{-8} annualized exceedance probability, and will continue to meet the 10-m thickness requirement set forth in the selection of the repository layout (BSC 2008 [DIRS 183627], Table 1, Parameter Number 01-21) that ensures that the unit will remain effective in damping the episodic infiltration transients (see excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). The fracturing of the PTn can, therefore, be excluded based on low probability because the probability of a cratering event sufficiently large to cause fracturing the PTn to less than 10-m thick is less than 10^{-8} per year.

Smaller crater diameters occur more frequently, but these are of insufficient size to result in direct exhumation or fracturing to the depth of the repository and are excluded through *low consequence*. Larger crater diameters occur less frequently and are less probable than the exceedance probability, and are therefore excluded from the TSPA as low probability events (Appendix D). Effects on infiltration due to changes in ecological factors due to small meteor craters or the effects of a near-surface explosion associated with a meteorite are also excluded based on low consequence because such events are expected to have only transient effects or to have no means of affecting the subsurface postclosure repository (see also excluded FEPs 1.4.03.00.0A (Unintrusive Site Investigation) and 1.5.01.02.0A (Extraterrestrial Events)). A modern example of a site in which the ecology has recovered is the Tungunska site in Siberia.

Meteors that result in crater diameters of 60 m (corresponding to the threshold annual probability of 10^{-8}) could trigger earthquakes with Richter magnitudes ranging from magnitude 5 to slightly less than magnitude 7 (Hills and Goda 1993 [DIRS 135281], Figure 18). Existing seismic analyses cover this range of magnitude (CRWMS M&O 1998 [DIRS 103731], Figures 7-15 and 7-16). Therefore, an earthquake caused by meteorite impact is excluded based on low consequence because it would not provide a significant contribution to the overall earthquake hazard. Earthquake hazards are already included and probabilistically weighted in the TSPA. The effects of changes in rock stress, such as those caused by seismic activity, are addressed in multiple FEPs such as excluded FEPs 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock), 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults); and 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures).

Because percolation is not significantly affected and no fracturing occurs down to the repository depth, with no associated waste exhumation, there is no mechanism for a meteorite impact at the threshold annual probability or greater to affect groundwater flux through the repository horizon. Therefore, the dose and release of radionuclides are not significantly changed.

Based on the preceding discussion, FEP 1.5.01.01.0A (Meteorite Impact) is excluded from the performance assessment conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability for exhumation and fracturing to repository depth and to the PTn unit within the repository target area.

FEP: 1.5.01.02.0A

FEP NAME:

Extraterrestrial Events

FEP DESCRIPTION:

Extraterrestrial events (e.g., supernova, solar flare, gamma-ray burster, and events associated with alien life forms) may affect long-term performance of the disposal system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Potential mechanisms linking extraterrestrial events to changes in the behavior of engineered and natural systems of an underground repository are not addressed in the scientific literature. Evaluating the effect of such events on the postclosure repository performance requires speculation and conceptualization of possible linkages between the event and repository performance.

High-energy radiation that enters the Earth's atmosphere from outer space is known as cosmic rays. Cosmic radiation of solar and galactic origin accounts for about 15% of the average natural background radiation dose (United Nations 1988 [DIRS 159566], p. 95) and is a part of the natural environment.

Proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]) address the protection of individuals from future radionuclide releases from the repository by placing limits on the annual dose from radiation that may be received by the RMEI. Radiation doses that do not originate from repository releases are not included in these standards. Therefore, estimating the dose that the RMEI would receive directly from the radiations emitted by extraterrestrial events is not required. The following discussion concentrates on the potential effects of extraterrestrial events only to the extent that they may affect long-term performance of the disposal system.

The extraterrestrial events that are the subject of this FEP include the powerful but infrequent events, such as supernovae and gamma ray bursts that occur randomly in the Milky Way galaxy and beyond, and have a potential of producing high radiation levels on Earth. Supernovae and gamma ray bursts are the most energetic known events in the universe. Supernovae release between 10^{43} to 10^{45} J of energy (most of which occurs as neutrino energy and about 10^{42} J as gamma radiation), while gamma ray bursts release the isotropic equivalent of about 10^{45} to 10^{47} J of gamma energy (Karam 2002 [DIRS 167872], pp. 491 to 492). Solar flares, another category of events included in this FEP, are coronal mass ejections from the sun, with the average energy release of about 10^{23} to 10^{24} J (Karam 2003 [DIRS 184906], p. 323).

Gamma ray bursts appear to occur about once every 10^{6} to 10^{7} years in galaxies similar to the Milky Way with periods of maximum emission lasting on the order of minutes (Karam 2002

[DIRS 167872], p. 492). Therefore, all the gamma ray bursts that are routinely registered by orbiting spacecraft originate outside our galaxy. The overall rate of supernovae is much higher, with one to two events occurring per century in the Milky Way galaxy and the duration of these events is much longer than the gamma ray bursts (Karam 2002 [DIRS 167872], p. 492).

Because radiation emitted by any object in interstellar space must first travel a considerable distance to reach the Earth, the energy fluence received at Earth is substantially reduced, primarily because of its decrease with the inverse square of the distance (Karam 2002 [DIRS 167872], Table 1). The attenuation by the interstellar medium is insignificant (Karam 2002 [DIRS 167872], p. 492). The energy fluence from extraterrestrial events is further reduced by Earth's atmosphere. The energy deposited in rocks and other materials at the repository level from the extraterrestrial events would be negligible because of the additional attenuation (shielding) of the external radiation by the rocks above the repository. The overburden thickness from the emplacement area to the topographic surface at Yucca Mountain is at least 200 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06), whereas 20 mm of rock thickness provides at least 7 orders of magnitude reduction in the photon energy absorbed by the rocks (i.e., the absorbed dose) (Karam 2002 [DIRS 167872], Table 2). The energy emitted in the form of neutrinos that is absorbed by Earth is insignificant.

In summary, extraterrestrial events would have a negligible effect on the performance of the repository from the direct energy deposition at the repository level. However, the energy released from nearby supernovae has a potential for causing climatic or other environmental changes that could indirectly affect the repository performance (Brakenridge 1981 [DIRS 167873], p. 81), as described below.

Studies of the potential effects of late Quaternary-Age supernovae on the terrestrial paleoenvironment have identified over 120 radio-emitting galactic supernovae remnants that occurred over the past 15,000 years, suggesting a rate of occurrence of approximately one such event per 100 years (Brakenridge 1981 [DIRS 167873], pp. 81 to 83). The largest inferred energy fluence received at Earth from these events was from the Vela supernova, which was calculated to have a peak energy fluence above Earth's atmosphere of about 40 J/m^2 (Brakenridge 1981 [DIRS 167873], Figure 1). It was postulated that the events of such magnitude have the potential to cause ozone depletion in the atmosphere for between two and six years, global cooling, and an increase in transfers of stratospheric nitrogen into tropospheric and fixed nitrogen on Earth's surface (Brakenridge 1981 [DIRS 167873], p. 85). Observable consequences of these effects include the existence of organic-rich zones in sediments (possibly caused by the influx of biologically available nitrogen), possible short-term global cooling caused by increased absorption of visible light in the stratosphere by NO_2 (Brakenridge 1981 [DIRS 167873], pp. 85 to 86), and possible increased ultraviolet-light penetration due to ozone layer depletion (Brakenridge 1981 [DIRS 167873], pp. 86 and 90 to 91). Others researchers observed nitrogen enrichment and ozone depletion (Ruderman 1974 [DIRS 167875], p. 1,079) as well as climate changes that occurred at the time of the Vela supernova (Arnold 2003 [DIRS 167638], p. 127; Novotna and Vitek 1991 [DIRS 167634], pp. 34 to 35). Alternative hypotheses exist that could explain the occurrence of the phenomena the Brackenridge attributes to that supernova (Brakenridge 1981 [DIRS 167873], p. 90); however, for the purposes of this evaluation it is conservative to assume that a supernova comparable to the Vela event could effect global climate.

The Vela supernova occurred 8,400 to 11,300 years ago (Brakenridge 1981 [DIRS 167873], p. 85), during a glacial transition (intermediate) climate (Sharpe 2003 [DIRS 161591], Table 6-5), and may have contributed to atmospheric cooling with an estimated range of 0.4 to 3 K (Brakenridge 1981 [DIRS 167873], p. 85). The postulated range of temperature decrease caused by the ionizing radiation from the supernova is comparable to the range of mean annual temperatures for the glacial transition climate, as represented by the future climate analogue locations (Sharpe 2003 [DIRS 161591], Table 6-3) and would not cause the climate transition to a different climate state. Other postulated changes such as ozone-layer depletion would be of lesser impact than small climate change itself. Therefore, the effect of such supernovae on the repository performance would not be significant.

Solar-related effects and their correlation with changes in natural systems on Earth are summarized in a conceptual statement by Lean (1997 [DIRS 167639], p. 61): "Numerous associations are evident between solar variability and terrestrial parameters that range from the Earth's surface to hundreds of kilometers above it, on the time scales from days to centuries." Lean (1997 [DIRS 167639], p. 61) points out that decadal cycles in sun activity are evident in temperatures at Earth surface and through the atmosphere, and also indicates that there is an apparent correlation between surface temperature and overall solar activity, but it is unclear whether variable solar radiation is responsible. Least certain is the extent to which changes in visible and infrared radiation, on the order of several orders of magnitude, modify global surface temperature and climate. Lean also suggests that there is a current inability to adequately quantify all climate and ozone controlling mechanisms, which adds ambiguities to assessments of global change (Lean 1997 [DIRS 167639], pp. 62 to 63).

Some of the examples of extraterrestrial events listed above (for example, supernovae, solar flares, gamma-ray bursts) are credible and could result in an influx of solar radiation, space radiation, or cosmic rays into the magnetosphere. Collectively, this can be referred to as "space weather." Maynard (1995 [DIRS 160888]), in discussing the uses of such "space weather" prediction, lists several types of operations that could be affected. They include spacecraft operations, satellite operations, GPS-locating operations (which are satellite based), space object tracking, over-the-horizon radar operations, high-frequency communications, telecommunications such as transatlantic fiber optic communications, geomagnetically induced currents in power transmission lines and transformers, applied direct currents for pipeline corrosion mitigation, and possible impacts on semiconductor manufacturing (likely related to power line fluctuations). This list of potentially affected systems is corroborated by Lean (1997 [DIRS 167639], pp. 57 to 61) and Cole (2003 [DIRS 167641], pp. 299 to 301). The potential effects of extraterrestrial events on these operations are not expected to affect postclosure performance.

This FEP definition also includes the potential effects of alien life forms. Aside from the hypothetical potential for microbial influx via meteorites, the presence of alien life forms has not been verified or documented in the scientific literature. The potential for effects from alien life forms (other than microbial activity) is, therefore, judged to be of low probability (not credible) based on the absence of verification of any such life forms in the scientific literature. The extraterrestrial transfer of microbes into the repository through a meteorite strike could be postulated. Meteorite strikes that are large enough to penetrate the repository are low-probability events based on excluded FEP 1.5.01.01.0A (Meteorite Impact). A few scientific papers have

postulated that microorganisms could have been transported to Earth within small meteorites (McKay 1996 [DIRS 184212]; Thomas-Keptra et al. 1998 [DIRS 184214]; Steele et al. 2000 [DIRS 184215]). These claims are, at present, controversial, but even if true, it is not credible that such microorganisms could escape their meteoric shell, be transported to the repository, and affect the repository performance in a significant manner. Based on this discussion, potential effects from alien life forms are of low probability to the long-term performance of the repository in the postclosure period.

In summary, omission of FEP 1.5.01.02.0A (Extraterrestrial Events) will have no significant adverse impact on long-term performance of the repository, and therefore, no significant impact to radiological exposure to the RMEI and radionuclide release to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319]), on the basis of low consequence.

FEP: 1.5.02.00.0A

FEP NAME:

Species Evolution

FEP DESCRIPTION:

Humans and other species living at or near the repository site may evolve in the future and their new behavior patterns and physiological characteristics may affect their likelihood contaminant exposure and its consequent health implications.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

10 CFR 63.305(b) [DIRS 180319] states, "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology. In all analyses done to demonstrate compliance with this part, the DOE must assume that all of those factors remain constant as they are at the time of submission of the license application." Therefore, speculation concerning species evolution is excluded on the basis of regulatory requirements in 10 CFR 63.305(b) [DIRS 180319].

FEP: 1.5.03.01.0A

FEP NAME:

Changes in the Earth's Magnetic Field

FEP DESCRIPTION:

Changes in the earth's magnetic field could affect the long-term performance of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Changes and fluctuations in the earth's magnetic field are known to be relatively common in geologic history. Biggin and Thomas (2003 [DIRS 167876], pp. 409 to 412) suggest that changes in the earth's magnetic field result from global-scale tectonic processes such as slab subduction and from mantle processes. During the last 160 million years, the number of pole reversals varies from 0 to 50 (Biggin and Thomas 2003 [DIRS 167876], Figure 11). The frequency of pole reversals varies, but is thought to be on the order 2 to 3 per million years (Gubbins 1999 [DIRS 185112]). There has been a demonstrable decrease in the earth's magnetic field intensity over the last few thousand years, and there is some evidence to suggest that a pole reversal may occur sometime during the next several thousand years (Odenwald 2003 [DIRS 160892]). The frequency of magnetic pole reversals, and the variation in field intensity with time, are corroborated by Johnson et al. (1995 [DIRS 185111], Figure 3) and Odenwald (2003 [DIRS 160892]).

The potential mechanisms linking the effects of magnetic field changes to changes in the behavior of repository engineered and natural systems are not addressed in published scientific literature. The timeframe of any magnetic reversal event is expected to be in the thousands of years, and since flow and transport phenomena and repository barriers have no known dependence on the magnetic field, direct effects would be of low consequence (also see excluded FEP 1.4.02.01.0A (Unintrusive Site Investigation)). Odenwald (2003 [DIRS 160892]) indicates that there are no identifiable fossil mutations or extinction events associated with any previous reversals. Pechala (1985 [DIRS 167633], p. 406) discusses the linkage between the earth's magnetic field and tropospheric circulation, and indicates that some authors use this relationship as a basis for explaining past changes in climate.

Of the possible longer-term effects of changes in the earth's magnetic field, only climate change is expected to affect the repository. Linkage to the magnetic changes could hypothetically exist because of the complex coupling of the thermosphere, ionosphere, and magnetosphere (Pechala 1985 [DIRS 167633], p. 406). However, no clear evidence exists in the literature that long-term climate change is connected with magnetic reversals, and therefore no basis exists for evaluating the range of possible future effects. As noted, changes in the magnetic field are common in geologic history, and the effect of such past events is therefore reflected in the range of climatic properties determined from field studies and observations, which are included in the TSPA and

discussed in included FEP 1.3.01.00.0A (Climate Change). Because the existing climate data implicitly includes the effect of magnetic field fluctuations that have occurred in the past and because direct effects of the magnetic field on the repository are of low consequence to barriers, flow, and radionuclide transport, omission of FEP 1.5.03.01.0A (Changes in the Earth's Magnetic Field) will not result in a significant adverse change to the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 1.5.03.02.0A

FEP NAME:

Earth Tides

FEP DESCRIPTION:

Small changes of the earth's gravitational field due to celestial movements (those of the sun and moon) cause earth tides and may, in turn, cause pressure variations in groundwater flow systems.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Kies et al. (1999 [DIRS 160882]) describe earth tides as follows: "tidal forces deform the earth; effects induced on fluids near the surface of the earth are documented by the observations of water level changes in wells. These changes are driven by alterations of the pore pressure induced by tidal deformation of porous and fluid-saturated crustal material." The pressure changes can also result in related effects such as fluctuations in underground gas concentrations (Kies et al. 1999 [DIRS 160882]).

The fluctuations in groundwater pressure fields can be readily measured. At Yucca Mountain, the magnitude of the effect on water levels is on the order of centimeters. For example, earth tide effects in borehole UE-25 p#1 are cited by Bredehoeft (1997 [DIRS 100007], p. 2,460), with measured fluctuations in groundwater levels of 2.05 cm. Water levels in boreholes at Paiute Mesa (on the Nevada Test Site) exhibit similar if slightly smaller fluctuations (Fenelon 2000 [DIRS 160881], p. 14). Clearly, such fluctuations are of low magnitude when compared with the much larger fluctuations introduced by climate variations or groundwater extraction.

As noted by Kies et al. (1999 [DIRS 160882]), the strain variations induced by earth tides are small (less than on the order of 10^{-8}), but are periodic and generally of known magnitude. Therefore, any significant cumulative effects of earth tides will be reflected in the present existing data for the hydrogeological system (consistent with proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394], p. 53319)). Because the fluctuations associated with earth tides are of such a small magnitude, any effect on the flow system is accounted for in the water level data used in deriving the hydrologic flow fields for the TSPA (SNL 2007 [DIRS 177391]).

Based on the above discussion, omission of FEP 1.5.03.02.0A (Earth Tides) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.01.01.0A

FEP NAME:

Waste Inventory

FEP DESCRIPTION:

The waste inventory includes all potential sources of radio toxicity and chemical toxicity. It consists of the radionuclide inventory (typically in units of curies), by specific isotope, and the non-radionuclide inventory (typically in units of density or concentration), including chemical waste constituents. The radionuclide composition of the waste will vary due to initial enrichment, burn-up, the number of fuel assemblies per waste package, and the decay time subsequent to discharge of the fuel from the reactor.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Modeling the waste inventory in the TSPA can be divided into two tasks. The first is to select those radionuclides important to dose calculations. The second is to determine which radionuclides are present in each type of waste and in what quantity.

The radionuclides of importance to dose calculations were assessed in *Radionuclide Screening* (SNL 2007 [DIRS 177424]). This information was incorporated in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472]) and is reproduced in Table 6-1[a] of that report. Waste package quantities are also described in *Total System Performance Assessment Data Input Package for Requirements Analysis for DOE SNF/HLW and Navy SNF Waste Package Overpack Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-02; SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-02). Nonradioactive chemically toxic waste is not included in the repository disposal inventory; nonradiological toxicity is discussed further in excluded FEP 3.3.07.00.0A (Non-Radiological Toxicity and Effects).

Nominal average waste package inventories of the important radionuclides for each type of waste are documented in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472]). Weighted average grams per package for the 32 important radionuclides and three waste types (commercial SNF, DOE SNF, and HLW) are listed in Table 7-1[a] of *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472]).

The weighted average waste inventory values (grams per package for each radionuclide for each waste type) (SNL 2007 [DIRS 180472], Table 7-1[a]), along with the uncertainty multipliers from Table 7-2 of *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472]), are input to GoldSim for use in the TSPA model. The uncertainty multipliers address uncertainties in the average waste package inventories due to factors such as uncertainties in the isotopic concentrations in spent fuel, uncertainties in the commercial SNF delivery forecasts,

uncertainties in the waste glass canister production estimates, and waste heterogeneity (SNL 2007 [DIRS 180472], Section 6.6).

FEP: 2.1.01.02.0A

FEP NAME:

Interactions Between Co-Located Waste

FEP DESCRIPTION:

Co-location refers to the disposal of CSNF, DSNF, HLW, and possibly other wastes in close proximity within the repository. Co-location might affect thermal outputs, chemical interactions, or radionuclide mobilization.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The following types of waste form are represented in the TSPA:

- Commercial SNF from boiling-water and pressurized-water reactors
- DOE SNF (including naval SNF), approximately 85% by weight MTHM of which is the N Reactor SNF currently stored at Hanford (DOE 2002 [DIRS 158405])
- HLW in the form of glass logs in stainless steel canisters.

The HLW and the DOE SNF (with the exception of naval SNF) are combined in specially designed waste packages for emplacement (codisposal). Codisposal waste packages are designed to contain either two glass logs and two multicanister overpacks for N Reactor SNF or five glass logs and one DOE SNF canister for other DOE SNF (SNL 2007 [DIRS 179567], Section 4.1.1). A small fraction of the codisposal waste packages will be loaded with an empty center slot and with the five outer slots holding four 24-inch-diameter HLW canisters and one 24-inch-diameter DOE SNF canister. The codisposal waste packages will be colocated randomly within an array predominantly consisting of commercial SNF waste packages, and will contain a relatively small fraction of the total waste.

The codisposal waste packages (CRWMS M&O 2000 [DIRS 147650], Table 8-1; CRWMS M&O 2000 [DIRS 147651], Table 8-1) are expected to be generally cooler than commercial SNF waste packages (SNL 2007 [DIRS 179196], Sections 6.6 and 6.7). Condensation that could occur due to development of hotter and cooler zones in the EBS is addressed in included FEPs 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)) and 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-Scale Cold Traps)). Considerations of the heat generated by radioactive decay of commercial SNF, DOE SNF, and HLW are addressed in included FEPs 2.1.11.01.0A (Heat Generated in EBS) and 2.1.11.02.0A (Non-Uniform Heat Distribution in EBS). Interactions among codisposed waste forms within a waste package are addressed in included FEP 2.1.01.02.0B (Interactions Between Co-disposed Waste).

The potential for chemical interactions between co-located waste packages will depend on the direction of groundwater flow in the vicinity of the waste packages. The waste packages will be distributed in horizontal tunnels in the repository and any water inflow into the EBS will move downward under the influence of gravity into the underlying invert and fractured rock (SNL 2007 [DIRS 177407], Section 6.3.1). Longitudinal dispersion of the radionuclide flux as it passes through the invert is expected to be negligible (SNL 2007 [DIRS 177407], Section 6.3.1.2). Therefore, any contaminants released from breached waste packages will migrate into the underlying rock and will not significantly interact with other waste packages along the tunnel. Hence, changes in the rates of waste package degradation and radionuclide mobilization due to chemical interactions between co-located waste packages is insignificant.

Based on the above discussion, omission of FEP 2.1.01.02.0A (Interactions Between Co-located Waste) will not result in a significant adverse change in the magnitude or timing of radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.01.02.0B

FEP NAME:

Interactions Between Co-Disposed Waste

FEP DESCRIPTION:

Co-disposal refers to the disposal of different waste types within the same waste package. Co-disposal might affect chemical interactions or radionuclide mobilization. At Yucca Mountain, the DSNF will be combined with HLW canisters within a waste package. This co-disposal with HLW within a waste package is unique to the DSNF and does not apply to the CSNF or Naval SNF placement within waste packages.

The DSNF will be contained within canisters that will be placed within the waste packages. Some DSNF waste packages may contain only DSNF canisters, while others may contain both DSNF and HLW canisters.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Codisposal waste packages are specially designed waste packages that will contain the HLW glass and DOE SNF waste forms. Current plans call for most codisposal waste packages to contain five HLW glass canisters and one DOE SNF canister, but some will contain two HLW glass canisters and two DSNF MCOs (SNL 2007 [DIRS 180472], Table 6-2[a]; SNL 2007 [DIRS 179567], Section 4.1.1 and Table 4-1, Parameter Number 04-07). The codisposal waste packages will not contain naval SNF as this will be emplaced separately. The codisposal packages will be emplaced randomly within an array comprised predominantly of commercial SNF waste packages.

Potential issues of concern regarding codisposal include chemical interactions between the two degrading waste forms and between the corroding HLW glass and DOE SNF disposal canisters that could occur within a breached waste package. The TSPA includes these interactions by accounting for the effects of waste form degradation and container corrosion on the in-package chemistry.

Interactions of vapor influx or liquid influx with DOE SNF and HLW glass in a breached codisposal waste package were simulated in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.3.1.3[a]), which used degradation models for DOE SNF (BSC 2004 [DIRS 172453], HLW glass (BSC 2004 [DIRS 169988], Section 8.1), and other waste package components. Condensed and seepage water compositions were used to calculate the range of potential water chemistries (e.g., pH) that could occur in a breached codisposal waste package. Calculations were performed for water interaction with HLW glass and for water interaction with HLW glass and DOE SNF. Degradation of HLW glass tends to generate high pH solutions, while DOE SNF degradation generates near-neutral pH solutions (SNL 2007 [DIRS 180506],

Sections 6.3.4[a] and 6.10.1[a]). These calculations indicate that the combined effects of degrading canisters, DOE SNF, and other waste package materials will moderate the pH values attained in condensed water and seepage water (SNL 2007 [DIRS 180506], Section 6.10.1[a]).

The resulting in-package water chemistry is made available to the TSPA as part of *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Sections 8.2 and 8.2[a]). The DOE SNF release rate model has no explicit dependence on water chemistry effects and will not be affected by changes in the solution chemistry that occur due to chemical interactions between codisposal packages or between waste forms within a package (BSC 2004 [DIRS 172453]).

The HLW glass degradation rate model contains explicit pH dependence and will be affected by changes in the solution pH within a codisposal package (BSC 2004 [DIRS 169988], Section 8.1). The HLW glass model does not depend on other properties of the solution.

FEP: 2.1.01.03.0A

FEP NAME:

Heterogeneity of Waste Inventory

FEP DESCRIPTION:

CSNF, DSNF, and HLW shipped to the repository may contain quantities of radionuclides that vary from waste package to waste package, fuel assembly to fuel assembly, and canister to canister. The composition of each of these waste forms may vary due to initial uranium enrichment, possible plutonium enrichment, and fuel burn-up, among other factors. The physical state within the waste form may also vary. For example, damaged fuel pellets or extremely high-burn-up fuels may have greater surface area exposed to any water penetrating a waste package than undamaged, low burn-up spent fuel. Given these potential differences in isotopic composition and physical condition, the mass of radionuclides available for transport may vary significantly among waste packages.

The different physical (structure, geometry), chemical, and radiological properties of the many forms of CSNF, DSNF, and HLW could result in differences in the corrosion and alteration rates based on waste-package composition. This could affect repository chemistry, breach times, dissolution rates, and availability of radionuclides for transport.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP addresses how the heterogeneities in the radionuclide inventory and in physical and chemical properties of the waste types (commercial SNF, DOE SNF, and HLW) are addressed in the TSPA.

As discussed in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472], Section 6.4) the repository waste forms are quite heterogeneous in radionuclide inventory (both isotopic content and radionuclide loading) per package, as a result of uranium enrichment, possible plutonium enrichment, and fuel burn-up among other factors. Heterogeneities in radionuclide inventory will occur at several scales (e.g., between individual fuel assemblies and waste form canisters) and will contribute to variability in radionuclide inventories in the waste packages (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-07; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07). The package-to-package radionuclide inventory variability is not significant for the TSPA because it samples across many realizations. For this reason, the TSPA uses an average waste package inventory for each radionuclide; heterogeneities in the radionuclide inventory are included in the TSPA through the uncertainty distributions that are used for the average initial radionuclide inventories in the waste packages (SNL 2007 [DIRS 180472], Sections 6.4, 6.6, and 7.1).

The different physical, chemical, and radiological properties of the various commercial SNF, DOE SNF, and HLW glass waste forms could result in differences in their alteration or corrosion rates, which may subsequently affect the repository chemistry, waste form degradation rates and availability of radionuclides for transport. The TSPA uses separate models to describe the degradation rates of commercial SNF, DOE SNF, and HLW glass waste forms (BSC 2004 [DIRS 169987]; BSC 2004 [DIRS 172453]; BSC 2004 [DIRS 169988]). The effects of heterogeneities in the physical, chemical, and radiological properties of these waste form types on their degradation rates are included in uncertainty distributions for the parameters in the degradation rate models. Commercial SNF heterogeneities associated with burnup and linear power history influence the gap and grain boundary inventories. The effects of heterogeneities in commercial SNF burnup and linear power history are included in the uncertainty distributions for the instantaneous release fractions that are used to model release of the gap and grain boundary inventories (BSC 2004 [DIRS 169987], Section 6.3). Heterogeneity of the DOE SNF inventory is addressed in included FEP 2.1.02.28.0A (Grouping of DSNF Waste Types into Categories). As discussed in *Defense HLW Glass Degradation Model* (BSC 2004 [DIRS 169988]), one area where the heterogeneity of the waste form is particularly pronounced is in the variation in the composition of waste glasses made to immobilize specific wastes at different DOE sites. The effect of waste glass compositions on the calculated degradation rate is taken into account through the range of values of the model parameter k_E. Ranges for the values of k_E in acidic and alkaline solutions are selected based on the results of laboratory tests with glasses that provide a wide range of compositions that bounds the range of concentrations of key glass components in HLW glasses, such as aluminum (BSC 2004 [DIRS 169988], Section 6.5.2).

FEP: 2.1.01.04.0A

FEP NAME:

Repository-Scale Spatial Heterogeneity of Emplaced Waste

FEP DESCRIPTION:

Waste placed in Yucca Mountain will have physical, chemical, and radiological properties that will vary spatially, resulting in variation in the mass of radionuclides available for transport from different parts of the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

As discussed in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472], Section 6.4.2) the repository waste forms are quite heterogeneous in radionuclide inventory (both isotopic content and radionuclide loading) per package, as a result of uranium enrichment, possible plutonium enrichment, and fuel burn-up among other factors. At the repository scale, waste form degradation and mobilization in the TSPA model is addressed using three representative waste forms: commercial SNF, which for modeling purposes also addresses naval SNF, DOE SNF, and defense HLW glass. These categories of waste will be placed in and disposed of in two types of waste packages: commercial SNF waste packages and codisposal waste packages, with the latter containing DOE SNF and defense HLW glass. Heterogeneity is greater for DOE SNF and defense HLW than it is for commercial SNF (SNL 2007 [DIRS 180472], Section 6.4.2).

For scenarios in which only a few packages breach, package-to-package heterogeneity could be important in quantifying exposure of the RMEI. This is discussed further in included FEP 2.1.01.03.0A (Heterogeneity of Waste Inventory). For the postclosure TSPA, however, these "few-package" scenarios are not significant to performance because only scenarios with many packages breached show calculated releases that approach the exposure limit. For multiple-package breach scenarios, package-to-package heterogeneity is directly addressed in the TSPA using uncertainty parameters for the average inventory within the commercial SNF and codisposal waste packages (SNL 2007 [DIRS 180472], Sections 6.4.2 and 6.6).

For the nominal scenario at the repository-scale, radionuclide dissolution and release depend more directly on groundwater infiltration than on the specific location of a waste package within the repository (since corrosion by groundwater is the primary mechanism for waste package degradation). Therefore, the resistance of the different waste forms to degradation is of key importance. The waste forms are treated as three representative categories: commercial SNF, DOE SNF and defense HLW (SNL 2008 [DIRS 183478], Section 6.3.7), since package-to-package heterogeneities are of less importance at the repository-scale (widespread degradation would average out any heterogeneities at the package-scale). Within the TSPA model, the generic waste types are coupled to spatial variations in percolation properties rather than to a specific location (SNL 2008 [DIRS 183478], Section 6.3.7.2.3). The process of waste form

degradation will be modeled by equations using empirical degradation rate formulae for the three representative waste form types: commercial SNF, DOE SNF, and defense HLW. Outputs from the waste form degradation and mobilization model component are provided for each representative waste package in seeping and nonseeping environments. For each percolation subregion, they provide the mass of radionuclides available for transport through the EBS; the concentration limits of radionuclides inside a failed waste package and in the invert; the concentrations of radionuclides, plutonium and americium, irreversibly attached (embedded in) waste form colloids; the concentrations of radionuclides, americium and plutonium, which are irreversibly attached to iron oxyhydroxide colloids; and the concentrations of radionuclides: americium, plutonium, protactinium, cesium, thorium, tin, radium, uranium, and neptunium, which are reversibly attached to colloids (SNL 2008 [DIRS 183478], Section 6.1.4.7). Various seepage and thermal-hydrologic environments are considered in the TSPA model.

FEP: 2.1.02.01.0A

FEP NAME:

DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)

FEP DESCRIPTION:

DSNF to be disposed in Yucca Mountain contains a variety of fuel types that include metallic uranium fuels; oxide and MOX fuels; Three Mile Island rubble; and heterogeneous fuels such as UAlx, U-ZrHx, and graphite fuels. In general, the composition and structure of these spent fuels are significantly different from CSNF, and the degradation, alteration, and dissolution may be different from the CSNF degradation.

Processes to be considered in this FEP include alteration and dissolution of the various DSNF waste forms, phase separation, oxidation of spent fuels, selective leaching, and the effects of the disposal canister on DSNF degradation.

SCREENING DECISION:

Included

TSPA DISPOSITION:

DOE SNF to be disposed of in Yucca Mountain is composed of a variety of fuel types including naval fuel (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07, and Section 4.1). The various DOE SNF types are classified into eleven groups, which are outlined in *DOE Spent Nuclear Fuel Grouping in Support of Criticality, DBE, TSPA-LA* (DOE 2000 [DIRS 118968], Section 8.1). The largest single DOE SNF type is the N Reactor SNF, which comprises approximately 85% by weight expressed as MTHM of the total DOE SNF (DOE 2002 [DIRS 158405]). For the TSPA, the eleven groups of DOE SNF are being treated as two types: those waste packages containing naval fuel and all the rest (BSC 2004 [DIRS 172453], Section 8.1).

The degradation model for DOE SNF other than naval fuel is described in *DSNF and Other Waste Form Degradation Abstraction* (BSC 2004 [DIRS 172453], Section 6.1). Up to 50% of the cladding of non-naval DOE SNF may be perforated prior to repository emplacement (Rechard 1995 [DIRS 101084], Section 11.3.1, pp. 11 to 24). For the TSPA, it is conservatively assumed that all non-naval DOE SNF cladding is breached and neither protects the fuel from exposure to the repository environment after the waste package is breached nor inhibits radionuclide transport away from the fuel. The TSPA also takes no credit for the corrosion resistance of the disposal canister or the waste package inner vessel. Therefore, once the waste package outer shell has failed, it is conservatively assumed that the DOE SNF is directly exposed to the water or air of the repository environment. The model used in TSPA analyses for non-naval DOE SNF degradation is instantaneous degradation or dissolution of the waste form upon exposure of the waste form to groundwater, resulting in complete dissolution of the waste form during a single-code time step (BSC 2004 [DIRS 172453], Section 8.1).

Because of the robust design of naval SNF, it is assumed that commercial SNF can be used as a surrogate for naval SNF under the range of expected repository environmental conditions (BSC 2004 [DIRS 172453], Section 5.1). The classified *Naval Nuclear Propulsion Program Technical Support Document for the License Application* provides the technical basis for using this approach.

FEP: 2.1.02.02.0A

FEP NAME:

CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)

FEP DESCRIPTION:

Alteration of the original CSNF (under wet or dry conditions) and dissolution of the uranium-oxide matrix can influence the mobilization of radionuclides. The degradation of UO_2 could be affected by a number of variables, such as surface area, burn-up, temperature, overall solution electrochemical potential (Eh), pH, and especially solutions containing significant concentrations of calcium, sodium, carbonate, and silicate ions, as well as availability of organic complexing materials. In turn, these water properties are affected by the alteration of the cladding, fuel matrix and other waste package internals.

SCREENING DECISION:

Included

TSPA DISPOSITION:

For the TSPA, it is assumed that all commercial SNF cladding (stainless steel and Zircaloy) is breached upon emplacement in the repository as discussed in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616]). Furthermore, following waste package failure, cladding unzipping is assumed to result in immediate exposure of bare fuel to the waste package environment along the entire length of the fuel rod (included FEP 2.1.02.23.0A (Cladding Unzipping)). The TSPA also takes no credit for corrosion resistance of the TAD canister or the stainless steel inner vessel of the waste package. Therefore, once the waste package outer shell has failed, it is conservatively assumed that the commercial SNF is directly exposed to the water or air of the repository environment.

Commercial SNF degradation following waste package failure is addressed in *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987]). The outputs from the report are the TSPA models for the instantaneous release fractions (f_i) and for the matrix fractional release rates (F_i) of radionuclides under acidic and basic conditions. The output also includes the parameter values used in the models and the associated distributions that capture the uncertainty in these parameters, notably, the uncertainties in the release of:

- Gap and grain-boundary inventory fractions of cesium, iodine, technetium, and strontium. These are modeled as an instantaneous release of the fraction (f_i) of the total inventory of each of these elements to be in the gap and grain-boundary regions.

- Fuel matrix inventory under basic and acidic conditions. An instantaneous radionuclide release rate model is to be used for any fuel that is exposed to humid air at temperatures greater than 100°C and is subsequently contacted by water.

As described in *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987], Sections 6.1 and 6.2), the commercial SNF model is designed to provide the fractional release rate of radionuclides (F_i) when the commercial SNF matrix is dissolved or otherwise altered upon exposure to water or humid air. The mathematical form of the model has six model parameters (A, a_0, a_1, a_2, a_3, and a_4) and four independent variables (absolute temperature, pCO_3, pO_2, and pH) (BSC 2004 [DIRS 169987], Sections 1, 6.4.1). The effects of surface area are included through the effective specific surface area parameter (A) (BSC 2004 [DIRS 169987], Section 6.4.1.5). At temperatures greater than 100°C, potential fuel oxidation may increase the fuel surface area. This increase in surface area is accounted for by modeling an instantaneous release for any fuel in a waste package that is exposed to humid air at temperatures greater than 100°C and is subsequently contacted by water (BSC 2004 [DIRS 169987], Section 8.2).

Some factors are not accounted for in the commercial SNF degradation rate model because their effects have been found to have a negligible effect on the commercial SNF degradation rate. Potential oxidation of fuel during preclosure handling operations has been shown to have negligible consequences to the RMEI dose (DTN: MO0506MWDTLVAC.000 [DIRS 174811]) and is not modeled. Effects of other factors, including burnup, secondary phase formation, and selective or congruent release, are discussed in *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987], Section 6.2.2.3). The burnup has a negligible effect on the commercial SNF degradation rate. Secondary phase formation and the resultant armoring of the waste form surface decrease the degradation rate and are not included in the conservative analysis.

In the TSPA, the commercial SNF degradation model parameters are used along with the in-package chemistry to calculate a commercial SNF degradation rate at each model time step. The degradation model parameters are determined by sampling from parameter distributions that incorporate uncertainty, while the in-package chemistry variables are calculated as part of the TSPA simulation.

FEP: 2.1.02.03.0A

FEP NAME:

HLW Glass Degradation (Alteration, Dissolution, and Radionuclide Release)

FEP DESCRIPTION:

Glass waste forms are thermodynamically unstable over long time periods, and will alter on contact with water. Radionuclides can be mobilized from the glass waste by a variety of processes, including degradation and alteration of the glass, phase separation, congruent dissolution, precipitation of silicates, co-precipitation of other minerals (including iron corrosion products), and selective leaching.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The expression for modeling the rate of glass degradation in the TSPA is provided in *Defense HLW Glass Degradation Model* (BSC 2004 [DIRS 169988], Section 8.1). The model addresses degradation of glass exposed to humid air or dripping water, and glass immersed in water. The glass degradation rate is calculated as a function of pH and temperature (BSC 2004 [DIRS 169988], Section 6.5.1 and Equation 13).

This rate accounts for the combined effects of water diffusion, ion exchange, and hydrolysis processes that lead to glass degradation when contacted by water. Explicit dependencies are given for variables tracked in TSPA calculations, including pH and temperature. A minimum relative humidity of 44% is required for glass degradation to occur (BSC 2004 [DIRS 169988], Section 6.5.5.3.2). The effects of environmental processes specific to the disposal conditions that affect glass degradation, such as water condensation and dripping, are captured in the model by the range of values of the k_E term. The results of tests in which those processes occur are used to determine bounding model parameter values. The range of the rate coefficient k_E also accounts for the range of glass durabilities (compositions) and the evolution of the solution chemistry contacting the glass. Although the rate equation is not explicitly time dependent, variables used in the model (pH, temperature, and relative humidity) depend on time so time dependence is implicitly addressed. The values for these parameters are obtained from other models. The release of radionuclides from HLW glass is modeled to be congruent with other glass matrix components. The release rates of boron measured in laboratory tests are used to determine the glass degradation rate. The radionuclide release rate is calculated as the product of the glass degradation rate, the exposed surface area, and the radionuclide inventory. *Defense HLW Glass Degradation Model* (BSC 2004 [DIRS 169988]) provides equations for calculating the glass degradation rate (described above) and the surface area; the radionuclide inventory is provided by another model report (SNL 2007 [DIRS 180472]).

Glasses having matrix compositions representative of HLW glasses were used in laboratory tests. These glasses provided levels of glass and glass phase separation and devitrification phases

representative of HLW glasses. The maximum rates calculated by the model were selected to bound the rates measured experimentally after the precipitation of silicate, iron silicate, and mineral phases. In this way, processes that affect the glass alteration rate, congruent dissolution, selective leaching, and precipitation of alteration phases, have been incorporated in the model through model parameters, even though only the temperature and pH dependencies are calculated. The range of values of the rate coefficient k_E provides rates consistent with those measured under various test conditions in which glasses were reacted in humid air, dripping water, and various immersion conditions. A triangular distribution of values for k_E is skewed to low values to reflect the greater likelihood that glass in the disposal system will be contacted by water vapor (which gives the lowest measured rates) rather than immersion (which gives the highest measured rates).

The range of k_E values also reflects the effects of glass composition and, to a large extent, the radionuclide inventory on glass degradation, since the waste glasses are formulated based on the waste compositions. Calculation of the radionuclide release rate accounts for the spatial heterogeneity of HLW glass (i.e., the distribution of various HLW glass) by using a representative glass log to represent all HLW glasses. The surface area of glass that is available for corrosion, and the average radionuclide inventory (BSC 2004 [DIRS 169988], Table 7.1), are calculated based on the characteristics and predicted numbers of glass logs to be received from different production facilities.

In the TSPA, the HLW glass degradation model is used along with the in-package chemistry to calculate a HLW glass degradation rate at each model time step. The degradation rate model parameters are determined by sampling from parameter distributions that incorporate uncertainty, while the in-package chemistry parameters are calculated as part of the TSPA simulation.

Because of the high temperatures that occur following an igneous intrusion, an instantaneous degradation rate is applied.

Glass cracking due to volume changes on cooling is another mechanism of degradation and is addressed in included FEP 2.1.02.05.0A (HLW Glass Cracking).

FEP: 2.1.02.04.0A

FEP NAME:

Alpha Recoil Enhances Dissolution

FEP DESCRIPTION:

During decay of certain radionuclides, alpha particles may be emitted with sufficiently high energies that the daughter nuclide recoils appreciably to conserve system momentum. A potential result of recoil is that certain radionuclides, such as ^{234}U, exhibit substantially greater dissolution rates (with the same solubility limits) and can be transported preferentially.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Many of the heavy radionuclides decay by emitting alpha particles with energies greater than 4.0 MeV (Parrington et al. 1996 [DIRS 103896], p. 48). To conserve momentum, part of the decay energy is imparted to the daughter nuclide causing it to recoil from the position of the parent nuclide.

Alpha recoil may be analyzed according to the conservation of momentum in the center-of-mass frame of reference. Suppose a radionuclide X (e.g., ^{238}U), at rest in the lab-system frame of reference (Figure 2.1.02.04.0A-1a), decays to radionuclide Y (e.g., ^{234}Th) by emitting an alpha particle (see Figure 2.1.02.04.0A-1b for the center-of-mass frame).

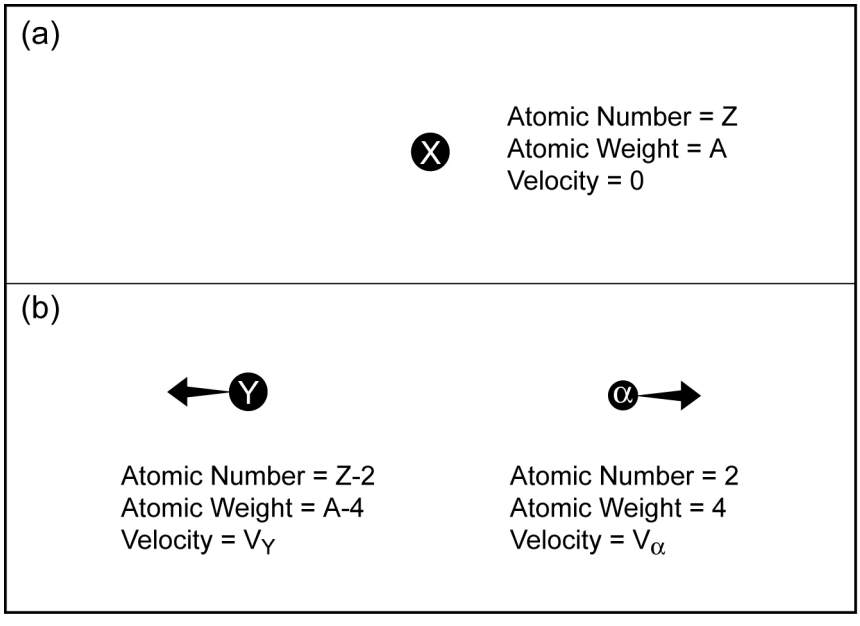

Figure 2.1.02.04.0A-1. Conceptual Illustration of Alpha Recoil Mechanics

Applying the conservation of momentum leads to Equations 2.1.02.04.0A-1 and 2.1.02.04.0A-2:

$$\text{Momentum Before} = \text{Momentum After} \qquad \text{(Eq. 2.1.02.04.0A-1)}$$

$$0 = M_Y V_Y + m_\alpha V_\alpha \qquad \text{(Eq. 2.1.02.04.0A-2)}$$

where

M_Y = Mass of the recoil nucleus

m_α = Mass of the alpha particle.

Therefore, the velocity of the recoil nucleus (in terms of the velocity of the alpha particle) is:

$$V_Y = -V_\alpha\left(\frac{m_\alpha}{M_Y}\right) \qquad \text{(Eq. 2.1.02.04.0A-3)}$$

The kinetic energy of the recoil nucleus can now be expressed in terms of the kinetic energy of the emitted alpha particle as:

$$KE(Y) = \frac{1}{2} M_Y V_Y^2 = \frac{m_\alpha}{M_Y}\left(\frac{1}{2} m_\alpha V_\alpha^2\right) = \frac{m_\alpha}{M_Y} KE(\alpha) \qquad \text{(Eq. 2.1.02.04.0A-4)}$$

Thus, the kinetic energy of the recoil nucleus is a small fraction of that given to the alpha particle. The energy of the alpha particle is dependent upon the proper mass defect value (the amount of mass converted into energy).

Both the emitted alpha particle and the recoiling daughter nucleus can displace other atoms. The number of atom displacements per alpha decay can be calculated by noting that when a recoil nucleus strikes an atom, it requires a minimum displacement energy, E_d, of approximately 25 eV to eject the struck atom from its lattice site (Foster and Wright 1973 [DIRS 144061], p. 296). The total number of displacements caused by a single alpha decay event is given by Equation 2.1.02.04.0A-5 (Foster and Wright 1973 [DIRS 144061], p. 296). Equation 2.1.02.04.0A-5 gives displacement units:

$$Disp(E) = \int_0^\infty P(T)K(E,T)\nu(T)dT = \int_{E_d}^{T_m} P(T)K(E,T)\nu(T)dT \qquad \text{(Eq. 2.1.02.04.0A-5)}$$

where

$P(T)$ = probability that an atom (primary knock-on), struck by either the emitted alpha or the alpha recoil atom, receiving energy T is displaced

$K(E,T)$ = probability for the transfer of kinetic energy T to the primary knock-on atom of energy E

$v(T)$ = total number of displacements in a cascade originating from a primary knock-on atom whose energy is T.

The expression is integrated over the energy range starting at the displacement threshold energy, E_d, and ending at the maximum energy that can be transferred to an atom, T_m. Because the displacement of atoms corresponds to a threshold event, $P(T)$ is modeled as a Heaviside step function (Foster and Wright 1973 [DIRS 144061], p. 297):

$$P(T) = \langle T - E_d \rangle^0 = \begin{cases} 0 & if \quad T < E_d \\ 1 & if \quad T \geq E_d \end{cases} \qquad \text{(Eq. 2.1.02.04.0A-6)}$$

To simplify the analysis, the probability for kinetic energy transfer is treated as being a uniform distribution over the applicable energy range:

$$K(E,T) = \frac{1}{T_m - E_d} \qquad \text{(Eq. 2.1.02.04.0A-7)}$$

The Kinchin-Pease model (Foster and Wright 1973 [DIRS 144061], p. 297) describes the total number of displacements that originate from a primary knock-on:

$$\nu(T) = \frac{T}{2E_d} + \frac{E_i - T}{2E_d}\langle T - E_i \rangle^0 = \begin{cases} T/2E_d & if \quad T \leq E_i \\ E_i/2E_d & if \quad T > E_i \end{cases} \qquad \text{(Eq. 2.1.02.04.0A-8)}$$

where

E_i = energy required for ionization.

The $2E_d$ in the denominator accounts for the displacement of the knock-on atom and the additional E_d for the striking atom to also leave the displacement site. The model also reasonably concludes there is an ionization threshold (E_i) below which displacements take place and above which only ionization takes place.

The total number of displacements is given by Equation 2.1.02.04.0A-9, which includes ionization interactions:

$$Disp(T_m) = \begin{cases} \int_{E_d}^{T_m} \frac{T}{2E_d T_m - 2E_d^2} dT & if \quad T_m \leq E_i \\ \int_{E_d}^{E_i} \frac{T}{2E_d T_m - 2E_d^2} dT + \int_{E_i}^{T_m} \frac{E_i}{2E_d T_m - 2E_d^2} dT & if \quad T_m > E_i \end{cases} \qquad \text{(Eq. 2.1.02.04.0A-9)}$$

$$= \begin{cases} \frac{T_m + E_d}{4E_d} & if\ T_m \leq E_i \\ \frac{E_i^2 - E_d^2}{4E_d(T_m - E_d)} + \frac{E_i T_m - E_i^2}{2E_d(T_m - E_d)} & if\ T_m > E_i \end{cases}$$

For the case of ^{238}U decaying to ^{234}Th, $KE(\alpha) = 4.196$ MeV (Lederer and Shirley 1978 [DIRS 142133]), $m_\alpha \cong 4.0$, and $M_{Th} \cong 234.0$, which results in a kinetic energy for the recoil nucleus of $KE(^{234}Th) = 0.072$ MeV. The kinetic energy of the recoil atom is much less than the ionization energy. Therefore, using the first version of Equation 2.1.02.04.0A-9 (with $E_d = 25$ eV), $Disp(^{234}Th)$ is equal to 720 displacements per alpha decay. This does not include replacement collisions along with focusing and channeling effects, which will significantly lower the estimate for displacements. If each of the secondary displacements follows a bifurcation process (i.e., 2^N equals 720), this would correspond to 9.49 bifurcation levels. This means that only those recoil nuclei originating within about 10 atom monolayers from the surface can escape directly into water. Given the isotropic nature of alpha recoil, only 50% of these recoil nuclei will initially be moving from the fuel towards the groundwater.

The emitted alpha particle can cause a much larger number of possible displacements owing to its larger kinetic energy. As noted above, the maximum energy for an alpha particle emitted from ^{238}U is 4.196 MeV. Since this energy is above the ionization value, the second version of Equation 2.1.02.04.0A-9 that contains two terms must be used to take into account the ionization by the alpha particles. Using the maximum alpha energy results in a value of 4,550 for $Disp(\alpha)$. When displacement from the emitted alpha particle is added to that of the recoil atom value, $Disp(^{234}Th)$, the net displacements are 5,270, which corresponds to approximately 12.4 bifurcation levels (i.e., the alpha recoils that can escape will occur in about the first 13 monolayers from the surface). Other estimates of the numbers of displacements per alpha decay in commercial SNF (Pelletier 2001 [DIRS 164034], Section 5.4.6.3.1) and defense HLW glasses (Wronkiewicz 1993 [DIRS 171709], Table 2) indicate that the number of displacements estimated above provides a conservative upper bound for the number of displacements that may be produced by alpha decay in commercial SNF and defense HLW glasses.

An upper bound to the enhancement of the dissolution rate due to direct escape of displaced atoms into groundwater contacting the waste forms may be determined based on the number of alpha decays per unit time within the first thirteen half-monolayers of the material surface that result in nuclei recoiling toward the groundwater. First, the mass of material in thirteen half-monolayers of SNF must be determined. The worst-case density for thorium (or even uranium) will be approximately that of pure plutonium metal, with a maximum density of 19.84 g/cm^3 (Wick 1980 [DIRS 143651], Table 7.1) and a monolayer thickness of approximately 3.0 Å (3.0×10^{-10} m). Therefore, over a surface area of 1.0 m^2, the first thirteen half-monolayers of SNF in the direction of the material surface have a mass of 0.0387 grams (19.84 g/cm^3 $\times$ 10^6 cm^3/m^3 $\times$ 13/2 monolayers $\times$ 3×10^{-10} m). The dissolution rate due to alpha decay is the product of the surface density (0.0387 g/m^2) and the fractional rate at which the SNF material experiences radioactive α-decay (the decay constant). Major constituents of final SNF and HLW on a mass basis have been determined to be ^{238}U, ^{235}U, ^{239}Pu, ^{236}U, and ^{240}Pu from inventory data in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472], Table 7-1[a]), and the fractional rates of α-decay for these radionuclides have been determined from their radiological half-lives. These major radionuclides are analyzed in Table 2.1.02.04.0A-1. The maximum enhancement of the dissolution rate for each radionuclide due to alpha recoil (0.0387 g/m^2 $\times$ fractional decay rate) is shown in column 5. The fractional decay rate for each radionuclide is given by the decay constant ($\lambda = ln(2)/\tau_{½}$).

The dissolution rates shown in Table 2.1.02.04.0A-1 may be compared with the dissolution rates of different waste forms due to chemical (nonnuclear) processes. Commercial SNF flow-through test dissolution data show rates ranging from 0.15 to 109 mg/m^2 per day (DTNs: MO0304PNLLPHDD.000 [DIRS 163441]; file: *CSNF MR REV2.xls*, Sheet A3; and MO0302PNLDUFTD.000 [DIRS 162385], RUN # 66 Data). When converted to the same units as used in Table 2.1.02.04.0A-1 by assuming 365.25 days per year, the dissolution rates are 0.05 to 39.8 g/m^2 per year. For defense HLW glass the initial dissolution rates are approximately 1 to 5 g/m^2 per day (BSC 2004 [DIRS 169988], Table 7-2). The alpha recoil dissolution rates shown in column 5 of Table 2.1.02.04.0A-1 are, thus, much less than the values associated with chemical processes.

In the TSPA model, DOE SNF degradation (except naval SNF) is modeled as instantaneous degradation or dissolution of the waste form upon exposure of the waste form to groundwater. For all groups of DOE SNF (except naval SNF), the upper-limit model produces complete dissolution of the waste form during a single-code time step upon exposure of the waste form to groundwater (BSC 2004 [DIRS 172453], Section 8.1). Alpha recoil enhanced dissolution of DOE SNF is inconsequential for this bounding modeling approach.

Radiation damage effects that may accumulate in commercial SNF (Piron 2001 [DIRS 162396]) and defense HLW (Wronkiewicz 1993 [DIRS 171709], Section 5.0) due to alpha recoil are addressed in excluded FEP 2.1.13.02.0A (Radiation Damage in EBS).

In summary, even when it is assumed that all radioactive decays result in alpha recoil, calculated increases in the dissolution rates of the different waste forms are insignificant compared to the dissolution rates associated with chemical processes. Based on the above discussion, omission of FEP 2.1.02.04.0A (Alpha Recoil Enhances Dissolution) will not result in significant adverse changes in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

Table 2.1.02.04.0A-1. Alpha Recoil Enhanced (from α and α-Recoil Atom) Dissolution Rates Due to the Major Mass-Based Constituents of SNF and HLW to be Disposed of in the Yucca Mountain Repository

Nuclide ID	Decay Mode	Half–Life [a] (years)	Fraction Decay Rate [b] (1/yr)	α–Decay Rate in 13 Half-Mono-Layers[c] ($g/m^2 \cdot yr$)
^{238}U	α, γ, SF	4.47×10^{9}	1.55×10^{-10}	6.00×10^{-12}
^{235}U	α, γ, SF	7.04×10^{8}	9.85×10^{-10}	3.81×10^{-11}
^{239}Pu	α, γ, SF	2.410×10^{4}	2.88×10^{-5}	1.11×10^{-6}
^{236}U	α, γ, SF	2.342×10^{7}	2.96×10^{-8}	1.15×10^{-9}
^{240}Pu	α, γ, SF	6.56×10^{3}	1.06×10^{-4}	4.09×10^{-6}

[a] Data obtained from Parrington et al. 1996 [DIRS 103896], p. 48.
[b] The fraction decay rate, also known as the decay constant, is given by $\lambda=\ln(2)/\iota½$, where $\iota½$ is the radionuclide half-life given by values in column 3.
[c] Each monolayer thickness is 3.0 Å (3.0×10^{-10} m), and the density has an upper bound of 19.84 g/cm^3 (theoretical density of pure plutonium metal (Wick 1980 [DIRS 143651])).

FEP: 2.1.02.05.0A

FEP NAME:

HLW Glass Cracking

FEP DESCRIPTION:

Cracking of the HLW glass on cooling and during handling means that the surface area of the glass is greater than the surface area of a monolithic block. The increase in the surface area could affect the rate of glass alteration and radionuclide dissolution.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The expression for exposed glass surface area developed to address this FEP is provided in *Defense HLW Glass Degradation Model* (BSC 2004 [DIRS 169988]). The surface area used to calculate the radionuclide release rate accounts for the effects of thermal cracking during manufacture and impact cracking during subsequent handling. The exposure factor ($f_{exposure}$) is used to model the combined effects of the added surface area due to cracking, the fraction of the surface that is accessible to water, and the reactivity of glass in tight cracks relative to glass at a free surface. The value of $f_{exposure}$ is selected for each realization from a triangular distribution with a minimum and most probable value of 4 and a maximum value of 17. The initial exposed surface area is calculated by using the following equation (BSC 2004 [DIRS 169988], Section 6.5.4, Equation 44):

$$S_0 = f_{exposure} \times (2\pi r_o^2 + 2\pi r_o \times L_o) \qquad \text{(Eq. 2.1.02.05.0A-1)}$$

where r_o is the internal radius of the average glass canister, and L_o is the length of the average glass canister.

As the glass degrades, the surface area is calculated as the product of the specific surface area of an average glass log ($f_{exposure} \times 2.70 \times 10^{-3}$ m^2/kg) and the mass of glass available at the beginning of the time step using the following equation (BSC 2004 [DIRS 169988], Section 6.5.4, Equation 48):

$$S = f_{exposure} \times 2.70 \times 10^{-3} \text{ m}^2/\text{kg} \times (2{,}710 \text{ kg} - \Sigma M_t \text{ kg}) \qquad \text{(Eq. 2.1.02.05.0A-2)}$$

where ΣM_t gives the loss of mass of the average glass log during all previous time steps (which has an associated loss of surface area) and the initial mass of the average glass log is 2,710 kg.

The value of M at each time step is calculated as the product of the glass degradation rate used for that time step and duration of the time step. The mass loss is used to calculate the loss in surface area assuming the mass loss is uniform over all surfaces.

As discussed in included FEP 2.1.02.03.0A (HLW Glass Degradation), following an igneous intrusion event, an instantaneous degradation rate is applied. Therefore, the exposure factor ($f_{exposure}$) is not applied under those conditions.

Citation	Title	DIRS
BSC 2004	*Defense HLW Glass Degradation Model*	169988

FEP: 2.1.02.06.0A

FEP NAME:

HLW Glass Recrystallization

FEP DESCRIPTION:

HLW glass recrystallization could occur and would lead to a less corrosion-resistant waste form. Recrystallization is a slow process and typically occurs only if a high glass temperature is maintained over a prolonged period.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The glass degradation model developed in *Defense HLW Glass Degradation Model* (BSC 2004 [DIRS 169988]) utilizes a range of model parameter values determined from experimentally measured dissolution rates of glasses having compositions similar to HLW glasses (BSC 2004 [DIRS 169988], Section 6.5.2.2). HLW glasses of various compositions will be disposed of in the repository and the value of the effective glass dissolution constant (k_E) takes into account uncertainty associated with glass composition, including the heterogeneity of the waste inventory, as well as the effect of the solution compositions (BSC 2004 [DIRS 169988], Section 6.5.1).

As part of the validation of the glass degradation model, the glass degradation rate has been shown to be insensitive to the presence of the crystalline phases formed by devitrification of the glass melt during manufacture. Published results show that the effects of devitrification on glass dissolution rates are included within the range of uncertainty in the rate measurements (BSC 2004 [DIRS 169988], Section 6.5.5).

In conclusion, glass recrystallization would have no effect on the overall HLW glass dissolution rate.

Based on the previous discussion, omission of FEP 2.1.02.06.0A (HLW Glass Recrystallization) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.07.0A

FEP NAME:

Radionuclide Release from Gap and Grain Boundaries

FEP DESCRIPTION:

While in the reactor at high temperatures, radionuclides such as I and Cs may migrate and preferentially accumulate in cracks in the fuel matrix, grain boundaries of the UO_2, and in the gap between the fuel and cladding. After the waste package fails and the cladding perforates, the release rate of this fraction of the radionuclides could be rapid.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Radionuclide release from gap and grain boundaries applies mainly to commercial SNF and similar fuel designs (such as MOX), which are fabricated from UO_2-based fuel pellets. In such SNF, a portion of some of the volatile fission product radionuclides can migrate to the fuel pellet grain boundaries and open gap areas of the fuel rods under the influence of the high temperature gradients during reactor operation (BSC 2004 [DIRS 169987], Section 6.2.1.1). The gap and grain boundary inventory is assumed in the TSPA to be accessible for dissolution into any water that penetrates the fuel cladding.

For the TSPA, it is conservatively assumed that all commercial SNF fuel cladding (stainless steel and Zircaloy) is breached upon emplacement in the repository as discussed in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2[a]). Furthermore, following waste package failure, cladding unzipping is assumed to result in immediate exposure of bare fuel to the waste package environment along the entire length of the fuel rod (SNL 2007 [DIRS 180616], Section 5.3; included FEP 2.1.02.23.0A (Cladding Unzipping)). Once the waste package outer shell has failed, it is conservatively assumed that the UO_2 fuel is directly exposed to the water or air of the repository environment and the gap and grain boundary inventories are immediately accessible for dissolution upon water contact.

As described in *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987], Section 6.3), the release of the gap and grain boundary radionuclide inventory is modeled as an instantaneous release fraction (f_i) where the subscript i refers to ^{137}Cs, ^{129}I, ^{90}Sr, and ^{99}Tc. Available experimental data are used to estimate the mean values, the ranges, and the distribution functions for f_i (BSC 2004 [DIRS 169987], Section 6.3). The gap and grain boundary release is modeled as an instantaneous release in one time step. These distributions are sampled at the beginning of each TSPA realization to determine the values of f_i that are used for the instantaneous release fractions during the course of the realization. At the high temperatures fuel pellets experience during reactor operation, a significant migration of gaseous radionuclides to the gap and grain boundaries occurs. However, at the much lower temperatures expected after waste package emplacement, the thermally driven migration of radionuclides to the gap and

grain boundaries is expected to be low enough that it can be considered to be included in the uncertainties in the instantaneous release fraction of the commercial SNF (BSC 2004 [DIRS 169987], Section 6.2.1).

FEP: 2.1.02.08.0A

FEP NAME:

Pyrophoricity from DSNF

FEP DESCRIPTION:

DSNF can contain pyrophoric material. Pyrophoric material could ignite and produce an adverse effect on repository performance. Pyrophoric events could affect the thermal behavior of the system and could contribute to degradation of the waste package, waste form, and cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Uranium metal-based fuel, such as Hanford's N Reactor SNF, is a potentially pyrophoric material. For the purposes of this FEP, a pyrophoric material is understood to be capable of igniting spontaneously under temperature, chemical, or physical/mechanical conditions specific to the storage, handling, or transportation environments (ASTM C 1454-00 [DIRS 152779], Section 3.2.9). Occurrence of a pyrophoric event (i.e, an event that involves self-sustained rapid chemical oxidation or self-sustained burning) in the repository could produce an adverse effect on repository performance by producing heat and increasing waste form degradation and radionuclide release rates.

Uranium metal and uranium hydride are regarded as pyrophoric materials in the DOE handbook, *Primer on Spontaneous Heating and Pyrophoricity* (DOE-HDBK-1081-94 [DIRS 103327]), but uranium oxides and carbide are not. The DOE SNF inventory consists of SNF "groups" (DOE 2000 [DIRS 118968]) that include metal-, oxide-, and carbide-based fuels. The uranium metal-based N Reactor SNF group (which accounts for about 85% by weight MTHM of the total DOE SNF inventory (DOE 2002 [DIRS 158405], Appendix D)) is potentially pyrophoric. This fuel is expected to be loaded into about 219 waste packages (SNL 2007 [DIRS 180472], Table 7-3[a]). This represents less than 2% of the 11,629 (SNL 2007 [DIRS 180472], Table 7-3[a]) waste packages to be included in the TSPA analyses.

N Reactor SNF is composed primarily of Zircaloy-clad metallic uranium. A substantial amount of the cladding has been breached, thereby exposing the metallic uranium to the K-basin water (and any other subsequent canister or dry storage) environment. Metallic uranium-based SNF has shown pyrophoric behavior when exposed to air environments (Abrefah et al. 1999 [DIRS 151226], Appendix C). Such pyrophoric behavior has been observed when finely divided uranium metal or uranium hydride have been exposed to air; limiting the air supply has been used to limit the rate of reaction and achieve controlled oxidation and stabilization of the material involved (Abrefah et al. 1999 [DIRS 151226], Appendix C4). Pyrophoric behavior has been observed during past operations involving handling and processing of N Reactor SNF at West Valley (Schulz 1972 [DIRS 159406]). However, assessment of these events concluded that they were most likely initiated by rapid oxidation of a zirconium/beryllium alloy in the cladding

weld beads that had been sensitized by exposure to nitric acid in the fuel dissolution operations involved (Schulz 1972 [DIRS 159406]). This initiation source is not relevant to the repository because the cladding in the disposed fuel will not have been sensitized by exposure to nitric acid. Other factors that could cause the N Reactor fuel to ignite in the repository are discussed below.

When oxidized in an air or water environment, metallic uranium-based fuels will produce uranium hydride and oxide as corrosion products. The uranium hydride corrosion product can be pyrophoric, particularly when in a fine particulate form or when a substantial amount of hydride has formed in the uranium metal matrix. Examination and testing conducted at Pacific Northwest National Laboratory on damaged N Reactor zirconium-clad uranium metal fuel showed small but discernable amounts of uranium hydride formed as precipitates within the metal (Marschman et al. 1997 [DIRS 149429], Section 3.4.2). The presence of these hydrides is believed to be responsible for the decreased ignition temperature observed during ignition testing of damaged/corroded N Reactor SNF samples compared to unirradiated or undamaged samples (Abrefah et al. 1999 [DIRS 151226], Tables 4.2 and 4.3). While bulk uranium metal is not pyrophoric at temperatures below 600°C, ignition temperatures in the range 277°C to 500°C were observed for the fuel samples from damaged and corroded N Reactor fuel elements (Abrefah et al. 1999 [DIRS 151226], Summary). The possibility exists that additional uranium-hydride will form during interim storage (Reilly 1998 [DIRS 149433], p. 30). Uranium-hydride inclusions tend to be concentrated near the exposed uranium metal fuel surface of damaged SNF (Abrefah et al. 1999 [DIRS 151226]; Marschman et al. 1997 [DIRS 149429]). The fraction of N Reactor SNF with cladding that is damaged enough to expose the metallic uranium core was not well understood when the decision was made to remove the fuel from wet storage and package the fuel within the MCOs (Abrefah et al. 1995 [DIRS 151125]). A characterization program was conducted to assess the extent of fuel damage prior to fuel packaging and fuel inspection was conducted during the packaging operation to ensure that limits on exposed fuel surface area were not exceeded within individual MCOs. However, as discussed below, uranium hydride inclusions in the metallic uranium matrix of damaged N Reactor SNF (i.e., fuel elements with breached cladding) potentially provide an ignition mechanism.

Uranium hydride and uranium metal undergo exothermic reactions with oxygen and water. The reaction rates increase with temperature, and the presence of uranium hydride in uranium metal is known to greatly accelerate the oxidation rate even at low temperatures (Haschke 1998 [DIRS 174075]). As a result, oxidation initiated at a low temperature can generate sufficient heat locally near the hydride inclusions that the heat transfer rate is insufficient to remove the heat. This causes the temperature to increase locally at the reaction site, which then accelerates the reaction rate leading to a feedback situation that can initiate and sustain a pyrophoric event. At lower temperatures, humidity can increase the rate of uranium metal corrosion by a water-catalyzed cycle until a maximum is reached, and then the rate decreases at higher relative humidity. Humidity effects are absent in the autothermic regime above 500°C (Haschke 1998 [DIRS 174075]). For these reasons, and because the standard enthalpy of the reaction with water vapor is lower than that for the reaction with oxygen due to the enthalpy needed to split the water molecules (Grenthe et al. 1992 [DIRS 101671]), the reaction with oxygen is the focus of this analysis. Because the rate of oxidation increases with the specific surface area of the material and also because the rate of heat transfer away from the reaction site is slower for particulate material than for bulk uranium, the ignition temperatures are expected to be lower for fine

particulate material. Regardless of the ignition temperature, for a spontaneous ignition of metallic uranium or uranium-hydride inclusions, or both, to occur and become a sustained pyrophoric event, there must be sufficient oxygen to support the continuing oxidation reactions. In the repository, the sources of oxygen that are potentially available to initiate and sustain a pyrophoric event in the codisposal waste packages containing N Reactor fuel are:

- Oxygen that could be produced from residual and bound water left in the MCOs after they are dried and closed.
- Oxygen or air ingress into the waste package through waste package breaches.

These potential sources of oxygen and how they are expected to influence and limit the pyrophoric events that might occur in the repository are discussed in the following paragraphs.

Oxygen from Residual Water in the Codisposal Waste Packages: The codisposal DOE SNF waste packages will be dried and filled with helium prior to emplacement in the repository (SNL 2008 [DIRS 173869], Appendix I). The N Reactor SNF contained within MCOs emplaced inside the codisposal waste packages are also dried and filled with helium (Garvin 2002 [DIRS 169141], Section 4.1.3.2). The amount of free and bound water that may remain in the MCOs after they are dried and closed is uncertain. The dominant form of this water is bound water in uranium and aluminum oxide hydrates with the estimated acceptable amount per MCO ranging up to 4.64 kg (Garvin 2002 [DIRS 169141], Table 4-4). In the repository, this water could be released and converted to free hydrogen and oxygen due to thermal and radiolytic decomposition of the uranium and aluminum oxide hydrates involved. If free oxygen and hydrogen are produced inside the codisposal packages, the oxygen will probably be scavenged by reaction with exposed uranium metal in the breached fuel because of the rapid kinetics of the uranium-metal/oxygen reactions (Haschke 1998 [DIRS 174075], Table 1). The fate of the free hydrogen is less clear. In studies of uranium-metal corrosion in moist air, neither hydrides nor hydrogen gas formed (Haschke 1998 [DIRS 174075], p. 150) suggesting that any evolved hydrogen is rapidly transformed to water on the U-metal surface under the conditions of this study. The production and fate of hydrogen is discussed further in excluded FEPs 2.1.12.03.0A (Gas Generation (H_2) from Waste Package Corrosion) and 2.1.13.01.0A (Radiolysis). Even if both MCOs in a codisposal package are each assumed to contain 4.64 kg water and it is also assumed all of the oxygen in this water is available as free oxygen to convert uranium-metal to UO_2 in a rapid pyrophoric event, it would oxidize only a very small fraction (0.5%) of the fuel in the waste package (see excluded FEP 2.1.11.03.0A (Exothermic Reactions in the EBS)). The heat energy released would be about 2.8×10^5 kJ, which would cause a waste package temperature increase of only 21°C even under conservatively assumed adiabatic conditions and conservatively assumed zero heat capacities of the two MCO and two HLW glass steel canisters. This is calculated by dividing 4,640 g H_2O by the approximate molecular weight of water, 18 g/mol to obtain 258 moles per MCO and then multiplying by two to get 516 moles H_2O, which is equilivent to 258 moles O_2 per waste package. Assuming the end product of the oxidation reaction is UO_2 and ignoring O_2 consumption by the in-package steels, the total energy released is 258 moles × 1,085 kJ/mol (Grenthe et al. 1992 [DIRS 101671], Table III.1) = 2.8×10^5 kJ or 2.8×10^8 J. Assuming adiabatic conditions (all energy is available to increase the waste package temperature (i.e., no radiative heat losses)) a maximum temperature increase for the waste package can be calculated. There are 2.43×10^7 g steel per waste package, not

including the steel of the two MCO and two HLW glass canisters (SNL 2007 [DIRS 179567], Table 4-10) and 1.1×10^7 g uranium-metal per waste package assuming that the waste package contains two MCOs each containing Mark IV fuel and scrap baskets containing the maximum fuel (3,804 kg uranium) and scrap (1,832 kg uranium) loadings (Garvin 2002 [DIRS 169141], Table 4-4). The specific heat capacity for austenitic steels is 0.5 J/g·°C (ASM International 1990 [DIRS 106780], p. 871). This value is not considerably different from the Alloy 22 specific heat capacity used in the multiscale thermohydrologic model (0.423 J/g·°C) (SNL 2008 [DIRS 184433], Table 4.1-1). The specific heat capacity for uranium-metal is 27.66 J/mol K (Grenthe et al. 1992 [DIRS 101671], Section V.1.1), which is equivalent to 0.12 J/g·°C. An approximate weighted average of 0.38 J/g·°C is used here for the steel and uranium-metal combined. The maximum temperature increase for the waste package due to emplaced water is calculated as 2.8×10^8 J/ waste package ÷ (3.49×10^7 g metal/ waste package × 0.38 J/ g·°C) = 21°C, a negligible quantity. Including the masses of steel in the MCO and HLW glass canisters would have resulted in an even lower calculated maximum temperature increase.

The adverse consequences for such a pyrophoric event are expected to be small because the TSPA model uses a bounding instantaneous degradation rate for DOE SNF (BSC 2004 [DIRS 172453], Section 8.1), and because a very conservative bounding estimate of the overall temperature increase (i.e., the adiabatic estimate discussed above) is sufficiently small that it is not expected to melt or otherwise degrade the codisposed glass waste forms. Degradation of the uranium metal fuel as a result of its oxidation in a pyrophoric event may cause the radionuclides in the oxidized fuel to be available for dissolution and transport when that fuel is contacted by water. Even in the absence of oxidation in a pyrophoric event, the TSPA model uses a bounding instantaneous degradation rate for the uranium-metal DOE SNF (BSC 2004 [DIRS 172453], Section 8.1), which considers that the radionuclide inventory in this fuel is available for dissolution and transport when the fuel is contacted by water. Therefore, a pyrophoric event will not adversely affect radionuclide release because the pyrophoric event will not increase the rate of radionuclide release beyond that already included in the TSPA model. Also, because a bounding estimate of the overall temperature increase (i.e., the adiabatic estimate discussed above) is small, it is not expected to melt or otherwise significantly degrade the HLW glass that is codisposed with the uranium-metal fuel. The expected effects of small temperature increases on the rate of degradation of HLW glass are discussed in FEP 2.1.11.03.0A (Exothermic Reactions in EBS).

Oxygen Ingress after Waste Package Breaching: In the absence of disruptive events, the breaches in the waste package outer shell through which ingress of oxygen might occur are expected to be stress corrosion cracks. Following pressure equilibration between the waste package void space and the drift air, it is expected that the SCC may allow oxygen ingress by the following processes:

- Counter-diffusion process involving helium, nitrogen, oxygen, and water vapor
- Pumping due to barometric pressure fluctuations
- Advective flow driven by buoyancy differences between the gasses inside and outside the waste packages.

Each of these processes and their effects on potential pyrophoric events in the repository are discussed below.

Oxygen Ingress by Diffusion: Upper bound estimates for the diffusive mass transport rate of oxygen into the waste package through SCC can be calculated using the approach described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.6.2).

The oxygen diffusion rate is calculated by applying Fick's First Law and making a number of reasonably bounding assumptions. The first assumption is that the oxygen concentration in the waste package is zero (i.e., all oxygen in the package is consumed by oxidation reactions involving the in-package steels or by the uranium-metal). This assumption is conservative because it maximizes the oxygen diffusion rate and consequently the heat produced. The remaining assumptions are that oxygen behaves as an ideal gas in this system and that steady-state conditions apply. The oxygen flux is then given by:

$$J_{O_2} = -cD_{O_2}\frac{dX_{O_2}}{dz} \qquad \text{(Eq. 2.1.02.08.0A-1)}$$

Where J_{O2} is the oxygen flux, c is the molar density of an ideal gas at standard pressure and 50°C (37.712 mol/m^3) calculated from the ideal gas molar volume of 0.022414 m^3 mol^{-1} at standard temperature and pressure (Lide 2000 [DIRS 162229], P. 1-8), D_{O2} is the binary diffusion coefficient for O_2 in air (2.37×10^{-5} m^2 s^{-1}) (SNL 2008 [DIRS 177407], Section 6.6.2), X_{O2} is the mole fraction of O_2 in air (0.20946) (Weast 1984 [DIRS 106170], p. F-162), and z is the waste package wall thickness (0.0254 m) (SNL 2007 [DIRS 179394], Table 4-3). Assuming a steady state and integrating with respect to z yields:

$$J_{O_2} = -c\frac{D_{O_2}}{\Delta z}\ln\frac{1-X_{O_2 inside\ waste\ package}}{1-X_{O_2 in\ air}} \qquad \text{(Eq. 2.1.02.08.0A-2)}$$

The flux is then scaled to the total area of the SCCs in the waste package.

Disruptive seismic events may cause damage to the waste package outer shell that leads to stress corrosion cracking in the damaged areas. The total area of the stress corrosion cracking breaches in the outer shell following a bounding seismic event provides an upper bound estimate of the breach area that may be available for oxygen ingress. The damaged area on the OCB of the codisposal waste package is bounded by 0.792 m^2 for this screening analysis. The value of 0.792 m^2 corresponds to the mean damaged area on a codisposal waste package with a 23-mm-thick OCB and intact internals at the 4.07 m/s PGV level and the 90% RST (SNL 2007 [DIRS 176828], Table 6-18). The value of 0.792 m^2 (rounded up to 0.8 m^2 for the analyses in this FEP) is considered a reasonable upper bound because:

- The PGV level of 4.07 m/s corresponds to the lowest exceedance frequency, 10^{-8} per year that is considered in the seismic scenario class. Damaged areas are significantly smaller for the more frequent seismic events that are expected to occur during the 10,000-year period for FEP screening. For example, the mean damaged area is 0.120 m^2 for a seismic event at the 1.05 m/s PGV level (SNL 2007 [DIRS 176828], Table 6-18),

which corresponds to an exceedance frequency of about 10^{-5} per year on the bounded hazard curve (SNL 2007 [DIRS 176828], Table 6-3). This value, 0.120 m^2, is more than a factor of six below the bound of 0.8 m^2.

- The uncertainty in the RST for Alloy 22 is represented as a uniform distribution between 90% and 105% of the yield strength of Alloy 22. The 90% RST level is the lowest bound of the uniform distribution. Damaged areas are significantly smaller at the 100% and 105% RST levels. For example, the mean damaged areas are 0.006 m^2 and 0.0 m^2 at the 4.07 m/s PGV level for the 100% and 105% RST levels, respectively (SNL 2007 [DIRS 176828], Table 6-18). These values are more than two orders of magnitude less than the bound of 0.8 m^2.

- The 23-mm-thick OCB corresponds to a thickness reduction of 2.4 mm from the initial thickness of the OCB. The thickness reduction of 2.4 mm overestimates the general corrosion and hence the plastic deformation (i.e., the damaged area) of the OCB during the first 10,000 years after closure. For example, the median corrosion rate of Alloy 22 at 100°C is 30.8 nm per year, based on the median uncertainty level in the distributions for general corrosion rates of Alloy 22 (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*, worksheet: "Data," cell M71). The value of 100°C represents a reasonable average temperature for the first 10,000 years after repository closure. The median time for a thickness reduction of 2.4 mm is then estimated as $(2.4 \times 10^{-3}$ m)/$(30.8 \times 10^{-9}$ m/yr) = 77,000 years, which is well beyond the 10,000-year period for FEP screen analyses.

- Not all seismic events cause damage to the codisposal waste package with intact internals, as shown by the probabilities in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Table 6-16). For example, the probability of damage is 0.559 for the 1.05 m/s PGV level at the 90% RST level. This probability goes to zero at the 100% and 105% RST levels.

Based on each of these factors, a damaged area of 0.8 m^2 for the codisposal waste package with intact internals provides a reasonable bound for the 10,000-year period for FEP screening. Assuming a bounding estimate of 1.31×10^{-2} for the SCC area density that could develop in the seismic damage region (SNL 2007 [DIRS 181953], Table 8-13), the breach surface area that would be available to admit oxygen into the waste package is about 1×10^{-2} m^2. Hence, a bounding estimate of the diffusive flux of oxygen is given by:

$$J_{O_2} = \frac{37.712 \frac{\text{mol}}{\text{m}^3} \cdot 2.37 \times 10^{-5} \frac{\text{m}^2}{\text{s}}}{0.0254\, m} \cdot \ln\left(\frac{1}{1 - 0.20946}\right) \cdot 1 \times 10^{-2} m^2 \cdot 3.156 \times 10^7 \frac{\text{s}}{\text{yr}} = 2610 \frac{\text{mol}}{\text{yr}}$$

(Eq. 2.1.02.08.0A-3)

If all of this oxygen is used to convert uranium metal to UO_2 for which the heat of formation is 1,085 kJ/mole uranium (Grenthe et al. 1992 [DIRS 101671], Table III.1), the corresponding heat generation rate is about 90 watts. This is calculated by converting the quantity of uranium-metal per MCO (3,804 kg uranium in the assembly baskets and 1,832 kg uranium in scrap baskets for

MCOs containing the maximum Mark IV fuel load with scrap basket, which was used because of initial exposed surfaces of uranium.) (Garvin 2002 [DIRS 169141], Table 4-4) to moles: (3,804 + 1,832) kg uranium × 1,000 g/kg ÷ 238 g uranium/mol = 23,689 moles uranium per MCO. Because there are two MCOs per waste package, there are 47,378 moles uranium metal per waste package. Therefore, the time required to complete the combustion of all the uranium metal in a waste package is approximately 18 years (47,378 moles uranium ÷ 2,610 moles O_2 per year) assuming the oxidation of one mole of uranium consumes one mole of O_2 to form UO_2. The corresponding heat generation is 2,610 moles/yr × 1,084.9 kJ/mol = 2.8×10^6 kJ/yr, which is equivalent to about 90 watts). This assumes that the pyrophoric reaction is self sustaining (i.e., that the heat energy is dissipated slowly enough from the reaction sites that the pyrophoric reaction continues and is limited only by the rate of oxygen supply). If it is assumed that U_3O_8 is the oxidation product (heat of formation on the basis of one uranium = 1,191.6 kJ/mol (Grenthe et al. 1992 [DIRS 101671], Section v.3.3.3.1)), then the oxidation of the fuel in the waste package occurs with a corresponding heat generation rate of approximately 74 watts.

As discussed above, the oxidation of the uranium metal fuel will not adversely affect radionuclide release because the TSPA model uses a bounding instantaneous degradation rate for DOE SNF other than naval SNF (BSC 2004 [DIRS 172453], Section 8.1). Because the heat output rate is small compared to the initial decay heat generation rates (SNL 2007 [DIRS 180472], Table 7-5[a]), the associated increase in the overall waste package temperature is expected to be small (see corroborating evidence below) and would therefore not lead to further degradation of the waste package outer shell that might increase the rate of oxygen ingress. Also, the small temperature increases involved are not expected to melt or otherwise degrade the codisposed glass waste.

Oxygen Ingress by Barometric Pumping: Barometric pressure fluctuations at the surface are transmitted to the repository horizon with some amplitude attenuation (BSC 2004 [DIRS 169734], Section 7.3.2). Pressure measurements made prior to excavation of the ESF indicated that the attenuated amplitude of the pressure fluctuations are less than 1% (BSC 2004 [DIRS 169734], Figure 7-27). For this analysis of oxygen ingress into a breached waste package due to barometric pressure fluctuations in the repository, it is conservatively assumed that the pressure fluctuations occur with a diurnal (twice daily) rhythm each involving a fluctuation of about 1%. Assuming that the pressures inside and outside the waste package are equilibrated in each of the twice-daily pressure fluctuations, the fractional rate at which the gasses in the void space of a breached waste are replaced by outside air is given by 1% × 2 per day = 2% per day. The void volume of the codisposal waste packages containing two MCOs packages is 7,400 liters (DTN: SN0702PAIPC1CA.001 [DIRS 180451], spreadsheet: *CDSP-2MCO Cell 1.xls*, sheet: "WP Cell 1 Moles & Surf Areas," cell: G11). Given that the mole fraction of oxygen in air is 0.20946 (Weast 1984 [DIRS 106170], p. F-162), the moles of oxygen ingress into a breached waste package as a result of barometric pumping can be calculated as: 7,400 liters × 0.02 × 365 days per year/22.4 liters per mole × 0.20946 (oxygen mole fraction in air) = 505 moles oxygen per year.

This is a relatively small rate of oxygen ingress compared to that calculated above for diffusion through SCCs. Hence, the effects of this source of oxygen ingress are small compared to those discussed above for oxygen ingress due to diffusion.

Oxygen Ingress by Flow Driven by Buoyancy Forces: The stress corrosion cracking that will lead to breaching of the waste package outer shell will develop over a period of time, which is expected to allow the initially slow rate of oxygen ingress to increase gradually as more through-wall SCCs develop. Hence, it is expected that any reactive uranium metal and uranium hydride will be stabilized as the SCCs are developing. However, it is instructive to examine the pyrophoric events that might ensue if all of the seismic-induced SCCs were to lead to through wall penetrations at one time.

An analysis of the quantitative response of the contents of a single MCO to hypothetical breaches and material/energy flow from the MCO (DOE 2004 [DIRS 173188]) provides corroborating evidence that pyrophoric events that are limited by the rate of oxygen ingress through large breaches (that may simulate buoyancy-driven flow through a large number of seismic-induced stress corrosion cracks) will not be highly energetic and will not lead to temperature increases in the waste package container that will cause the area of the container breaches to increase as the event unfolds. The analysis did not perform a mechanistic determination of the location, size, or quantity of hypothetical breaches in the MCO, but rather used a range of hole sizes arranged in a two-hole configuration to evaluate the response of the MCO. The two-hole configuration analyzed consisted of one lower and one upper hole in a vertically oriented MCO. This configuration maximizes the rate of air ingress by providing a chimney effect in which air flows in through the lower hole and out through the upper hole. Features of the MCO, basket internals, and the N Reactor SNF are modeled in the analysis. The Hanford interim storage safety basis data were used in the model, which represents the credible extremes of the characterization data. The reactive surface area (uranium metal and uranium hydride) was distributed to achieve the highest localized fuel temperatures. This configuration is similar to a match head, where the reactive surface area is concentrated at the tip of the fuel element. The objective was to determine if enough heat is generated by oxidation to heat the remaining bulk uranium (uranium unaffected by corrosion) in the fuel element to high enough temperatures that accelerated uranium oxidation would occur in the bulk uranium. More disperse distributions of the reactive surface area would lower peak temperatures, but increase the consumption of uranium metal over a greater period of event time. In the case of the two-hole breach, hole sizes of 0.75 inches and less show oxidation of only reactive material (uranium metal with reactive surface area and uranium hydride). Peak external MCO wall temperatures for the 0.75-inch two-hole breach are approximately 315°C (600°F), which is reached about 12 days after the event initiation and remains fairly constant until it drops rapidly with the extinction of the event after about 27 days (DOE 2004 [DIRS 173188], Figure A-20). The temperature of the bulk uranium in the fuel elements does not exceed the surface temperature where accelerated uranium oxidization would occur. Thus, if a more disperse distribution of the reactive surface area is present, the surface temperatures of the fuel elements would certainly not reach temperatures where accelerated oxidation would occur. There is no evidence of hydrogen accumulating in quantities permitting deflagration or detonation. These results demonstrate the event does not reach a highly energetic or an explosive state. Breaches with unequal sizes did not exacerbate the temperature response. The reaction is limited by flow through the smaller of the two holes regardless of whether the smaller hole was the lower or upper hole.

The results for two 0.75-inch holes are expected to overestimate the buoyancy-driven flow through SCCs because they allow more air inflow than the SCC breaches in the waste package even when the bounding estimates discussed above are used for SCC breaches following a

seismic event. The estimated brach area for a single SCC through the WPOB is 7.682 mm^2 (SNL 2008 [DIRS 177407], Section 6.6.2, Table 6.3-3). This corresponds to an equivalent radius of 0.156 cm or 0.061 inches. Because the gas inflow and outflow velocities are small (< 1 ft/s) the mass flow rates through the breach openings will scale approximately as the fourth power of the equivalent radius in accordance with Poiseuille's equation. Hence, an estimate of the number of SCCs needed to give the same mass flow rate as one 0.75-inch-diameter hole is:

$$((0.75/2)/0.061)^4 = 1{,}428$$

The SCC breach area of 1×10^{-2} m^2 discussed above for the waste package outer shell following a seismic event corresponds to about $1 \times 10^{-2} / 7.68 \times 10^{-6} = 1{,}302$ SCCs, which is less than the 1,428 number that would be equivalent to a 0.75-inch-diameter hole and much less than the 2,856 number that would be equivalent to two 0.75-inch holes.

Therefore, the uranium metal fuel meets the pyrophoricity acceptance requirements applicable to waste form postclosure performance (DOE 2007 [DIRS 169992], Section 4.2.5).

Based on the previous discussion, omission of FEP 2.1.02.08.0A (Pyrophoricity from DSNF) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.09.0A

FEP NAME:

Chemical Effects of Void Space in Waste Package

FEP DESCRIPTION:

If waste packages and/or DSNF canisters are not completely filled, then the unfilled inert gas or air-filled volume could influence water-chemistry calculations.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP evaluates the effects of the unfilled void space in the waste packages on in-package chemistry. Radionuclide accumulation in the gap between the waste form and cladding is addressed in included FEP 2.1.02.07.0A (Radionuclide Release from Gap and Grain Boundaries). The model for in-package chemistry is composed of two conceptual models, the vapor influx model and the liquid influx model (SNL 2007 [DIRS 180506], Section 6.3[a]). The vapor influx model addresses the situation in which water vapor enters the breached waste package and condenses. The liquid influx model addresses the situation in which liquid water seeps or drips into the breached waste package. These models differ from each other in the chemistry of the water to which the waste forms are exposed in a breached waste package. In evaluating the in-package water chemistry, the entire initial void volume in the waste package (derived from SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-01; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07), is taken to be filled with liquid and gas and includes any void volume in a canister and any void volume in the waste form. The in-package chemistry model, thus accounts for the unfilled void space in the waste package and its impact on the in-package chemistry. The inert gas (helium) is not expected to persist long after breach. Therefore, it is not expected to react materially with in-package fluids.

In the conceptual model, the void spaces within a waste package are filled by liquid water in equilibrium with atmospheric gases. This has the effect of putting the gas phase in close contact with the liquid and solid phase reactants in the system (SNL 2007 [DIRS 180506], Section 6.3.1[a]). Sensitivity studies were conducted that varied the ratio of water to reactants, which is equivalent to varying the ratio of water to air (SNL 2007 [DIRS 180506], Section 6.6.1[a]), and that varied the composition of the air in contact with the water (SNL 2007 [DIRS 180506], Section 6.6.4[a]). The effect of water–air ratio was not included in the abstraction because it is negligible compared to other uncertainties that were incorporated into the abstraction (SNL 2007 [DIRS 180506], Section 6.6.1[a]). The sensitivity of the composition of the air was included in the abstractions for pH and total carbonate by incorporating the functionality of CO_2 fugacity and relative humidity. Therefore, the chemical composition of the void space was investigated and incorporated into the model.

FEP: 2.1.02.10.0A

FEP NAME:

Organic/Cellulosic Materials in Waste

FEP DESCRIPTION:

Degradation of cellulose in the waste could affect the long-term performance of the disposal system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The waste materials (i.e., commercial SNF, DOE SNF, and HLW glass) are not expected to contain organic/cellulosic materials other than trace amounts that might be included in the sealed canisters. Control and specification of technical information needs on the organic content of sealed waste form canisters (DOE 2007 [DIRS 169992], Sections 4.2.6, 5.4.1B(4), and 5.4.3.C) and waste form and TAD canister design parameters (SNL 2007 [DIRS 179394], Table 4-1) will be used to confirm consistency between the contents of the waste form canisters emplaced in the repository and the technical basis for the TSPA. The TSPA includes the expectation that organic materials, other than trace amounts, will not be included in the sealed waste form canisters.

The important factors that will influence the degradation of commercial SNF, DOE SNF, and HLW in the repository are addressed in Section 6 of the modeling reports for each of these waste forms (BSC 2004 [DIRS 169987]; BSC 2004 [DIRS 172453]; BSC 2004 [DIRS 169988]) and are included in the corresponding FEPs (2.1.02.02.0A (CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)), 2.1.02.01.0A (DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)), and 2.1.02.03.0A (HLW Glass Degradation (Alteration, Dissolution, and Radionuclide Release)). As documented in Section 6 of the reports cited above, the important waste form degradation processes are oxidation and dissolution of the commercial SNF and DOE SNF matrices and hydrolysis and dissolution of the HLW glass matrix. The effects of trace organic/cellulosic materials are relatively unimportant compared to these processes. The anticipated low activity of microbes (excluded FEP 2.1.10.01.0A (Microbial Activity in EBS)) indicates that significant conversion of organic/cellulosic materials to degradation-enhancing organic acids will not occur. Therefore, inclusion of trace amounts of organic/cellulosic materials in the waste is not expected to affect the waste form degradation.

The important factors that influence the dissolved concentrations of elements with radioactive isotopes and waste form and in-drift colloid concentrations are addressed in *Dissolved Concentration Limits of Elements with Radioactive Isotopes* (SNL 2007 [DIRS 177418], Section 6.4.1) and *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.3.1 and 6.3.13) and included FEPs 2.1.09.04.0A (Radionuclide Solubility, Solubility Limits, and Speciation in the Waste Form and EBS) and 2.1.09.16.0A (Formation of Pseudo-Colloids (Natural) in EBS). The effects

of trace amounts of organic/cellulosic materials on the dissolved and colloid concentrations are expected to be relatively unimportant compared to the effects of the factors that are included. Potential effects of organic materials on dissolved concentrations are also addressed in excluded FEP 2.1.09.13.0A (Complexation in EBS).

In summary, the emplaced waste is expected to contain only trace amounts of organic/cellulosic materials that will not affect the degradation of the waste forms or the dissolved and colloid concentrations of elements with radioactive isotopes.

Based on the previous discussion, omission of FEP 2.1.02.10.0A (Organic/Cellulosic Materials in Waste) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.11.0A

FEP NAME:

Degradation of Cladding from Waterlogged Rods

FEP DESCRIPTION:

Failed fuel rods (attributed to breaches caused by manufacturing defects and reactor operations) comprise a small fraction of the fuel rods that are currently being stored in commercial reactor spent fuel pools. Failed fuel contains water in the fuel rod void space that may promote degradation of the spent fuel cladding. Such fuel is referred to as "waterlogged." The moisture remaining in a "dried" fuel rod is used to determine the extent of degradation of spent fuel cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapour into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, DOE SNF cladding (with the exception of naval SNF cladding) is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Based on the above discussion, even if further degradation of cladding in waterlogged rods were to occur, omission of FEP 2.1.02.11.0A (Degradation of Cladding from Waterlogged Rods) will not result in a significant adverse change in the magnitude or time of radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed

10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

10 CFR 63	Energy: Disposal of High-Level Radioactive Wastes in a Geologic Repository at Yucca Mountain, Nevada	180319
70 FR 53313	Implementation of a Dose Standard After 10,000 Years	178394

FEP: 2.1.02.12.0A

FEP NAME:

Degradation of Cladding Prior to Disposal

FEP DESCRIPTION:

Certain aspects of cladding degradation may occur before the spent fuel arrives at Yucca Mountain. Possible mechanisms include rod cladding degradation during reactor operation, degradation during wet spent fuel pool storage, degradation during dry storage, and rod degradation during shipping (i.e., from creep and from vibration and impact) and fuel handling.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Cladding degradation prior to receipt at the repository can occur during reactor operation, SNF pool storage, dry storage, transport, and handling. The condition of DOE SNF and commercial SNF cladding at the time of emplacement in the repository is discussed in the following paragraphs.

A significant but unquantified fraction of the N Reactor fuel, which constitutes about 85% of the MTHM of DOE SNF (BSC 2004 [DIRS 172453], Section 6.1.7), will have damaged cladding at the time of emplacement in disposal canisters (Abrefah et al. 1995 [DIRS 151125]). There has been insufficient characterization of the condition of the DSNF cladding to establish its initial condition and the effectiveness of the cladding as a barrier to radionuclide transport. For the purposes of TSPA it is considered that all DOE SNF cladding (with the exception of naval SNF cladding) is breached at the time of its arrival to the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact. DOE SNF cladding itself is further discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

The amount of initial "out of reactor" commercial SNF cladding damage is expected to be low, as documented in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616]), which is based on utility data collected from multiple sources. However, a decision has been made not to take cladding credit for the TSPA (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). For the purposes of TSPA it is considered that all commercial SNF cladding is breached at the time of its arrival at the repository and will neither inhibit groundwater contacting the commercial SNF fuel matrix nor the release of radionuclides from the commercial SNF after groundwater contact (SNL 2008 [DIRS 183478], Section 6.3.7.3).

Localized (Pitting) Corrosion of Cladding

FEP DESCRIPTION:

Localized corrosion in pits could produce penetrations of cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Based on the above discussion, omission of FEP 2.1.02.16.0A (Localized (Pitting) Corrosion of Cladding) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

10 CFR 63	Energy: Disposal of High-Level Radioactive Wastes in a Geologic Repository at Yucca Mountain, Nevada	180319
70 FR 53313	Implementation of a Dose Standard After 10,000 Years	178394

FEP: 2.1.02.17.0A

FEP NAME:

Localized (Crevice) Corrosion of Cladding

FEP DESCRIPTION:

Localized corrosion in crevices could produce penetrations of cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, even if localized (crevice) corrosion of cladding were to occur the additional impact of this FEP on cladding (other than naval SNF cladding) performance is of low consequence and will not affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment. Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Based on the previous discussion, omission of FEP 2.1.02.17.0A (Localized (Crevice) Corrosion of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate

compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

INPUTS:

FEP: 2.1.02.18.0A

FEP NAME:

Enhanced Corrosion of Cladding from Dissolved Silica

FEP DESCRIPTION:

High dissolved silica content of waters may enhance corrosion of cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commerical SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.18.0A (Enhanced Corrosion of Cladding from Dissolved Silica) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.19.0A

FEP NAME:

Creep Rupture of Cladding

FEP DESCRIPTION:

At high temperatures (>400°C) for sufficiently long time intervals, creep rupture of Zircaloy cladding on spent fuel can occur and produce small perforations in the cladding to relieve stress. After the waste package fails, the fuel can react with water and radionuclides can escape over time from the fuel rod.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is conservatively considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, DOE SNF cladding (with the exception of naval SNF cladding) is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.19.0A (Creep Rupture of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.20.0A

FEP NAME:

Internal Pressurization of Cladding

FEP DESCRIPTION:

Increased pressure within the fuel rod due to the production of helium gas could contribute to cladding failure.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.20.0A (Internal Pressurization of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.21.0A

FEP NAME:

Stress Corrosion Cracking (SCC) of Cladding

FEP DESCRIPTION:

Stress corrosion cracking (SCC) mechanisms can contribute to cladding failure. These mechanisms can operate both from the inside out from the action of fission products, or from the outside in from the actions of salts or other chemicals within the waste package.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is conservatively considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, DOE SNF cladding (with the exception of naval SNF cladding) is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DSNF fuel matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.21.0A (Stress Corrosion Cracking (SCC) of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

INPUTS:

Table 2.1.02.21.0A-1. Direct Inputs

70 FR 53313	Implementation of a Dose Standard After 10,000 Years	178394

FEP: 2.1.02.22.0A

FEP NAME:

Hydride Cracking of Cladding

FEP DESCRIPTION:

Cladding contains hydrogen after reactor operation. The cladding might pick up more hydrogen from cladding general corrosion (wet oxidation) after the waste package is breached. The hydrogen can exist both as zirconium hydride precipitates and as hydrogen in solid solution with zirconium. Hydrides might also form from UO_2 oxidation after waste package and cladding perforation. In addition, hydrides may dissolve in warmer areas of the cladding and migrate to cooler areas. Hydrogen can also move from places of low stress to places of high stress, causing hydride reorientation or delayed hydride cracking. The buildup of hydrides can cause existing cracks to propagate by delayed hydride cracking or hydride embrittlement.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, DOE SNF cladding (with the exception of naval SNF cladding) is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.22.0A (Hydride Cracking of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the

RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

INPUTS:

Table 2.1.02.22.0A-1. Direct Inputs

Input	Source	Description

70 FR 53313	Implementation of a Dose Standard After 10,000 Years	178394

FEP: 2.1.02.23.0A

FEP NAME:

Cladding Unzipping

FEP DESCRIPTION:

In either dry or wet oxidizing conditions and with perforated fuel cladding, the UO_2 fuel can oxidize. The volume increase of the fuel as it oxidizes can create stresses in the cladding that may cause gross rupture of the fuel cladding (unzipping).

SCREENING DECISION:

Included

TSPA DISPOSITION:

The axial splitting or "unzipping" of commercial SNF cladding is caused by the volume increase associated with the formation of fuel or cladding corrosion products (excluded FEP 2.1.09.03.0A (Volume Increase of Corrosion Products Impacts Cladding)). Unzipping of commercial SNF cladding is expected to occur after the fuel cladding is perforated, and it leaves fuel pellets exposed to the waste package internal environment.

For the TSPA, it is considered that all commercial SNF fuel cladding (stainless steel and Zircaloy) is breached on emplacement in the respository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.1.2.2[a]).

Experiments carried out at Argonne National Laboratory involving two commercial SNF fuel rod segments with perforated cladding found that unzipping along the length of each fuel rod segment occurred in less than two years due to the fuel-side cladding corrosion (Cunnane et al. 2003 [DIRS 162406], Section 2a). Dry oxidation of the commercial SNF fuel (oxidation of UO_2 to U_3O_8) could also result in rapid cladding unzipping. Dry oxidation of the fuel in commercial SNF rods with breached cladding is expected to occur under the expected low humidity and high temperature conditions in the repository if the waste package fails soon after repository closure. Wet oxidation of the fuel in commercial SNF rods with breached cladding following waste package failure is also expected to result in rapid cladding unzipping.

Commercial SNF cladding unzipping is included in the TSPA model by assuming that the commercial SNF cladding is breached on emplacement in the repository and that cladding unzipping exposes bare fuel along the entire length of the fuel rod immediately following waste package failure. No credit is taken for the commercial SNF cladding playing any role in limiting exposure of the fuel to the repository environment or in limiting radionuclide release from the fuel.

DOE SNF and naval SNF cladding are discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding) and in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Cunnane et al. 2003	*Yucca Mountain Project Report, Waste Form Testing Work*	162406

FEP: 2.1.02.24.0A

FEP NAME:

Mechanical Impact on Cladding

FEP DESCRIPTION:

Mechanical failure of cladding may result from external stresses, such as rockfall or impact from waste package internals. Seismic-induced impacts are addressed in several separate FEPs.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is conservatively considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.24.0A (Mechanical Impact on Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

70 FR 53313	Implementation of a Dose Standard After 10,000 Years	178394

FEP: 2.1.02.25.0A

FEP NAME:

DSNF Cladding

FEP DESCRIPTION:

DSNF to be disposed in Yucca Mountain contains a variety of fuel types that may not be similar to CSNF. Some of the fuel types may have initial cladding-degradation characteristics that are different from those for CSNF. Therefore, the effectiveness of DSNF cladding as a barrier to radionuclide mobilization might be different from CSNF. This FEP addresses all types of DSNF cladding except Naval SNF cladding.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

About 85% by weight MTHM of the DOE SNF is from the N Reactor (DOE 2002 [DIRS 158405], Appendix D), a significant but unquantified fraction of which will have damaged cladding at the time of emplacement in their canisters (Abrefah et al. 1995 [DIRS 151125]). There has been insufficient characterization of the condition of the DOE SNF cladding (other than the observations of extensive damage to the N Reactor SNF cladding) to establish the effectiveness of the cladding. Because the cladding integrity of most DOE SNF will not be extensively characterized, the TSPA model uses an upper limit model for DOE SNF (with the exception of naval SNF) degradation that takes no credit for cladding in either protecting the fuel from exposure to the repository environment or in limiting radionuclide release as discussed in *DSNF and Other Waste Form Degradation* (BSC 2004 [DIRS 172453], Sections 6.2 and 8.1). Also, because the TSPA model takes no credit for DOE SNF canister integrity once the waste package has breached, it is modeled that the DOE SNF is directly exposed to repository water or air environment.

The TSPA model considers all DOE SNF (with the exception of naval fuel) cladding will be breached on emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal). Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Based on the above discussion, omission of FEP 2.1.02.25.0A (DSNF Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.25.0B

FEP NAME:

Naval SNF Cladding

FEP DESCRIPTION:

DSNF to be disposed of in Yucca Mountain has a variety of fuel types that may not be similar to the CSNF to be disposed. Some of the fuel types may have initial cladding-degradation characteristics that are different from those for the CSNF. Therefore, the effectiveness of DSNF cladding as a barrier to radionuclide mobilization might be different from CSNF. This FEP addresses Naval SNF structure only.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Naval Nuclear Propulsion Program cladding and SNF performance is discussed in *Naval Nuclear Propulsion Program Technical Support Document for the License Application*, Section 2.3.7, which is a classified document. Waste packages containing naval SNF are conservatively modeled in TSPA as commercial SNF waste packages.

FEP: 2.1.02.26.0A

FEP NAME:

Diffusion-Controlled Cavity Growth in Cladding

FEP DESCRIPTION:

Diffusion-controlled cavity growth is a possible creep rupture mechanism that could occur under the temperature and pressure conditions that prevail during dry storage of spent fuel. It might also occur during disposal.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached upon emplacement in the repository, as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact. Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.26.0A (Diffusion-Controlled Cavity Growth in Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.27.0A

FEP NAME:

Localized (Fluoride Enhanced) Corrosion of Cladding

FEP DESCRIPTION:

Fluoride is present in Yucca Mountain groundwater, and zirconium has been observed to corrode in environments containing fluoride. Therefore, fluoride corrosion of cladding may occur in waste packages.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached upon emplacement in at the repository, as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Section 6.2.1.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact. Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, omission of FEP 2.1.02.27.0A (Localized (Fluoride Enhanced) Corrosion of Cladding) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.02.28.0A

FEP NAME:

Grouping of DSNF Waste Types into Categories

FEP DESCRIPTION:

Several hundred distinct types of DSNF may potentially be stored in the repository. These represent many more types than can viably be examined for their individual effect on the repository. A limited number of representative or bounding degradation models must be selected and/or abstracted.

SCREENING DECISION:

Included

TSPA DISPOSITION:

DOE SNF to be disposed of in Yucca Mountain is composed of a variety of fuel types packaged in a number of configurations (BSC 2004 [DIRS 172453]; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07). *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472]) considered all fuel types and the quantities of each fuel type when compiling the nominal radionuclide inventory in grams per package and uncertainty distributions for radionuclides important to dose calculations for the TSPA.

For degradation rate determination, the various DOE SNF types have been classified into eleven groups for the purpose of TSPA analyses (BSC 2004 [DIRS 172453]; DOE 2000 [DIRS 118968]). The largest single DOE SNF type is the N Reactor SNF uranium metal (Group 7), which comprises approximately 85% by weight expressed as MTHM of the total DOE SNF (DOE 2002 [DIRS 158405], Appendix D). N Reactor SNF degradation models are adopted as a surrogate for the entire DOE SNF inventory, except for the naval SNF (Group 1) (BSC 2004 [DIRS 172453]). Naval fuel is treated as commercial SNF in the TSPA. This grouping and implementation simplifies the TSPA model for computational efficiency while ensuring that the great majority of DOE SNF degradation is captured in a bounding fashion.

In addition to being the largest DOE SNF inventory type by weight, N Reactor SNF degradation can be used to represent degradation of the entire DOE SNF inventory because: (1) a significant fraction of the N Reactor SNF will be damaged at the time of emplacement in their canisters, and (2) the N Reactor SNF degradation rates are greater than those for most other groups (BSC 2004 [DIRS 172453], Section 6.2 and Table 6-9). The group that potentially has greater dissolution rates than N Reactor SNF is the mixed-carbide-fissile fuel waste particles in a nongraphite matrix (Group 3). Group 3 waste would not serve as an appropriate DOE SNF degradation surrogate because the total inventory of the Group 3 SNF is less than 0.001% of DOE SNF waste (DOE 2002 [DIRS 158405], Appendix D). The immobilized plutonium ceramic waste form is not included in this discussion because the DOE Office of Environmental Management has decided to use the majority of the excess defense plutonium as MOX fuel in commercial reactors

as the preferred disposition path rather than immobilization in a ceramic waste form (67 FR 19432 [DIRS 162618]).

As discussed in *DSNF and Other Waste Form Degradation Abstraction* (BSC 2004 [DIRS 172453], Section 6.3), a single conservative upper-bound model is used in TSPA to model degradation of the DOE SNF inventory other than naval SNF. This approach gives complete dissolution of the waste form during a single-code time step upon exposure of the waste form to groundwater.

FEP: 2.1.02.29.0A

FEP NAME:

Flammable Gas Generation from DSNF

FEP DESCRIPTION:

DSNF to be disposed in Yucca Mountain will contain a small percentage of carbide fuel. When carbide is exposed to water, flammable gases such as methane and ethene, ethylene, and acetylene (the latter two are referred to as ethane and ethyne respectively by the International Union of Pure and Applied Chemistry) are generated. If these gases ignite, localized increases in temperature can occur, which might affect fuel degradation. The area around the ignition point may be mechanically and/or thermally perturbed, which could affect waste package or host-rock properties in the adjacent area of the EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The only fuel waste types capable of producing organic flammable gases, such as methane, and ethane, are the uranium-thorium carbide and the plutonium-uranium carbide DOE SNF because they are the only spent nuclear fuels containing more than trace quantities of carbon. These gases are formed by the reaction of the carbides with liquid water or water vapor. Only a small percentage (approximately 1% or 25 MTHM) of DOE SNF contains uranium/thorium carbide fuels. There is only about 100 kg of plutonium/uranium carbide DOE SNF (DOE 2002 [DIRS 158405], Table D-1). The carbide spent nuclear fuels will be present in about 5% of the waste packages (DOE 2004 [DIRS 169354], p. D-580). These carbide fuels will not be included in the 2-MCO/2-DHLW codisposal waste packages that will contain the potentially pyrophoric uranium metal fuel discussed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF) (SNL 2007 [DIRS 179567], Section 4.1). The effect of H_2 gas production is discussed in excluded FEPs 2.1.12.03.0A (Gas Generation (H_2) from Waste Package Corrosion) and 2.1.13.01.0A (Radiolysis).

Uranium/thorium carbide fuels were used in the Fort St. Vrain and Peach Bottom Unit 1, reactor Cores 1 and 2. The Peach Bottom Core-1 reactor pellets are relevant, since pellets from this reactor are not encased in the tough, corrosion-resistant, silicon-carbide shells used in the other reactor cores. As discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding), it is considered in the TSPA that DOE SNF (with the exception of naval SNF) cladding is breached upon emplacement in at the repository and that the bare fuel is instantaneously exposed to the waste package environment when the waste package fails. The exposed fuel can possibly produce flammable hydrocarbons. Only 1.663 MTHM of Peach Bottom Core-1 pellets (DOE 1998 [DIRS 122980], Appendix B, p. 14) contained in 103 waste packages (DOE 1998 [DIRS 122980], Table 1-1, p.1-8) will be disposed in the repository. This is small compared to the 24.667 MTHM of high-integrity fuel (contained in 545 waste packages) from the Fort St.

Vrain and Peach Bottom cores (DOE 1998 [DIRS 122980], Appendix B, p. 14, and Table 1-1, p. 1-8). Thus, less than 7% {1.663/(1.663 + 24.667)} of the carbide fuel is low-integrity pellets.

An analysis of degradation and hydrocarbon production from graphite-matrix carbide fuels was conducted (Propp 1998 [DIRS 149395]). This study assessed the vulnerability of graphite-matrix SNF to oxidation by the ambient atmosphere in a geologic repository after fuel canister breach and examined the gases generated due to carbide combustion. Thermochemical and kinetic data were scrutinized for potential reactions between the graphite and the H_2O/O_2 system over the temperature range of 200°C to 400°C. This evaluation led to the following predictions and conclusions:

- Carbon dioxide is thermodynamically favored as the principal product of combustion of graphite in the presence of H_2O and/or O_2.
- Carbon monoxide may form; however, it will subsequently be consumed to form CO_2.
- The potential for direct reaction of water with graphite is small.
- Neglecting radiolysis, the decomposition of water into elemental hydrogen and oxygen is negligible and the reverse reaction (formation of water) is favored.
- Methane formation is not significant.

The kinetic analysis assumed an Arrhenius-type rate expression and concluded that the values of the reaction rate constant are very small but exhibit strong temperature dependence. The time required for a total carbon mass loss of 1 mg/cm^2 from a sample exposed under these conditions was calculated. Even at 400°C, the rate is "so small as to be of no practical consequence," it requires two years to produce this insignificant mass loss. This corresponds to a material thickness loss of 0.4 mm in 190 years. Therefore, oxidation of the carbide-bearing SNF upon waste package breach is not anticipated to be a concern (Propp 1998 [DIRS 149395], Summary).

Additionally, DOE SNF will be widely dispersed throughout the repository, as will any flammable gas produced. Like most of the DOE SNF waste packages, the carbide fuel will be placed in a DOE SNF canister and packaged with five HLW glass canisters in each waste package (SNL 2007 [DIRS 179567], Section 4.1.1). So the carbide fuel is inherently dispersed and any gas produced from carbide fuel would be dispersed as well. Since carbide can react to form flammable gases only in the presence of water, it is reasonable to assume that this process would be preceded by failure of the waste package and degradation of the fuel's graphite matrix. Therefore, pressure buildup following gas release in a waste package will be insignificant.

With the exception of intermittent perched zones, both the matrix and the fractures within the host rock above and below the repository horizon have a relatively high degree of gas-phase saturation and permeability (BSC 2004 [DIRS 170035], Section 6.1). Additionally, airflow through Yucca Mountain maintains repository pressures close to atmospheric pressure (SNL 2007 [DIRS 184614], Section 6.4). These conditions will promote a dispersive gas flow path between the repository and host rock, thus diluting any potential flammable-gas concentrations to levels below the ignition point. Given these conditions, any flammable gas

produced, once released, will quickly disperse and be diluted due to the presence of in situ non-flammable gases (nitrogen and argon in the air, and water vapor) in the repository (see excluded FEP 2.1.12.01.0A Gas Generation (Repository Pressurization)).

In summary, considering the small quantity of carbide fuel capable of generating flammable gas, the durability of the graphite fuel matrix used in these fuels, the dispersion of carbide waste among waste packages and across the repository and the low probability of ignition due to high rock permeability, and the fact that an upper bound instantaneous degradation rate model is used in TSPA for DOE SNF even in the absence of any hypothetical effects of flammable gas on radionuclide release, flammable gas generation from DOE SNF is insignificant.

Based on the previous discussion, omission of FEP 2.1.02.29.0A (Flammable Gas Generation from DSNF) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.01.0A

FEP NAME:

General Corrosion of Waste Packages

FEP DESCRIPTION:

General corrosion may contribute to waste package failure.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The outer corrosion barrier of the waste package, referred to here as the waste package outer barrier or WPOB, will be constructed of Alloy 22, a highly corrosion resistant Ni-Cr-Mo alloy. General corrosion of the WPOB is included in the TSPA. The effects of dry-air oxidation, humid-air and aqueous general corrosion, microbially influenced corrosion, and aging and phase instability on the WPOB are discussed in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519]). Initiation of aqueous corrosion processes requires the existence of a stable water film on the metal surface. The relative humidity at which this water layer forms is a strong function of the physical condition (e.g., cleanliness, surface roughness, etc.) of the metal surface (ASM International 1987 [DIRS 103753], pp. 80 to 82). As the surface condition of the waste package may vary in terms of the aforementioned characteristics, in the TSPA the onset of general corrosion of the WPOB is modeled as occurring independently of the in-drift temperature and relative humidity, and therefore is initiated at the time of repository closure (SNL 2007 [DIRS 178519], Section 8.2). Note that no barrier to flow performance credit is taken for the stainless steel liner or the TAD canister. Once the WPOB fails, it is assumed that these vessels fail in a manner that allows the in-drift environment to contact the waste form and allows water or water vapor to enter the failed waste package.

The WPOB general corrosion model was developed using data obtained from experiments conducted in mixed ionic environments as well as simple salt solutions including highly concentrated chloride brines and chloride brines containing nitrate ions. The general corrosion model has been validated against data obtained at temperatures as high as 180°C. For temperatures in excess of 180°C, the thin-film aqueous environment required to support general corrosion may not be sustainable under atmospheric pressures relevant to the repository. Therefore, application of any general corrosion rate at elevated temperature will consistently overestimate the rate of material degradation. The need to use this approach stems from the difficulty in defining a clear cut-off temperature where general corrosion would no longer be considered. Therefore, the general corrosion model should be applicable over all repository exposure environments (SNL 2007 [DIRS 178519], Sections 7.2.1 and 8.2). Because general corrosion is considered to be operative for the entire repository operation period, it could lead to degradation and breach of waste packages in the repository.

The effect of microbial activity on the general corrosion process of the WPOB is represented by a general corrosion rate-enhancement factor (SNL 2007 [DIRS 178519], Section 8.2). A more detailed discussion on the effect of microbial activity is provided in included FEP 2.1.03.05.0A (Microbially Influenced Corrosion (MIC) of Waste Packages) and in *General and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Sections 6.4.5 and 8.2).Thermal instability in metal alloys can result in the precipitation of secondary phases within the metal matrix; this process is sometimes referred to as phase instability. Phase instability was determined to have an insignificant effect (see excluded FEP 2.1.11.06.0A (Thermal Sensitization of Waste Packages)) on the general corrosion of the WPOB, and is therefore not included in the TSPA, as documented in *General and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.6.1).

Comparative analysis of the corrosion rates from the polarization resistance technique showed insignificant effects of welding and thermal aging of the waste WPOB on the general corrosion rates. It was determined that the aging of the base metal and welds of the WPOB under the thermal conditions expected in the repository would not affect the corrosion performance of the WPOB, and will not be specifically modeled in the TSPA (SNL 2007 [DIRS 178519], Section 6.4.6). Thermal aging (sensitization) of waste packages is discussed further in excluded FEP 2.1.11.06.0A (Thermal Sensitization of Waste Packages).

Penetration rates for general corrosion are provided in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Sections 6.4.3 and 8.2). General corrosion rates of the WPOB were estimated using the weight-loss of Alloy 22 crevice geometry specimens after a 5-year exposure in the LTCTF. The corrosion rate data were fit to a Weibull distribution and the uncertainty in the fitting process is represented as three distributions corresponding to low, medium and high levels of uncertainty in the fitting process. These distributions are randomly sampled such that the low and high general corrosion rate distributions are each used for 5% of realizations and the medium general corrosion rate distribution is used for 90% of realizations (DTN: MO0703PAGENCOR.001 [DIRS 182029], file: *BaseCase GC CDFs.xls*).

The temperature dependence of the general corrosion rate is represented by an apparent activation energy that was developed using data from polarization resistance tests (SNL 2007 [DIRS 178519], Sections 6.4.3.4 and 8.2). Data from several environments were used to calculate the temperature dependence using a linear mixed effects model with individual environments differentiated in the fitting procedure by use of a solution-dependent random effects vector. The temperature dependence is estimated by an apparent activation energy having a mean of 40.78 kJ/mol and a standard deviation of 11.75 kJ/mol with the range of sampled values restricted to −3 and +2 standard deviations (DTN: MO0703PAGENCOR.001 [DIRS 182029], file: *BaseCase GC CDFs.xls*). The entire variance in the values used to describe temperature dependence is attributed to uncertainty (SNL 2007 [DIRS 178519], Sections 6.4.3.3.2 and 8.2).

As discussed above, general corrosion of the WPOB is included in the TSPA. It is implemented for the groundwater protection standard (10 CFR 63.331 [DIRS 180319]), and the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). In the case of human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), general corrosion of

the WPOB is not implemented in the assessment of the earliest time at which intrusion would be recognized by the drillers because that is determined by drip shield corrosion rates (SNL 2008 [DIRS 183478], Section 6.7.2).

FEP: 2.1.03.01.0B

FEP NAME:

General Corrosion of Drip Shields

FEP DESCRIPTION:

General corrosion may contribute to drip shield failure.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The design requirements for drip shields include corrosion resistance as well as structural strength. Corrosion resistance is required so the drip shields can perform their seepage water diversion function with high reliability. Structural strength is required so the drip shield can protect the waste package against damage resulting from the impact and static load of rockfall and/or drift collapse weighing several tons, resulting from degradation of the drift walls and crown. Rockfall is discussed in excluded FEP 2.1.07.01.0A (Rockfall). The seepage water diversion function is performed by the Titanium Grade 7 drip shield plate material while the structural support function is performed by the Titanium Grade 29 support material (SNL 2007 [DIRS 179354], Table 4-2, Parameter Numbers 07-04).

General corrosion of the drip shield is included in the TSPA. The effects of dry-air oxidation, humid-air and aqueous general corrosion, microbially influenced corrosion, and aging and phase instability on the drip shield are discussed in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778]). The corrosion resistance of titanium alloys is the result of a continuous, highly adherent, and protective oxide passive film on the metal surface. This passive film is stable over a wide range of potentials and pH values (SNL 2007 [DIRS 180778]). Initiation of aqueous corrosion processes requires the existence of a stable water film on the metal surface. The relative humidity at which this water layer forms is a strong function of the physical condition of the metal surface (ASM International 1987 [DIRS 103753], pp. 80 to 82), and thus it is assumed that a water layer will form at all relative humidities. As such, in the TSPA, general corrosion of the drip shield is modeled as being operative at the time of repository closure (SNL 2007 [DIRS 180778], Section 6.1.8[a]).

The penetration rates due to aqueous general corrosion for Titanium Grade 7 are estimated based on weight-loss measurements conducted at the LTCTF (DTN: LL030410012251.056 [DIRS 169583], file: *Ti-7 2 & one half Year Coupon Corrosion Rates Sup12 SN241.xls*). Testing was performed in a wide range of plausible generic test media including SDW, SCW and SAW. The compositions of these test media are summarized in DTN: LL040803112251.117 [DIRS 171362]. The general corrosion rates were higher for the samples exposed to aqueous SCW at 60°C and aqueous SCW at 90°C than for all other samples (SNL 2007 [DIRS 180778], Figures 6-2[a] and 6-3[a]). Based on these observations, the weight-loss data set was divided into three environmental groups with distinctively different rate distributions as follows:

aggressive condition (SCW aqueous at 90°C), intermediate condition (SCW aqueous at 60°C) and benign condition (all remaining included data) (SNL 2007 [DIRS 180778], Section 6.1.5[a]).

The higher corrosion rates calculated for samples exposed to the SCW environment may well be the result of the combined action of fluoride and chloride ions in solution. Fluoride additions to chloride-bearing solutions have been observed to cause an increase in the passive current density of Titanium Grade 7 measured under applied potential conditions (Brossia and Cragnolino 2001 [DIRS 162420], Figures 9 and 10; Brossia and Cragnolino 2004 [DIRS 180832], Figures 8 to 10). Thus, the weight-loss data collected in the fluoride-bearing SCW environment are the most appropriate data available for estimating the corrosion rate of titanium under aggressive repository conditions.

The concentration of fluoride within Yucca Mountain pore waters is anticipated to be very low (SNL 2007 [DIRS 177412], Table 4.1-3), but may be increased due to evaporative concentration (DTN: SN0701PAEBSPCE.001 [DIRS 180523]). Due to the low potential concentrations of fluoride in the environment on the drip shield surface both prior to and following evaporative concentration on the waste package surface, the impact of fluoride on the drip shield will be minimal (SNL 2007 [DIRS 180778], Section 6.5.7). The use of the aggressive condition data to represent general corrosion behavior under seepage conditions will therefore consistently overestimate the general corrosion rate of the outer surface of the drip shield on a time-averaged basis.

Because no long-term data from the LTCTF are available for general corrosion rate of Titanium Grade 29 in repository-relevant environments, the Titanium Grade 29 general corrosion rate is calculated from the long term Titanium Grade 7 data. Titanium Grades 7 and 29 were tested in four environments representing seepage and deliquescent brine environments expected in the repository (SNL 2007 [DIRS 180778], Table 6-7[a]), and from that data a CDF of conversion ratios was calculated (SNL 2007 [DIRS 180778], Table 6-8[a]). This CDF is sampled once per realization in TSPA and the value selected is used as a multiplier on the general corrosion rate determined for Titanium Grade 7 to calculate the general corrosion rate for Titanium Grade 29 (SNL 2007 [DIRS 180778], Section 6.2.2[a]).

While the outer surface of the drip shield may be exposed to seepage water and dust films, the inner surface will not (SNL 2007 [DIRS 180778], Sections 6.3, 6.5.2, and 6.5.3). Therefore, general corrosion of the inner and outer surfaces of the drip shield is modeled by using different sets of corrosion data: the outer surface corrosion rate is based on analysis of the aggressive condition data and the inner surface corrosion rate is based on analysis of the benign condition data as described in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.1.2[a]). For each realization of TSPA (SNL 2008 [DIRS 183478], Section 6.3.5), a single general corrosion rate is sampled from each general corrosion rate distribution. The two sampled values are then applied once each to the outer and inner surfaces of each drip shield simulated during the given realization. Using this conceptual model for drip shield general corrosion, all drip shields in the repository fail by general corrosion at the same time.

General corrosion of the drip shield is included in the TSPA. It is implemented in TSPA for all three standards: the groundwater protection standard (10 CFR 63.331 [DIRS 180319]), the

individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])), and the human intrusion standard (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). In the case of human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), the rate of general corrosion is used to determine the earliest time at which intrusion would be recognized by the drillers (SNL 2008 [DIRS 183478], Section 6.7.2).

FEP: 2.1.03.02.0A

FEP NAME:

Stress Corrosion Cracking (SCC) of Waste Packages

FEP DESCRIPTION:

Waste packages may become wet at specific locations that are stressed leading to stress corrosion cracking (SCC). The possibility of SCC under dry conditions or due to thermal stresses are also addressed as part of this FEP.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Stress corrosion cracking of the waste package outer barrier is included in the TSPA. Stress corrosion cracking can occur via three possible mechanisms:

(1) Through propagation of fabrication flaws in the waste packages. This is included under nominal repository conditions and is discussed in included FEP 2.1.03.08.0A (Early Failure of Waste Packages).

(2) Through propagation of incipient cracks that can occur on the waste package outer barrier closure welds (since these cannot be annealed to relieve tensile stress). This is included under nominal repository conditions and is discussed in *Stress Corrosion Cracking of Waste Package and Drip Shield Materials* (SNL 2007 [DIRS 181953]).

(3) Through seismic events. This is discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]). A network of through-wall cracks is assumed to form instantaneously following a seismic event of sufficient magnitude to induce residual stresses exceeding a threshold stress level. This network of cracks allows diffusive release of radionuclides through the waste package outer barrier. Seismic effects are discussed in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components), as well as excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damages EBS Components).

Stress corrosion cracking of the waste package outer barrier closure weld regions is included as part of the waste package degradation analyses. *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 8.4, Table 8-15) provides input for the treatment of waste package degradation by SCC of the waste package closure weld regions. Stress corrosion cracking of the TAD canister and stainless steel waste package inner vessel is not modeled because no flow performance credit is taken for these components after breach of the waste package outer barrier. Once the waste package outer

barrier fails, it is assumed that these vessels fail in a manner that allows the in-drift environment to contact the waste form and allows water or water vapor to enter the waste package.

As emplaced, stresses in the waste package Alloy 22 outer cylinder, including internal pressure stresses and contact stresses between waste package and pallet, are designed to be below the 0.9 to 1.05 times yield strength SCC-initiation criterion (SNL 2007 [DIRS 181953], Table 8-3; SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-05). Therefore, in the absence of seismic activity, only the closure weld regions, where tensile residual stresses exist, are potentially susceptible to SCC initiation and propagation. The weld regions are susceptible to SCC because: (1) welding can produce high residual tensile stress in the weld area, (2) there is a much higher density of flaws due to fabrication and welding in the welds than in the base metal, and (3) welding could result in segregation and nonequilibrium brittle phases, the occurrence of which could enhance the susceptibility of materials to SCC. In the current design, all the welds, with the exception of the final closure welds, are subject to solution heat treatment to relieve the tensile residual stress when the entire Alloy 22 canister is heat-treated before the loading of the waste. Seismic events of a significant magnitude may lead to regions of plastic deformation that have the potential of leading to sustained residual tensile stresses. These resultant sustained residual tensile stresses may initiate cracks and drive them through the wall. The crack opening area for through-wall cracking initiated by seismic events has been developed for the waste package material and is described in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.7). The breach criteria are based on a threshold stress, which is also discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.2). Seismic effects are discussed in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components), as well as excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damages EBS Components).

In the absence of seismic activity, weld residual stress is the only type of stress of concern for the waste package outer barrier. The stress mitigation of the outer lid closure weld will be by plasticity burnishing, which will impart a layer of compressive residual stress to a minimum depth of 3 mm (0.12 in.) (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-17; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-17). Based upon previous analyses using a compressive depth of 1.9 mm, a minimum mitigated depth of 4.6 mm (0.1811 in.) can be achieved for stress levels less than 90% of yield strength (BSC 2004 [DIRS 171499], Section 3.1.1.4.6). As described in *Waste Package Closure System Description Document* (BSC 2004 [DIRS 171499], Section 3.1.1.4.6), the performance acceptance criterion for stress mitigation is:

> Tensile stress from welding in the area near the intersection of the outer lid and outer barrier shall be mitigated by imparting a layer of compressive residual stress to a minimum depth of 1.9 mm (0.0748 in) and limiting tensile stress to 90 percent of yield stress to a minimum depth of 4.6 mm (0.1811 in).

According to the results of controlled plasticity burnishing in *Controlled Plasticity Burnishing (CPB) for Developing a Very Deep Layer of Compressive Residual Stresses in Rectangular Specimens of Alloy 22 for Yucca Mountain Nuclear Waste Package Closure Weld* (Woolf 2003

[DIRS 178059]), the desired through-wall stress profile at the closure weld can be produced by the plasticity burnishing process.

Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials (SNL 2007 [DIRS 181953]) provides stress and stress-intensity factor profiles; a threshold stress for crack initiation; a threshold stress-intensity factor for propagation; incipient crack size and density; and an estimate of crack-opening size. As discussed in the SCC report (SNL 2007 [DIRS 181953], Section 6.4), the slip dissolution–film rupture model is used to evaluate SCC crack propagation. *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.3) provides weld flaw size, density, and orientation distributions after non-destructive examination and repair.

Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials (SNL 2007 [DIRS 181953]) describes the results of SCC crack-initiation measurements under constant load conditions while immersed in a basic saturated water solution. Alloy 22 exhibits excellent SCC resistance, as cracking was not observed for any of the 120 Alloy 22 specimens covering a variety of metallurgical conditions (including the as-welded condition). The applied stress ratios used in the experiments were up to about 2.1 times the yield strength of the as-received material and up to 2.0 times the yield strength of the welded material. This stress ratio corresponds to an applied stress of about 89% to 95% of the ultimate tensile strength. The high degree of SCC-initiation resistance for Alloy 22 is corroborated by the results of high magnification visual examination of a number of Alloy 22 U-bend specimens exposed to a range of relevant environments at 60°C and 90°C in the LTCTF; no evidence of SCC initiation has been observed in these U-bend specimens after five years of exposure (SNL 2007 [DIRS 181953], Section 6.2.1.2.1).

Stress corrosion cracking can be initiated on a smooth weld surface (with incipient cracks) or at an existing weld flaw. Incipient cracks are considered to be 50-μm (0.05-mm) deep at the time of their nucleation and will be initiated on smooth surfaces when general corrosion has penetrated to the depth at which the tensile stress profile exceeds the threshold stress. Stress profiles reflect any stress mitigation performed, so stress mitigation is incorporated in the model. The threshold stress is taken to be 90% to 105% of the yield strength. Because weld flaws are already formed, they do not require a stress threshold to nucleate. However, most of the weld flaws are embedded within the material and are not exposed to the environment. As general corrosion proceeds, some initially embedded weld flaws may be exposed to the environment while others are corroded away. The evolution of the number of weld flaws is not considered in detail. Instead, only the fraction of weld flaws embedded within the outer one-fourth (0.25) of the weld thickness is considered capable of propagation.

The presence of stable “liquid” water is required to initiate corrosion processes (including SCC) that are supported by electrochemical corrosion reactions. Typically, a threshold relative humidity is used to simulate such a corrosion initiation condition (e.g., ASM International 1987 [DIRS 103753], pp. 80 to 82). In the waste package degradation analysis (SNL 2007 [DIRS 181953]), no threshold relative humidity is used (i.e., SCC occurs, if all stress and stress intensity factor criteria are satisfied, under any exposure conditions).

The discussion in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components) indicates that thermal expansion is not a source of stress and, therefore, not a driving force for SCC in the repository.

In summary, SCC of the waste package outer barrier is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure at proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) and with the groundwater protection standard at 10 CFR 63.331 [DIRS 180319]. As opposed to general corrosion, waste package SCC is a localized effect and will not significantly affect overall waste package mechanical properties. Therefore, the earliest time after disposal that the waste package would degrade sufficiently that a human intrusion could occur without recognition by the drillers (SNL 2008 [DIRS 183478], Section 6.7.2) would not be affected, and SCC of the waste package is not included in the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) due to low consequence.

FEP: 2.1.03.02.0B

FEP NAME:

Stress Corrosion Cracking (SCC) of Drip Shields

FEP DESCRIPTION:

Drip shields may become wet at specific locations that are stressed leading to stress corrosion cracking (SCC). The possibility of SCC under dry conditions or due to thermal stresses are also addressed as part of this FEP.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The principal postclosure functions of the drip shield are to prevent: (1) rockfall from impacting and damaging the waste package, and (2) seepage waters from contacting the waste package. As explained below, if SCC were to occur in either the seepage diverting Titanium Grade 7 drip shield plate material or the Titanium Grade 29 structural support component material, it would not significantly subvert the drip shield functions. Stress corrosion cracking in the drip shield plate material is assumed to occur under repository conditions in regions where sustained tensile stresses exceed a threshold tensile stress value of 80% of the at-temperature yield strength, as discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.8.3.3, Table 6-32). If SCC is initiated, it is conservatively assumed that it will immediately propagate through-wall (SNL 2007 [DIRS 181953], Section 6.8.4.2.2). For the Titanium Grade 29 structural support component material, the threshold tensile stress value is 50% of the at-temperature yield strength (SNL 2007 [DIRS 181953], Table 6-32). The principal sources of stress that could result in SCC in the Titanium Grades 7 and 29 drip shield materials are: (1) weld-induced residual stress, (2) plasticity-induced residual stress caused by seismic events, and (3) stress produced by rockfalls and drift collapse (SNL 2007 [DIRS 181953], Section 6.8). In addition, thermal loading has the potential to induce stresses in the drip shield components.

Stress relief of tensile residual stresses in the welded regions of the drip shield will be accomplished by furnace heating at 1,100°F ± 50°F for a minimum of 2 hours (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-13). ASM Handbook data (Boyer et al. 2003 [DIRS 174636], pp. 608 to 609) indicates that this heat treatment will be sufficient to decrease stress levels below the threshold stresses for initiation of SCC in the drip shield materials. Therefore, properly annealed drip shields are not subject to SCC upon emplacement. The potential for early drip shield failure due to low probability manufacturing defects including improper drip shield heat treatment is considered in included FEP 2.1.03.08.0B (Early Failure of Drip Shields).

As summarized in excluded FEP 2.1.07.02.0A (Drift Collapse), non-seismic drift collapse will result in only minor degradation or collapse of the drift (including enlargement). This will result

in only minor and localized deviations from the currently predicted thermal and hydrologic conditions, and minimal consequences to the EBS components including the drip shield.

As discussed in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components), the drip shield connectors are designed to allow for thermal expansion with no effect on drip shield performance up to at least 300°C. Since the drip shield is farther from the heat source (i.e., the decaying waste forms), its temperature will be lower than the waste package surface temperature. As discussed in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components), the peak waste package surface temperature could exceed 300°C in the event of a low probability seismic-induced drift collapse with low thermal conductivity rubble occurring within the first 90 years following closure. However, the probability of generation of such conditions is less than one in 10,000 within the first 10,000 years of disposal. Within a few hundred years of closure, the waste package surface temperature drops below 200°C (SNL 2008 [DIRS 179962], Section 7.1). Therefore, no thermal expansion stresses high enough to initiate SCC will result from thermal loading in the repository. However, even if SCC were to initiate during this relatively short time period, as discussed later, the consequences relative to the seepage diversion function of the drip shield would be negligible.

Seismic effects on drip shield degradation are discussed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), included FEP 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components), and excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damage to EBS Components). Rockfall and early failure of the drip shield are discussed in more detail in excluded FEP 2.1.07.01.0A (Rockfall) and included FEP 2.1.03.08.0B (Early Failure of Drip Shields), respectively. More details on the treatment of SCC as a result of seismic effects on drip shield performance due to SCC are discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Sections 6.10, 6.12, and 7.1).

The tightness of stress corrosion cracks in passive alloys such as Titanium Grade 7 (i.e., small crack-opening displacement) as well as their tortuosity will preclude the advection of liquids and solids through these cracks as discussed in excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids through Cracks in the Drip Shield). Therefore, since the primary role of the Titanium Grade 7 drip shield plates is to keep water from contacting the waste package, SCC of the Titanium Grade 7 drip shield plates does not compromise the design purpose of the drip shield.

Further, since propagation of SCC in Titanium Grade 7 is a result of repetitive passive film rupture, anodic dissolution, and repassivation events at the just-initiated or propagating crack tip (SNL 2007 [DIRS 181953], Section 6.8.4.1), there is no effect of SCC on the surrounding material that could lead to other corrosion degradation modes. However, since SCC does result in the formation of tight crevices, the potential effect of crevice corrosion in Titanium Grade 7 does need to be considered. Crevice corrosion of Titanium Grade 7 is evaluated in excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields) and excluded FEP 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces Due to Deliquescence).

Under hot, dry conditions such as occur during about the first 100 years following repository closure, it may be possible for so-called hot salt cracking to occur on any tensile stressed regions of the drip shields in areas where salt deposits may be present. Unlike SCC, however, hot salt cracking is not observed below about 260°C (ASM International 1987 [DIRS 101992], p. 688),

which is above the maximum drift wall and drip shield temperatures under expected conditions (SNL 2008 [DIRS 179962], Section 6.4.3.3, Figure 6.4.3-3). If hot salt cracking occurs under unexpected conditions in which drip shield temperatures exceed 260°C, it will result in a crack morphology similar to SCC (ASM International 1987 [DIRS 101992], p. 688). Thus, if it were to occur, the expected impact on drip shield seepage diversion would be the same as for SCC (i.e., negligible).

Stress corrosion cracking, once initiated, is conservatively assumed to propagate immediately through-wall in the Titanium Grade 7 drip shield plate material. However, for the case of deformation-induced secondary type stresses that may result from rockfall or seismic impact, because of the high creep induced stress relaxation rate observed for Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 6.8.5.1 and 6.8.3.1.2 and Figure 6-72) and the relatively low stress corrosion crack growth rates measured for Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 6.8.4.2), it is expected that for regions with initiated SCC, the propagating crack tip stress intensity factor will decrease over time and drop below the threshold value, K_{ISCC}, needed to continue crack propagation. This is expected to lead to partial through-wall crack arrest (SNL 2007 [DIRS 181953], Section 6.8.5.1). In contrast to Titanium Grade 7, for the Titanium Grade 29 structural support material, the stress relaxation rate is lower because of its higher creep resistance (BSC 2005 [DIRS 174715], Attachment I, Figure I-13). However, the measured crack growth rate of annealed Titanium Grade 29 (approximately 5×10^{-9} to 6×10^{-9} mm/s at 25 ksi√in (27.5 MPa√m) at 150°C (SNL 2007 [DIRS 181953], Figure 6-78(a)) is much lower than that of annealed Titanium Grade 7 (approximately 1.3×10^{-8} mm/s at 110°C at 27.3 ksi√in (30 MPa√m)) (SNL 2007 [DIRS 181953], Figure 6-76(a)) even though the Titanium Grade 29 rate was measured at a higher temperature than that of Titanium Grade 7. Further, since it is observed that crack growth rates in Titanium Grade 7 drop by about two orders of magnitude as a result of 20% plastic deformation (SNL 2007 [DIRS 181953], Table 6-33), the growth rate for Titanium Grade 29 is also expected to drop significantly in regions of high residual stress levels (i.e., in regions deformed due to rockfall or seismic impacts). For a one order of magnitude drop in rate (i.e., to ~5×10^{-10} mm/s (~0.0158 mm/yr) at 25 ksi√in (27.5 MPa√m)), crack propagation through the 76-mm-thick Titanium Grade 29 structural supports (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-08) would take a significantly longer time, about 5,000 years, compensating for the lower stress relaxation rate. Further, at some stage of its propagation, when the crack becomes sufficiently large, it will affect the overall stiffness (compliance) of the drip shield resulting in crack blunting, or, in the case of a confined drip shield, in load and stress redistribution. This crack blunting or redistribution of stress will reduce stress concentrations and the resultant stress intensity factors and thus inhibit further crack propagation.

Thus, SCC does not affect the ability of the drip shield to maintain its seepage diversion function and it will continue to prevent rockfall from damaging the waste package. Therefore, omission of FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.03.0A

FEP NAME:

Localized Corrosion of Waste Packages

FEP DESCRIPTION:

Localized corrosion (pitting or crevice corrosion) could enhance degradation of the waste packages.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Localized corrosion is corrosive attack at discrete sites or in a nonuniform manner. Based on a conservative linear growth model, the rate of localized corrosion penetration, if it occurs, is generally higher than the rate of general corrosion penetration and could lead to eventual breach of waste packages.

The two main routes through which an aqueous solution could come into contact with the waste package surface are dust deliquescence and seepage. The possibility of localized corrosion of the WPOB due to brines produced by dust deliquescence is discussed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence). Localized corrosion initiation due to seepage water contact is discussed here. The potential impact of dripping condensate on waste package corrosion is discussed in excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield).

Localized corrosion of the WPOB is conservatively considered to be able to initiate regardless of relative humidity (SNL 2007 [DIRS 178519], Section 5.1), although in reality localized corrosion can only initiate under certain exposure conditions (SNL 2007 [DIRS 178519], Section 6.4.4). Localized corrosion requires the presence of at least a thin aqueous film in contact with the metal surface for a period of time. This is required to establish separate cathodic and anodic areas on the metal surface. The persistence of the thin aqueous film will depend on the temperature of the alloy surface. If the temperature of the alloy surface is significantly higher than the boiling point of pure water, then the water film–alloy interface may not exist because the aqueous film should evaporate upon contact with the alloy surface. However, seepage water can exist on the waste package surface at temperatures in excess of the normal boiling point of pure water due to elevation of boiling point by the presence of dissolved species. As mentioned in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.4.2), seepage water is not expected to contact the waste package surface if the waste package surface temperature exceeds 120°C. Even if the WPOB temperature is 120°C or lower, seepage water will not be able to contact the waste package surface if the drip shield is intact. Consequently, the localized corrosion model is evaluated only if the waste package temperature is below 120°C (SNL 2007 [DIRS 178519], Sections 8.3.1 and 6.4.4) and the overlying drip shield has failed. Drip shield degradation is discussed in included

FEPs 2.1.03.01.0B (General Corrosion of the Drip Shields) and 2.1.03.08.0B (Early Failure of Drip Shields), and excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields). Localized corrosion in the form of pitting generally occurs on boldly exposed surfaces whereas that in the form of crevice corrosion takes place in occluded regions as discussed in *General Corrosion and Localized Corrosion of the Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.4). Although both pitting and crevice corrosion can initiate on Alloy 22 surfaces, crevice corrosion is the only form of localized corrosion that is modeled. This is a conservative treatment because the initiation thresholds for crevice corrosion, in terms of exposure parameters such as chemistry and temperature, are lower than those required for pitting corrosion (SNL 2007 [DIRS 178519], Section 5.3). Crevices may be formed on the waste package surface at occluded regions such as in between the waste package and its supports and potentially beneath mineral scales, corrosion products, dust, rocks, etc. The chemical environment in a creviced region may be more severe than the near-field environment due to the buildup of metal cations in solution resulting from the corrosion process, as well as the migration of potentially aggressive anions from the near-field environment. Metal ion hydrolysis can lead to the accumulation of hydrogen ions and a corresponding decrease in pH. Electromigration of chloride ions (and other anions) into the crevice must occur to balance the charge within the creviced region. Chloride ions can cause initiation of crevice corrosion on the Alloy 22 WPOB and are, therefore, generally referred to as "aggressive" ions.

The WPOB localized corrosion model is used in the TSPA to evaluate the extent of WPOB degradation by localized corrosion under the expected repository environmental conditions over the regulatory performance period. The submodels included in the WPOB localized corrosion model are the crevice repassivation potential, long-term corrosion potential, and crevice corrosion propagation models (SNL 2007 [DIRS 178519], Section 6.4.4). If localized corrosion initiates, the fraction of the WPOB surface contacted by seepage water is considered to be affected by localized corrosion (SNL 2007 [DIRS 178519], Section 8.3.1).

According to *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 8.3.1), localized corrosion of the WPOB may occur when the corrosion potential (E_{corr}) is equal to or greater than a threshold potential ($E_{critical}$), that is, $\Delta E = (E_{critical} - E_{corr}) \leq 0$. The magnitude of ΔE is an index of the localized corrosion resistance, i.e., the larger the positive difference, the greater the resistance to localized corrosion. The localized corrosion model uses the crevice repassivation potential (E_{rcrev}) as the critical potential for the crevice corrosion initiation analysis (i.e., $E_{critical} = E_{rcrev}$). The crevice corrosion initiation model components (i.e., E_{corr} and E_{rcrev}) are functions of the exposure conditions (temperature, pH (E_{corr} only), chloride ion concentration, and nitrate ion concentration, but not relative humidity as noted previously). The localized corrosion model assumes that, once initiated, localized corrosion of the waste package outer barrier propagates at a (time-independent) constant rate. This is a conservative assumption because it is known that the crevice corrosion propagation rate decreases with time (SNL 2007 [DIRS 178519], Section 6.4.4.8).

Anions containing nitrogen, carbon, and sulfur, which are present in the repository groundwater, exhibit varying degrees of inhibitive effects on localized corrosion (Thomas 1994 [DIRS 120498]; Dunn et al. 2004 [DIRS 173813]). Inhibitive anions counteract the effects of aggressive anions (e.g., chloride ions), which tend to accelerate dissolution and breakdown of the oxide passive films formed on Alloy 22. Nitrate ions have a strong inhibitive effect on localized

corrosion of Alloy 22 in chloride-containing solutions (SNL 2007 [DIRS 178519], Section 6.4.4.3). A study of welded Alloy 22 samples in 0.5 M NaCl solutions at 95°C demonstrated that the nitrate ion is an effective inhibitor of localized corrosion of Alloy 22, when the nitrate-to-chloride concentration ratio is greater than 0.2 (Dunn and Brossia 2002 [DIRS 162213]). Dunn et al. (2004 [DIRS 173813]) and Ilevbare (2005 [DIRS 173814]) have shown that sulfate ions decrease the localized corrosion susceptibility of Alloy 22 in chloride-containing solutions. Dunn et al. (2004 [DIRS 173813]) also concluded that carbonate anions were almost as effective as nitrate anions in inhibiting the initiation of localized corrosion on Alloy 22 and that bicarbonate anions inhibited localized corrosion to a lesser extent. The relationship between the inhibitive and aggressive anions corresponds to competitive adsorption or ion exchange at a fixed number of sites on the oxide surface (Thomas 1994 [DIRS 120498]). Inhibitive anions overcome the effects of aggressive anions through participation in competitive adsorption such that the adsorbed inhibitive anions reduce the surface concentration of aggressive anions below a critical value (Thomas 1994 [DIRS 120498]).

The WPOB crevice corrosion initiation model is used to evaluate the crevice corrosion initiation behavior of the Alloy 22 WPOB. The Alloy 22 WPOB contains solution-heat-treated welds and base metal that have had the solution-heat-treated film removed as well as low-plasticity-burnished closure weld regions (e.g., SNL 2007 [DIRS 179394], Section 4.1; Table 4-1, Parameter Number 03-17). Initiation of localized corrosion may be possible when seepage water contacts the waste package outer barrier surface. If the exposure temperature is greater than or equal to 20°C, and less than or equal to 120°C, then to implement the WPOB crevice corrosion initiation model, the empirical correlations for the long-term corrosion potential (E_{corr}) and crevice repassivation potential (E_{rcrev}) (SNL 2007 [DIRS 178519], Section 8.3.1) are evaluated in accordance with the following implementation rules.

(a) If the nitrate ion-to-chloride ion ratio in the environment exceeds 1, then evaluate E_{rcrev} and E_{corr} at a nitrate ion-to-chloride ion ratio of 1. If the molality of chloride ion is less than 0.0005 molal, the nitrate ion-to-chloride ion ratio should be evaluated with a chloride-ion concentration of 0.0005 molal.

(b) If the molality of chloride ion in the environment exceeds 20 molal, then evaluate E_{rcrev} and E_{corr} at a chloride-ion molality of 20 molal. If the molality of chloride ion is less than 0.0005 molal, then evaluate E_{rcrev} and E_{corr} at a chloride-ion molality of 0.0005 molal.

(c) If the pH in the environment exceeds 10, then evaluate E_{corr} at a pH of 10. If the pH in the environment is less than 1.9, then initiate localized corrosion.

If crevice corrosion initiates, then crevice corrosion propagates at a constant rate throughout the simulation period regardless of changes in the bulk chemical exposure environment. This is a conservative modeling assumption (SNL 2007 [DIRS 178519], Assumption 5.4) and is used because the localized corrosion model does not account for the possibility of crevice corrosion repassivation or stifling. Nitrate ions inhibit localized corrosion initiation (SNL 2007 [DIRS 178519], Section 6.4.4.3). In addition, carbonate and sulfate ions may have an inhibitive effect on localized corrosion. Therefore, because only nitrate ions are accounted for in the model, the results for solutions with significant amounts of other potentially inhibitive ions in addition to

nitrate are conservative (SNL 2007 [DIRS 178519], Section 8.3.1). The model results for the beneficial effects of the inhibitive ions combined with alkaline pH conditions of the typical carbonate-containing waters in the repository are consistent with the experimental observations on the immunity of Alloy 22 to localized corrosion in those waters (SNL 2007 [DIRS 178519], Section 7.2.3).

Before waste loading, the waste packages (base-metal and fabrication welds) will be solution-annealed for 20 minutes at about 1,120°C to 1,150°C and then quenched (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-16). This heat treatment results in the formation of a solution-annealed oxide film on the WPOB surface. Torres et al. (2006 [DIRS 182745], Figures 3.2.2.2(f) and 3.2.2.4(f)) observed that the crevice repassivation potentials of welded Alloy 22 specimens solution-annealed at about 1,120°C for 20 minutes with the solution-annealed oxide film removed were not significantly different from the crevice repassivation potentials of as-welded Alloy 22 specimens. The presence of the solution-annealed oxide films increases the Alloy 22 crevice repassivation potential in concentrated solutions, but decreases it in less concentrated solutions (Etien et al. 2005 [DIRS 182742]; Rebak et al. 2006 [DIRS 182744]). As the WPOB crevice repassivation potential model was developed using crevice repassivation potentials from Alloy 22 specimens without solution-annealed oxide films, and the solution-annealing oxide film could increase the uncertainty in predictions of localized corrosion initiation of the WPOB at lower chloride concentrations, the solution-annealing oxide film will be removed during waste package fabrication (SNL 2007 [DIRS 179394], Section 4.1).

The WPOB localized corrosion initiation model outputs consisting of mean values of model coefficients along with associated uncertainties are documented in Section 8 of *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Table 8-2). The entire variance of the crevice corrosion initiation model (i.e., the crevice repassivation potential model and the long-term corrosion potential model) is attributed to uncertainty. Variability in the crevice repassivation potential and long-term corrosion potential is represented with the temporally and spatially varying waste package temperature and water chemistry contacting the waste packages. An appropriate distribution of the Alloy 22 crevice corrosion propagation rate is provided in Table 8-3 of *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519]). The variation in crevice corrosion propagation rate is attributed to uncertainty.

Alloy 22 crevice samples were tested for over 5 years in three different solutions (simulated dilute water, simulated concentrated water , and simulated acidified water) at 60°C and 90°C in the LTCTF. The crevice corrosion data of the WPOB material (Alloy 22) that were generated in fully immersed conditions were assumed to be applicable to the crevice corrosion processes of the waste package in contact with thin water films (under porous layers of dust and mineral precipitates) having the same water chemistry as the fully immersed condition (SNL 2007 [DIRS 178519], Section 5.5). None of the crevice samples has shown any indication of localized corrosion attacks after being tested for over five years (SNL 2007 [DIRS 178519], Section 7.2.4). Stereomicroscope and scanning electron microscope examination of the crevice specimens tested in the LTCTF for five years clearly showed no preferential dissolution at any grain boundary, confirming the absence of intergranular attack (Wong et al. 2004 [DIRS 174800]).

In summary, localized corrosion of the WPOB is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure at proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) and with the groundwater protection standard at 10 CFR 63.331 [DIRS 180319]. Although pitting and crevice corrosion of Alloy 22 are possible, only crevice corrosion is represented in the WPOB degradation model. In the TSPA model, it is assumed that, once initiated, localized corrosion of the waste package outer barrier propagates at a constant rate. In the TSPA model, no credit is taken for the corrosion resistance of the disposal/TAD canister or the waste package inner vessel. Therefore, once the waste package outer barrier has failed, it is conservatively assumed that the waste form is directly exposed to the water or air of the repository environment. The crevice corrosion initiation model is intended exclusively for evaluating the long-term localized corrosion susceptibility of the WPOB and is not intended for short-term transient behavior.

As opposed to general corrosion, waste package localized corrosion is by definition a localized effect and will not significantly affect overall waste package mechanical properties. Therefore, the earliest time after disposal that the waste package would degrade sufficiently that a human intrusion could occur without recognition by the drillers (SNL 2008 [DIRS 183478], Section 6.7.2) would not be affected, and localized corrosion of the waste package is not included in the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) due to low consequence.

FEP: 2.1.03.03.0B

FEP NAME:

Localized Corrosion of Drip Shields

FEP DESCRIPTION:

Localized corrosion (pitting or crevice corrosion) could enhance degradation of the drip shields.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Titanium and its alloys are resistant to general and localized corrosion due to the formation of a protective oxide layer on the metal surface in the presence of oxygen and moisture (Jones 1996 [DIRS 105076], p. 524). Both of these conditions are expected to be persistent within the repository. The drip shield plates are to be fabricated from Titanium Grade 7 (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04), which is alloyed with 0.15% palladium for increased localized corrosion resistance. The drip shield structural support members are to be fabricated with Titanium Grade 29 (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04), which is higher strength titanium containing approximately 6% aluminum, 4% vanadium, and 0.1% ruthenium, the latter of which is added to improve localized corrosion resistance, analogous to the impact that palladium has in Titanium Grade 7.

In *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 5.6), localized corrosion of the titanium drip shield is assumed to initiate when the corrosion potential (E_{corr}) equals or exceeds the threshold potential for breakdown of the passive film ($E_{critical}$). A correlation between exposure parameters (temperature, chloride ion concentration, and pH) and the difference between the critical potential ($E_{critical}$) and the corrosion potential (E_{corr}) (i.e., $\Delta E = E_{critical} - E_{corr}$) was developed to indicate when localized corrosion could be initiated. Localized corrosion initiates when ΔE is less than or equal to zero (i.e., when E_{corr} is greater than or equal to $E_{critical}$). The critical or threshold potential is defined as the potential where the current density in the forward portion of an anodic cyclic polarization scan rapidly increases, rather than the potential at which any specific value of the current density is achieved (SNL 2007 [DIRS 180778], Section 6.6.1). The results show, for Titanium Grade 7, that the mean ΔE is generally in excess of 1 V over all anticipated ranges of pH, chloride concentration, and temperature (SNL 2007 [DIRS 180778], Section 6.6.3) in the repository. Localized corrosion of Titanium Grade 7 is not expected to initiate in repository-relevant environments even at pH values as high as 14 (SNL 2007 [DIRS 180778], Section 8.4).

For the drip shield application in the repository, there is an early period of dry air exposure prior to aqueous exposure. During this time, the drip shield will be subjected to a long period of slow thermal oxidation resulting in the formation of a thick and relatively defect-free oxide coating on the Titanium Grades 7 and 29 components of the drip shield (SNL 2007 [DIRS 180778], Section 6.4.1). An increase in the oxide film thickness, coupled with a decrease in defect

concentration in the oxide film, will decrease the susceptibility of the passive film to fluoride-induced breakdown and, hence, fluoride-chloride-induced localized corrosion of the drip shield (SNL 2007 [DIRS 180778], Section 6.5.7). Handbooks (e.g., Revie 2000 [DIRS 159370], p. 865; ASM International 1987 [DIRS 103753], p. 669) indicate that damaged titanium oxide films can re-heal instantaneously if at least trace amounts of oxygen are present. Project analyses indicate that the repository will always support oxidizing exposure conditions (SNL 2007 [DIRS 177412], Section 8.1); therefore, such oxide films are expected to form, and be stable, in the period prior to the contact of the drip shield by any seepage water.

The presence of crevices and concentrated calcium and magnesium chloride solutions and their influences on corrosion were also evaluated in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Sections 6.5.8, 6.6.4, and 6.6.5). The results in that report (SNL 2007 [DIRS 180778], Section 6.6.5) show that the passive film on Titanium Grade 7 is stable in concentrated calcium and magnesium chloride solutions and the passive current density is not increased under such conditions. The minimum ΔE observed in these studies (obtained in 9 *M* $CaCl_2$ at 150°C) is 1.4 V (SNL 2007 [DIRS 180778], Table 21), which supports the exclusion of localized corrosion in these environments.

As discussed in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.5.7), the presence of dissolved fluoride ions can, under certain conditions, increase the general corrosion rate of titanium alloys, including Titanium Grades 7 and 29, and possibly destabilize the passive film. As discussed below, while certain fluoride-containing environments have been found to initiate localized corrosion, under repository-relevant exposure conditions the passive film on titanium is expected to remain stable.

Short-Term Tests and Fluoride Effects:

The literature results for fluoride effects on titanium corrosion include experiments conducted under a wide range of fluoride, chloride, nitrate, pH, and temperature conditions. In addition, the applied experimental approaches also vary, including both uninstrumented exposure testing as well as standard electrochemical techniques. It should be noted that the aforementioned combination of varying environmental and electrochemical conditions utilized throughout the literature hinder the establishment of general conclusions from any one result.

The scientific literature includes observations of both localized corrosion and enhanced general corrosion resulting from exposure of titanium alloys to certain fluoride bearing electrolytes (Pulvirenti et al. 2003 [DIRS 162574]; Pulvirenti et al. 2002 [DIRS 159841]; Lorenzo de Mele and Cortizo 2000 [DIRS 159833]; Brossia and Cragnolino 2001 [DIRS 162420]; Brossia and Cragnolino 2004 [DIRS 180832]; Lian et al. 2005 [DIRS 173979]; Lian et al. 2006 [DIRS 183947]).

Localized corrosion of Titanium Grade 7 in the form of pitting attack and, in one case, SCC has been reported by Pulvirenti et al. (2003 [DIRS 162574]; 2002 [DIRS 159841]) in a simulated groundwater environment augmented with both fluoride and chloride. In that study, samples were exposed under open circuit conditions to chloride-fluoride solutions at several temperatures and pH values. Pitting was observed in 1 *M* (35,500 ppm) chloride plus 0.1 *M* (1,900 ppm) fluoride at pH values from 6.5 to 7.2 at 105°C, but not in that same environment at 160°C

(Pulvirenti et al. 2002 [DIRS 159841], Tables 3 and 4). In cases where pitting was observed, initiation tended to be at mechanical defects on the metal surface, and Pulvirenti theorized that the initiation sites were probably contaminated with iron deposited during production of the sample based upon the experimental observation that pitting did not initiate at defects made with a diamond scribe. It should also be noted that pitting was not observed in an environment containing 48,000 ppm chloride and 14,400 ppm fluoride at 105°C, suggesting that the aggressiveness of such solutions is not a direct function of the fluoride content. Cyclic polarization testing revealed a decrease in repassivation potential with increasing chloride concentration for chloride-fluoride solutions, and suggested an inhibiting effect by nitrate but no inhibiting effect by sulfate (Pulvirenti et al. 2003 [DIRS 162574], Figure 1 and Table 2).

The behavior of Titanium Grade 7 in environments containing 1 *M* chloride with fluoride additions up to 0.1 *M* was evaluated using cyclic polarization and open circuit exposures of creviced samples by Lian et al. (2006 [DIRS 183947]). Results of this testing were consistent with that reported by Pulvirenti et al. (2003 [DIRS 162574]; 2002 [DIRS 159841]). Cyclic polarization in deaerated 1 *M* NaCl plus 0.1 *M* NaF at pH 8 and 95°C showed Titanium Grade 7 to be active during the reverse scan until E_{corr} was reached with localized attack reported following the polarization scan, indicating that Titanium Grade 7 will not remain passive in this environment under free-corrosion conditions (Lian et al. 2006 [DIRS 183947], Figure 7). This result was corroborated with open circuit testing in the same environment where localized attack was observed after two weeks of exposure (Lian et al. 2006 [DIRS 183947], Table 2).

Brossia and Cragnolino (2001 [DIRS 162420]; 2004 [DIRS 180832]) used short-term electrochemical testing in chloride-fluoride solutions to elucidate the effect of fluoride on the corrosion behavior of Titanium Grade 7. In contrast to the other studies cited above, Brossia and Cragnolino primarily observed an influence of fluoride on the passive current density. They found that increasing fluoride concentration in 1 *M* NaCl at 95°C resulted in increased passive current density up to values approaching 10^{-4} $A \cdot cm^{-2}$ (Brossia and Cragnolino 2004 [DIRS 180832], Figures 8 and 9). Addition of nitrate and sulfate to a chloride-fluoride solution did not appreciably alter the passive current density compared to the binary chloride-fluoride solution (Brossia and Cragnolino 2004 [DIRS 180832], Figure 10). In these experiments the samples were anodically polarized to 0 V versus saturated calomel electrode and the measured steady-state current reported as the passive corrosion rate. These results may not be directly applicable to the nominal conditions in the repository as the drip shield materials will be at open circuit rather than anodically polarized.

Localized corrosion of Titanium Grade 1 (unalloyed titanium containing neither platinum nor ruthenium) in the form of blisters was reported by de Mele and Cortizo following a 6-day exposure to synthetic saliva (pH equal to 6.5) with the addition of 0.2 *M* fluoride (Lorenzo de Mele and Cortizo (2000 [DIRS 159833]). They observed that if fluoride ions were added shortly after electrode immersion (while the oxide film was still growing and, hence, defective), the corrosion potential decreased rapidly (probably due to attack of the oxide). However, if the oxide film was allowed to grow for four days, then addition of the same amount of fluoride ions had no observable effect over the subsequent two days of exposure. These data suggest that growth or healing of the oxide prior to introduction of fluoride may decrease the initial susceptibility to oxide breakdown.

Corrosion of Titanium Grade 7 was measured by Lian et al. (2005 [DIRS 173979]) in 1 *M* NaCl + 0.1 *M* NaF at 95°C and pH values of 4, 8, and 11. Annealing samples for 3 hours at 593°C prior to exposure had the effect of decreasing the passive current density and increasing the open circuit potential. An annealed sample exposed under open circuit conditions in pH 8 solution had an initially low corrosion rate compared to a freshly polished sample; however, the corrosion rate of the annealed sample increased after 4 days of exposure to a value similar to that of the polished sample. Samples exposed to the pH 4 electrolyte underwent localized attack during a one-week open circuit exposure independent of the annealing treatment, although the annealed sample suffered less attack. It was concluded that the thick thermal oxide that forms during annealing can improve the corrosion resistance of Titanium Grade 7 but could not prevent the fluoride ion attack at low pH. It should be noted that the only samples reported to suffer localized corrosion in this study were those exposed to acidic conditions (pH 4). Extrapolation of this behavior to higher pH values representative of expected repository conditions is not appropriate, and localized corrosion is not expected at repository-relevant pH values.

Long-Term Tests and Fluoride Effects:

While the literature cited above suggests that under specific non-repository-relevant combinations of pH, temperature, [Cl^-] and [F^-], it is possible to initiate localized corrosion on Titanium Grade 7, as demonstrated below, localized corrosion will not initiate for repository-relevant environments. The influence of fluoride on titanium corrosion under repository-relevant conditions can be gained by examination of the localized corrosion results from multi-year tests conducted at the LTCTF, in which Titanium Grades 7 and 16 were evaluated.[1] Excellent corrosion behavior was observed on noncreviced and creviced Titanium Grade 7 and Grade 16 specimens during 2.5- and 5-year exposures, respectively; the general corrosion rates obtained were low, and no initiation of localized corrosion was observed (SNL 2007 [DIRS 180778], Section 6.5.1). Tests included exposure of samples to fluoride-bearing SCW (about 1,000× ionic concentration of J-13 well water with target composition of: 1,400 mg/L fluoride (0.07 *m*); 6,700 mg/L chloride (0.19 *m*); 6,400 mg/L nitrate (0.1 *m*); 16,700 mg/L sulfate (0.17 *m*); and 27 mg/L (0.001 *m*) to 49 mg/L (0.0017 *m*) silica at a pH value of ~9.8 to 10.2 (DTN: LL040803112251.117 [DIRS 171362], file: *LL040803112251.117 Table 1.pdf*)). The SCW environment contains nitrate and fluoride at a concentration ratio of 1.4:1 and contains other anions such as sulfate and bicarbonate; the resulting chemical composition is benign towards localized corrosion of titanium.

Repository Relevant Environments and Fluoride Effects:

Although the concentrations of fluoride and chloride that have been shown to cause initiation of localized corrosion on Titanium Grade 7 (e.g., 1 *M* chloride plus 0.1 *M* fluoride (Pulvirenti et al. 2003 [DIRS 162574]; Lian et al. 2006 [DIRS 183947])) are possible under normal repository conditions, the expected repository environments are more complex, containing additional cationic and anionic species, and are better represented by the SCW environment. A comparison of the SCW environment, the chloride-fluoride environment where localized corrosion has been

[1] It is important to emphasize that Titanium Grade 16 has less than half the level of palladium as Titanium Grade 7 and as such is considered to be less corrosion-resistant than Titanium Grade 7. This provides an additional level of confidence that Titanium Grade 7 will not be susceptible to localized corrosion over longer exposure times.

observed, and the Group 1 water predicted by the near-field chemistry model[2] is shown in Table 2.1.03.03.0B-1. While the chloride and fluoride concentrations of the evaporated in-drift waters are greater than the SCW, the presence of additional anions in the system inhibits localized corrosion from initiating. Therefore, the SCW environment is most appropriate in assessing the potential for initiation of localized corrosion under expected repository conditions.

Higher fluoride levels can result when potential seepage waters predicted by the near-field chemistry model are evaporatively concentrated on the drip shield surface (peak of 0.71 *m*, DTN: SN0701PAEBSPCE.001 [DIRS 180523], folder: Lookup Tables\ PCE Gp 1 LUT, files: *1jp2t30.xls* and *1lp2t30.xls*). However, a GoldSim analysis (DTN: MO0709TSPALOCO.000 [DIRS 182994], file: *LA_v5.000_LC_Initiation_Analysis_v2_ Conceptual_ Description.pdf*) demonstrates that the repository conditions required for highly elevated fluoride do not or only rarely occur. The simulation determines that an environmental boundary condition exists where water that has the highest WRIP, a parameter from the near-field chemistry model that typically lowers calcium and thereby increases fluoride, is unable to reach the repository horizon while the relative humidity is below 85%; these two conditions must occur simultaneously to begin to approach the 0.71 *m* fluoride levels cited previously, as seen by inspection of the evaporative seepage water lookup tables (DTN: SN0701PAEBSPCE.001 [DIRS 180523], folder: Lookup Tables).

Conceptually, this environmental boundary exists because to attain a high WRIP value, the water percolating through the mountain must see an extended thermal plume, which can only occur after peak in-drift temperatures have been reached and after which the relative humidity will be increasing. At both the expected and elevated WRIP levels, while temperatures are between 70°C and 100°C (no seepage is expected above 100°C), the concentrations of F^- are similar (compare the near-field chemistry water compositions in Table 2.1.03.03.0B-1). As the drip shield temperatures come down below 70°C, higher relative humidity prevails, such that while higher water–rock interaction may occur, resident seepage compositions are becoming more dilute. These environmental constraints, based on a GoldSim total system performance analysis in conjunction with inspection of the evaporative seepage water lookup tables (DTN: SN0701PAEBSPCE.001 [DIRS 180523]), constrain fluoride levels to below 0.2 *m*. For the expected repository conditions, the levels of fluoride achieved due to evaporative concentration appear constrained below 0.2 *m* for Group 1 seepage, and less than 0.01 *m* for seepage Groups 2 through 4.

[2] Extensive analysis of TSw porewater compositions from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and determined to fall into four compositional "groups" (SNL 2007 [DIRS 177412], Section 6.6). Group 1 water has distinctly lower calcium concentrations and higher pH (SNL 2007 [DIRS 177412], Figure 6.6 17); as such, it consistently has the highest potential fluoride concentrations of the four group waters when evaporated.

Table 2.1.03.03.0B-1. Comparison of Solutions from Corrosion Testing with the Expected Repository Compositions

Water Identity	a_w	T (°C)	pH	Cl	F	NO_3	SO_4	HCO_3	Na	K	Source

NOTES: Activity of water (multiply by 100 to express as relative humidity) from DTN: LL060904312251.186 [DIRS 178283]. Lian et al. [DIRS 183947] and Pulvirenti et al. 2002 [DIRS 159841] activity is estimated as average of a similar monovalent mixture (1 *m* NaCl + 0.15/0.05 *m* KCl, files *19.3o* and *20.3o*). SCW from file: *2f.3o*. NFC results are directly from source 4.

Units of chemical species are in molar (*M*) for Lian et al. 2006 [DIRS 183947] and Pulvirenti et al. 2002 [DIRS 159841], and molal (*m,* mole solute per kg water) for all others. Values are rounded to simplify comparison.

This review of the experimentally observed influences of fluoride on titanium corrosion and comparison of the test environments to expected repository environments shows that while combinations of chloride and fluoride may cause localized corrosion initiation on titanium, no localized corrosion has been observed after up to 5 years of exposure to SCW, which is the most relevant fluoride-bearing test environment (SNL 2007 [DIRS 180778], Section 7.5). Additionally, similar long-term exposures were performed under two other aqueous conditions termed SAW and SDW, also with no observed initiation of localized corrosion (SNL 2007 [DIRS 180778], Section 6.6.4). In light of the above discussion, localized corrosion of Titanium Grade 7 is not expected to initiate under relevant repository exposure conditions. The passive film is expected to be stable even when crevices are present and the material is exposed to concentrated solution environments containing chloride (e.g., calcium or magnesium chloride) and fluoride ions alongside other species such as nitrate.

In addition to the Titanium Grade 7 plate material discussed previously, the drip shield will also have a series of Titanium Grade 29 structural members (SNL 2007 [DIRS 179354], Table 4-2, Parameter Numbers 07-01 and 07-04). Titanium Grade 29 differs compositionally from Titanium Grade 7 and, as such, can exhibit a different electrochemical response under certain environmental conditions. Cyclic polarization testing of noncreviced Titanium Grades 29 and 7 specimens at 120°C and 150°C in multi-ionic electrolytes containing various levels of $CaCl_2$, KCl, KNO_3, $NaNO_3$, NaCl, Na_2SO_4, NaF, and NaBr revealed similar behavior for the two alloys,

and specifically, that no localized attack was observed for either material following polarization (Andresen and Kim 2006 [DIRS 178239], Table 11 and Figures 46 to 53). Additionally, a limited set of cyclic polarization experiments were performed on creviced samples in concentrated NaCl plus KCl with and without KNO_3 and NaF at temperatures at or above 110°C (DTN: LL070800612251.197 [DIRS 183159], file: *Ti Gr 7 Gr 29 Electrochemical Developed Aug07*). In the case of Titanium Grade 7, the critical potentials were consistently high. In the case of the Titanium Grade 29, the passive current density was increased to greater than 20 mA/cm^2 in most cases (consistent with observations from the literature (Brossia and Cragnolino 2004 [DIRS 180832], Figures 8 and 9) discussed previously), hindering the use of critical potentials such as the E_{20} (i.e., the potential at which the measured current density exceeds 20 $\mu A/cm^2$). Furthermore, unlike Titanium Grade 7, crevice corrosion was initiated at large anodic polarizations ($E_{applied}$ > 1V versus SSC), and as a result, considerable hysteresis is present in the cyclic polarization scans, making the repassivation potential (i.e., E_{RCO} – the potential at which the return portion of the polarization scan crosses the upwards scan) the most appropriate critical potential to use in the case of Titanium Grade 29. If ΔE is calculated as $E_{RCO} - E_{corr}$, its magnitude is consistently large and greater than zero, with values ranging from 492 to 2,276 mV for the environments presented in DTN: LL070800612251.197 [DIRS 183159]. Given the large positive values observed for ΔE, initiation of localized corrosion for unpolarized samples under such conditions is not expected.

As discussed above, localized corrosion was observed on Titanium Grade 7 under certain specific combinations of pH, temperature, $[Cl^-]$, and $[F^-]$. As such, it follows that under similar conditions, localized corrosion could potentially initiate on Titanium Grade 29, given that it is less resistant to localized corrosion than Titanium Grade 7. Furthermore, there is no long-term data for Titanium Grade 29 as there is for Titanium Grade 7. Given this lack of data, it may be possible for localized corrosion to initiate on Titanium Grade 29 under some subset of repository environments, similar to those discussed above for Titanium Grade 7. This subset of environments is only considered possible when "aggressive" seepage water, as discussed in *General and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.1.6[a]), is present on the drip shield surface. The only Titanium Grade 29 structure exposed to such conditions is the side support framework; the crown support framework of the drip shield is underneath the Titanium Grade 7 plates and therefore is in the benign environment, which is incapable of initiating localized corrosion.

The consequence of any localized corrosion of the Titanium Grade 29 side framework would be to make the drip shield more susceptible to failure under rock load and subsequent buckling of the sidewall, but there would not be any increase in the snap-through failure of the crown failure mode (SNL 2007 [DIRS 176828], Section 6.8.3.1). In the event of framework collapse where the Titanium Grade 7 plates are still intact, the drip shield continues to function as a barrier to seepage, as discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], p. 6-232, item e). As this is the primary purpose of the drip shield in the performance assessment, an increase to the side framework failures under rock load due to possible localized corrosion of Titanium Grade 29 would not have a significant affect on dose calculations.

In conclusion, localized corrosion of the drip shield sufficient to affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment will not occur. Omission of FEP 2.1.03.03.0B (Localized Corrosion of Drip

Shields) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.04.0A

FEP NAME:

Hydride Cracking of Waste Packages

FEP DESCRIPTION:

The uptake of hydrogen and the formation of metal hydrides may mechanically weaken the waste packages and promote degradation.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Hydrogen generated at cathodic sites on a corroding metal may be absorbed into the metal and, if present at a sufficiently high concentration, could degrade the mechanical properties and potentially increase the metal's susceptibility to crack initiation and/or propagation. The hydrogen concentration achieved within a material is a direct function of the rate at which atomic hydrogen is generated at the metal surface (e.g., the rate of the water reduction reaction on a corroding metal), which in turn defines the surface coverage of adsorbed hydrogen. The subsurface absorbed hydrogen concentration (i.e., atomic hydrogen dissolved in the metal matrix at the metal surface) achieved is determined by this surface coverage combined with the efficiency through which it is absorbed into the metal. Once hydrogen has been absorbed into the metal, it will then migrate further into the material via diffusional processes. This migration will continue until there is no longer a chemical potential gradient to drive diffusion (i.e., the bulk hydrogen concentration is equivalent to the subsurface hydrogen concentration). The term hydrogen embrittlement is used to refer to the deleterious impact of hydrogen on the mechanical properties of a material. Hydrogen-induced cracking results from the combined action of absorbed hydrogen and residual or sustained applied tensile stresses, whereby crack initiation and/or propagation occurs at lower stress levels than in the absence of absorbed hydrogen. In the case of nickel-based alloys such as Alloy 22, hydrogen embrittlement typically manifests as a reduction in fracture toughness or an overall loss of ductility (ASM International 1987 [DIRS 103753], pp. 650 to 652). It should be noted that solid solution strengthened nickel-based alloys such as Alloy 22 do not form a hydride phase.

The Alloy 22 waste package, when emplaced, is protected by the drip shield. The drip shield will prevent any fallen ground support from contacting the waste package, thereby eliminating the chances of galvanic coupling. Likewise, the pallet will keep the waste package from contacting the invert (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03), thereby precluding the galvanic coupling between the waste package and any material (such as carbon steel) in the invert. However, in the event that either the drip shield or the pallet fail to prevent electrical isolation of the waste package from the metals in the support structure or invert, hydrogen-induced cracking of Alloy 22 will still not take place due to the properties discussed in the following text. Hydrogen-induced cracking of the internal stainless steel components will not occur prior to waste package breach due to the insignificant degree of corrosion (excluded

FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach)), and thus, lack of sufficient hydrogen production (from the cathodic reactions supporting any metal oxidation).

Hydrogen-induced cracking of the waste package outer barrier (Alloy 22) will not occur under repository-relevant exposure conditions for the following reasons:

- The rate of general corrosion for Alloy 22 under repository-relevant conditions is extremely low (SNL 2007 [DIRS 178519], Sections 6.4.3 and 8.2). As such, the supporting cathodic reaction rate, even if assumed to be entirely due to the water reduction reaction, will not result in a sufficiently large absorbed hydrogen concentration to embrittle Alloy 22 (ASM International 1987 [DIRS 103753], p. 652).

- Fully annealed and uncoupled Ni-Cr-Mo alloys (such as Alloy 22) are effectively immune to hydrogen-induced cracking (ASM International 1987 [DIRS 103753], pp. 650 to 652; Gdowski 1991 [DIRS 100859], Section 5.12). Alloy 22 is a Ni-Cr-Mo alloy, and each waste package will be fully annealed (with the exception of the closure weld, which will be stress-mitigated).

- Although Ni-Cr-Mo alloys, such as Alloy 22, are susceptible to hydrogen-induced cracking when heavily cold-worked and cathodically charged with hydrogen (via an impressed current or galvanic couple to a more active material) in environments containing substantial concentrations of hydrogen recombination poisons such as hydrogen sulfide or arsenic trioxide, such conditions are not repository-relevant. These recombination poisons dramatically increase the surface coverage of the metal with adsorbed atomic hydrogen, thereby increasing the achievable subsurface hydrogen concentration (Asphahani 1978 [DIRS 160352], Section III.3 and Table 8; ASM International 1987 [DIRS 103753], p. 651). These environmental and electrochemical conditions are far outside the realm of what may take place on the waste package surface, including contact of the waste package with more active materials such as carbon steel from the invert or other features within the drift, which is not expected to occur. Even in cases where the microstructure could be rendered susceptible to hydrogen embrittlement, the cathodic reaction rate on the Alloy 22 surface is far too low to achieve an embrittling concentration (ASM International 1982 [DIRS 103753], p. 652).

- Aging of Ni-Cr-Mo alloys at temperatures around 500°C can lead to ordering, or grain-boundary segregation of deleterious elements such as phosphorus, which can increase susceptibility to hydrogen-induced cracking (ASM International 1987 [DIRS 103753], p. 169; Asphahani 1978 [DIRS 160352]). For the waste package surface to exceed 300°C, a seismic event of sufficient magnitude must occur within approximately 90 years after closure, resulting in drift collapse and subjecting a waste package to an unfavorable combination of a high thermal output surrounded by low-conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about one in 10,000 within the first 10,000 years after closure (SNL 2008 [DIRS 179962], Table 6.5-5). Even if such ordering or grain-boundary segregation of deleterious elements were to occur, the hydrogen concentrations required to cause embrittlement of a Ni-Cr-Mo alloy that had

been thermally aged as described previously can not be achieved without a substantial externally applied cathodic current density in environments that promote hydrogen uptake.

- As discussed in excluded FEP 2.1.09.09.0A (Electrochemical Effects in EBS), contact between the Alloy 22 waste package outer barrier and Titanium Grade 7 drip shield is not expected. However, if it were to occur, galvanic corrosion would not be expected to take place. Both of these materials are electrochemically passive under repository-relevant conditions. As such, there will be little or no galvanic interactions between the two materials. (ASM International 1987 [DIRS 103753], p. 675), and thus there would be no significant increase in hydrogen uptake in either material due to metal-to-metal contact.

To summarize, (1) fully annealed Ni-Cr-Mo alloys (including Alloy 22) are highly resistant to hydrogen-induced cracking even when heavily cold-worked or thermally aged to induce ordering or grain boundary segregation of sulfur or phosphorus, requiring hydrogen concentrations far in excess of what might be achieved within Yucca Mountain to cause embrittlement; (2) the extremely low corrosion rates exhibited by Alloy 22 in repository environments will not generate sufficient hydrogen to cause hydrogen-induced cracking; and (3) if other materials from within the drift (e.g., drip shield, pallet, etc.) come into contact with the waste package, the resultant galvanic couples will not result in an increased rate of metal oxidation, and thus will not cause increased hydrogen production and uptake at the waste package surface. Therefore, hydrogen embrittlement will not occur, and hydrogen-induced cracking (e.g., hydride cracking) of the waste package is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311, 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP NAME:

Hydride Cracking of Drip Shields

FEP DESCRIPTION:

The uptake of hydrogen and the formation of metal hydrides may mechanically weaken the drip shields and promote degradation.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

The drip shield plates are to be fabricated from Titanium Grade 7, an α-titanium alloy, 15-mm thick (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04). The drip shields are supported by Titanium Grade 29, an α+β titanium alloy, support beams (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04). The Titanium Grade 29 drip shield support beams, which are external to the drip shield and exposed to seepage water and are more prone to hydrogen absorption than the crossmembers located on the underside of the drip shield (SNL 2007 [DIRS 179354], Table 4-2). Failure of the drip shields due to general corrosion is discussed in included FEP 2.1.03.01.0B (General Corrosion of Drip Shields).

Hydrogen absorption in both α-titanium and α-β titanium alloys can occur when three general conditions are simultaneously met (Covington 1979 [DIRS 151097], pp. 378 to 381; Schutz and Thomas 1987 [DIRS 144302], p. 673; SNL 2007 [DIRS 181339], Section 6.1.2):

(1) A mechanism exists for generating nascent (atomic) hydrogen on the surface (e.g., the water reduction reaction is a thermodynamically viable cathodic reaction).

(2) The temperature of the drip shield is above approximately 80°C (175°F) such that a surface film of hydride is not formed and the diffusion rate of hydrogen into α-titanium is significant.

(3) Either (a) the solution pH is less than 3 or greater than 12, or (b) impressed potentials are sufficiently cathodic to induce the redox transformation of Ti^{4+} to Ti^{3+} within the passive TiO_2 oxide (approximately −0.7 V versus the saturated calomel reference electrode under near neutral conditions).

By assuming that the only viable cathodic reaction on the titanium surface is the water reduction reaction, condition (1) is always met as long as aqueous corrosion occurs. At certain repository locations, where temperatures are greater than or equal to 80°C (175°F) and concentrated groundwater is present, conditions (2) and (3) may also be satisfied. However, it should be noted that while the aforementioned three conditions are necessary requirements for hydrogen absorption, they are not sufficient in determining if hydrogen embrittelment will take place. A

critical hydrogen concentration within the metal must be achieved in order to reduce the mechanical properties to the extent that hydrogen-induced cracking can occur (SNL 2007 [DIRS 181339], Section 8). It should also be noted that given the oxic conditions that will prevail within any given drift, the assumption that the cathodic current density is solely due to the water reduction reaction will consistently overestimate the hydrogen production rate as the oxygen reduction reaction, the expected cathodic reaction, is assumed not to occur.

The term hydrogen embrittlement is used to refer to the deleterious impact of hydrogen on the mechanical properties of a material. Hydrogen-induced cracking results from the combined action of hydrogen and residual or sustained applied tensile stresses, whereby crack initiation and/or propagation occur at lower stress levels than in the absence of absorbed hydrogen. The critical hydrogen concentration of Titanium Grade 7 is estimated as 1,000 ppm (μg/g) (SNL 2007 [DIRS 181339], Section 5.2). The critical hydrogen concentration of Titanium Grade 29 is estimated as between 400 and 600 ppm (μg/g) (SNL 2007 [DIRS 181339], Section 5.2[a]). The value of f_h, fractional hydrogen absorption efficiency, is conservatively selected as 0.015 (SNL 2007 [DIRS 181339], Sections 8.1 and 8.3.2). By using the 2.5-year general corrosion rates obtained for Titanium Grade 7 obtained at the LTCTF, the 0.999 probability value from the upper 97.5% uncertainty bound general corrosion rate of Titanium Grade 7 in the aggressive environment (90°C SCW) is about 58 nm/yr (SNL 2007 [DIRS 181339], Table 4-1[a]). At 10,000 years, the hydrogen content in the drip shield thus calculated is 105 μg/g (SNL 2007 [DIRS 181339], Section 8[a] and Table 8-1[a]), which is well below the critical hydrogen concentrations for Titanium Grade 7.

Because no long-term data from the LTCTF are available for general corrosion rate of Titanium Grade 29 in repository-relevant environments, the Titanium Grade 29 general corrosion rate is calculated from conversion factors based upon short-term experiments as discussed in *General and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.2.2[a]). By using the Titanium Grade 29/Titanium Grade 7 corrosion rate ratio multiplier values, the absorbed hydrogen concentrations in Titanium Grade 29 drip shield support beam material are calculated in *Hydrogen-Induced Cracking of the Drip Shield* (SNL 2007 [DIRS 181339], Section 6.2[a]). Using the 75th percentile multiplier and the 0.999 probability value from the upper 97.5% uncertainty bound of the Titanium Grade 7 general corrosion rate in the specified aggressive environment, at 10,000 years, the hydrogen content in the drip shield structural support material (Titanium Grade 29) is 84 μg/g. Using the 95th percentile multiplier and the 0.999 probability value from the upper 97.5% uncertainty bound of the Titanium Grade 7 general corrosion rate in the specified aggressive environment, at 10,000 years, the hydrogen content in the drip shield structural support material (Titanium Grade 29) is 191 μg/g. These conservatively calculated hydrogen content values are well below the critical hydrogen concentrations for Titanium Grade 29 (400 to 600 ppm) (SNL 2007 [DIRS 181339], Section 8.1[a] and Table 8-2[a]).

The locally hydrided regions that may potentially result from galvanic effects (e.g., from failed rock bolts or ground supports contacting the drip shield surface) will not be sufficiently large in magnitude such that they result in hydrogen-induced cracking as illustrated in *Hydrogen-Induced Cracking of the Drip Shield* (SNL 2007 [DIRS 181339], Section 6.3.2). The rationale presented in the reference includes the following points: (1) the contact area is small and has a low anode-to-cathode area ratio, (2) the presence of seepage is anticipated to be intermittent at

temperatures greater than or equal to 80°C (175°F), (3) sustaining the water reduction reaction under the repository conditions is unexpected, and (4) the titanium drip shield and the steel component surfaces that may contact it will experience a long period of dry conditions where the temperature is greater than or equal to 85°C (185°F), resulting in the formation of a thermal oxide, in effect passivating both materials, thereby minimizing any potential galvanic interactions and preventing increased hydrogen absorption.

When a titanium alloy containing an appreciable concentration of aluminum (e.g., Titanium Grade 29) is welded with an aluminum-free alloy (e.g., Titanium Grade 7), an abrupt concentration gradient of aluminum is formed at the weld fusion line. This concentration gradient has been found to drive uphill diffusion of hydrogen from the aluminum-rich material to the aluminum-poor material, resulting in the formation of hydride bands along the weld fusion line, increasing the susceptibility of the weld region to hydrogen embrittlement (SNL 2007 [DIRS 181339], Section 6.3[a]). To eliminate the potential for hydride band formation due to hydrogen redistribution, the weld filler metal utilized will be Titanium Grade 28 (SNL 2007 [DIRS 179354], Table 4-2; SNL 2007 [DIRS 181339], Section 6.3[a]). That is, welds made between Titanium Grade 7 plates and Titanium Grade 29 support beams will be conducted utilizing Titanium Grade 28 filler material. Titanium Grade 28 has an aluminum content of 2.5% to 3.5 %, providing an intermediate level between the Titanium Grade 7 plates and Titanium Grade 29 support beams. As a result, the abrupt aluminum concentration gradient that has been found to result in hydrogen redistribution and the enhanced hydride formation can take place when high aluminum alloys are welded with a low aluminum filler metal is avoided (SNL 2007 [DIRS 181339], Section 6.3[a]; Kennedy 1993 [DIRS 177388]).

Based on the previous dicscussion, FEP 2.1.03.04.0B (Hydride Cracking of Drip Shields) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 2.1.03.05.0A

FEP NAME:

Microbially Influenced Corrosion (MIC) of Waste Packages

FEP DESCRIPTION:

Microbial activity may either directly (e.g., direct enhancement of the dissolution rate) or indirectly (e.g., through the formation of chemical species, which in turn support increased metal oxidation) enhance the corrosion rate of the waste package, leading to an acceleration of the corrosion rate beyond the levels anticipated based upon the bulk environment to which it is exposed.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Microbially influenced corrosion is the contribution to the corrosion rate of a metal or alloy due to the presence, activity, or both, of microorganisms. Limited microbial populations and effects are expected in the repository (SNL 2007 [DIRS 178519], Section 6.4.5), and microbial activity in the EBS is excluded on the basis of low consequence in FEP 2.1.10.01.0A (Microbial Activity in EBS).

Microbially influenced corrosion most often occurs due to the increase in anodic or cathodic reactions due to the direct impact of microorganisms on the alloy or by indirect chemical effects on the surrounding solution (SNL 2007 [DIRS 178519], Section 6.4.5). Microbially influenced corrosion of the waste package is discussed in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.5). The effect of MIC on waste package corrosion is incorporated via an MIC enhancement factor (i.e., MIC increases the general corrosion penetration rate). In this approach, the abiotic corrosion rate is multiplied by the MIC enhancement factor, f_{MIC}. The magnitude of the enhancement factor was determined by comparing the electrochemical behavior of Alloy 22 in a solution inoculated with bacteria cultured from the Yucca Mountain site, to its behavior in a sterile solution of the same chemical composition. The test solution was inoculated with microbes cultured from the Yucca Mountain site including sulfate-reducing, acid-producing, iron-oxidizing, and slime-producing bacteria. The range of the MIC enhancement factor is uniformly distributed between 1 and 2 and is attributed to variability (SNL 2007 [DIRS 178519], Sections 6.4.5 and 8.2). It is applied to the waste package outer barrier general corrosion rate when the relative humidity at the waste package outer barrier surface is greater than a threshold relative humidity value sampled from a uniform distribution between 75% and 90% (SNL 2007 [DIRS 178519], Sections 6.4.5 and 8.2), where the threshold relative humidity defines the minimum relative humidity required for bacterial colonization to take place and potentially impact the corrosion process. MIC has not been evaluated in detail for possible impacts on the stainless steel inner vessel because the TSPA model does not take credit for corrosion resistance of that material. This treatment of MIC is applied to all waste packages.

Despite the fact that microbial activity is expected to have little impact on the in-drift chemical environment, as discussed previously, MIC of waste packages is implemented for the groundwater protection standard (10 CFR 63.331 [DIRS 180319]), and the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])). In the case of human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), MIC of waste packages is not implemented in the assessment of the earliest time at which intrusion would be recognized by the drillers because that is determined by drip shield corrosion rates (SNL 2008 [DIRS 183478], Section 6.7.2).

FEP: 2.1.03.05.0B

FEP NAME:

Microbially Influenced Corrosion (MIC) of Drip Shields

FEP DESCRIPTION:

Microbial activity may either directly (e.g., direct enhancement of the dissolution rate) or indirectly (e.g., through the formation of chemical species, which in turn support increased metal oxidation) enhance the dissolution rate of the drip shield, leading to an acceleration of the corrosion rate beyond the levels anticipated based upon the bulk environment to which it is exposed.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Microbial activity in the EBS is discussed in detail in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS). That evaluation concluded that the repository will impose severe environmental constraints upon the growth of any viable populations of microbes. FEP 2.1.10.01.0A (Microbial Activity in EBS) is excluded, therefore, on the basis of low consequence. However, even if microbial activity were to occur on the drip shield, MIC will not compromise the ability of the drip shields to perform in accordance with their design intent, and as such will not significantly change radionuclide releases to the accessible environment or radiological exposures to the RMEI.

The drip shield is to be composed of two titanium alloys: Titanium Grade 7 for the plate material, and Titanium Grade 29 for the structural support (SNL 2007 [DIRS 179354], Table 4-2). Microbially influenced corrosion of titanium is discussed in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.7.2). Corrosion handbooks and literature reviews indicate that there have been no recorded case histories that document MIC of titanium and its alloys (Revie 2000 [DIRS 159370], Chapter 47; Little 1996 [DIRS 131533]; Brossia 2001 [DIRS 159836], Section 4.1.3). Titanium's immunity to microbially influenced corrosion stems from the stability of the TiO_2 passive film in environments containing the typical species present as the result of biogenic activity (Brossia 2001 [DIRS 159836], Section 4.1.3). Microbial activity can result in the formation of a wide variety of chemical species that have been associated with the enhanced corrosion of ferrous and other materials. As an example, sulfate-reducing bacteria biogenically reduce sulfate to sulfide (Borenstein 1994 [DIRS 118912], Section 2.3.1; Little 1997 [DIRS 100774], Figure 1). However, such bacterially generated species have not been demonstrated to induce enhanced corrosion of titanium. This includes the production of ammonia, sulfides, nitrites, ferrous ions, and organo-sulfur compounds that are often produced from anaerobic activity (Brossia 2001 [DIRS 159836], Section 4.1.3). Production of nitrates, polythionates, thiosulfates, and oxygen from biogenic activity associated with aerobic activity similarly does not significantly increase the corrosion rate of titanium alloys (Brossia 2001 [DIRS 159836], Section 4.1.3).

Typically, what has been observed in the case of titanium alloys exposed to biologically active environments during laboratory and in-service evaluations is the formation of a biofilm on the metal surface (Brossia 2001 [DIRS 159836], Section 4.1.3). While titanium may be susceptible to biofouling (i.e., accumulation of biologically produced material), the biofilm does not compromise the integrity of the passive film, and therefore biofouled titanium maintains its resistance to localized corrosion processes (Revie 2000 [DIRS 159370], Chapter 47).

Steep gradients in dissolved oxygen and pH can exist within biofilms, with aerobic and near-neutral pH in the outer layers becoming acidic and low in O_2 close to the metal surface (Shoesmith 1997 [DIRS 151179], Section 6). Biogenic production of hydrogen peroxide within biofilms has been observed experimentally at millimolar levels, the amount of which is thought to be controlled by bacterial enzymes generated during the aerobic respiration process (Shoesmith 1997 [DIRS 151179]). Hydrogen peroxide maintains a low pH (<3) near the metal by oxidizing metal cations that then undergo hydrolysis. These chemical changes have been demonstrated to ennoble (i.e., shift the corrosion potential to more positive values) high molybdenum stainless steels and superalloys by as much as 500 mV (Shoesmith 1997 [DIRS 151179], Section 6, Figure 16). It is reasonable to assume that a similar degree of ennoblement could take place for titanium, as it is also a highly polarizable material in the environments being considered here. As shown in Figures 19 and 20 of *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.6.3), the mean ΔE for Titanium Grade 7 in chloride solutions is at least 1,000 mV at acidic pH values (i.e., localized corrosion will not initiate even if the corrosion potential is increased by 1000 mV). Based upon this data, localized corrosion of Titanium Grade 7 will not be caused by bacterially induced ennoblement. Ennoblement can, however, lead to several beneficial effects, including thickening of the passive film and a decrease in the number and density of film defects (Shoesmith 1997 [DIRS 151179], Sections 3 and 6).

Based on the previous discussion, microbial activity will not significantly increase the kinetics of either anodic or cathodic reactions taking place on the drip shield surface. Consequently, there will be no significant impact of microbial activity on either the general or localized corrosion rates of titanium alloys (including Titanium Grades 7 and 29) under the exposure conditions anticipated within the repository. Omission of FEP 2.1.03.05.0B (Microbially Influenced Corrosion (MIC) of Drip Shields) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.06.0A

FEP NAME:

Internal Corrosion of Waste Packages Prior to Breach

FEP DESCRIPTION:

Aggressive chemical conditions within the waste package could contribute to corrosion from the inside out. Effects of different waste forms, including CSNF and DSNF, are considered in this FEP.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The waste package design requirements preclude internal corrosion of the waste package and contained material prior to breach. As discussed below, the current waste package design requires all waste packages to be dried and inerted with helium gas (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04). If a container is helium tight, no significant amount of oxidizing gases can enter it.

According to the current waste package design, all waste forms will be contained in waste form specific canisters. For example, the CSNF will be contained in TAD canisters made of 300 series stainless steel (e.g., Stainless Steel Type 316L) (SNL 2007 [DIRS 179394], Section 4.1.1.4). Individual TAD and naval canisters and combinations of DOE SNF and HLW canisters (referred to as codisposal) will be placed inside a waste package consisting of a Stainless Steel Type 316 inner vessel contained within an Alloy 22 waste package outer barrier (SNL 2007 [DIRS 179567], Section 4.1.1). All waste packages will be dried and backfilled with helium gas to achieve less than 0.43 mol (7.7 g) of H_2O in a 7 m^3 volume (e.g., a TAD canister volume) (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-04) in a manner similar to NUREG-1536 (NRC 1997 [DIRS 101903], Section 8.V.1). This amount of residual water can only cause a negligible amount of corrosion because 0.43 moles of water can produce 0.11 moles of Fe_3O_4 (per $3\ Fe + 4\ H_2O \rightarrow Fe_3O_4$) or about 4,800 mm^3 of Fe_3O_4 (given that the molar volume of Fe_3O_4 is 44.7 cm^3 (ASM International 1987 [DIRS 103753], p. 64, Table 2)). The inner vessel of the TAD canister waste package configuration has a nominal length, L, of 5,499.10 mm and a nominal diameter, d, of 1,821.2 mm (SNL 2007 [DIRS 179394], Table 4-3), so that the outer surface area of the inner vessel is about 3.7×10^7 mm^2 (calculating surface area as $2\pi(d/2)^2 + \pi dL$). Thus, 4,800 mm^3 of Fe_3O_4 corresponds to a layer of corrosion product about 0.13-µm thick ($4{,}800\ mm^3/3.7 \times 10^7\ mm^2$). This thickness is negligible compared to the thickness of the waste package outer barrier, inner vessel, or a TAD canister. Consideration of other corrosion products such as Fe_2O_3, Cr_2O_3, and NiO, or the surface areas of other waste package configurations or components would not alter this conclusion. Likewise, the potential presence of small quantities of residual boric acid (from the reactor SNF pools) cannot alter this conclusion, as the total corrosion of the waste package internals prior to breach is limited by the

water content alone. As discussed in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components), the impact of this thin corrosion product layer is not expected to lead to significant thermal expansion stresses in the waste package. Therefore, the presence of an inert atmosphere inside the waste packages and TAD canisters will severely limit oxidation (by oxygen gas and water vapor) within waste packages, and thereby preserve the chemical and physical stability of the waste form. The presence of an inert gas atmosphere will also ensure negligible corrosion degradation prior to breach of the waste packages (i.e., breach of both the outer barrier and inner vessel).

Residual moisture contained in the waste packages at the time of emplacement could cause corrosion on the internal surface of the waste package inner vessel. Previously waterlogged SNF rods within the waste package may serve as the source of this residual moisture (Kohli and Pasupathi 1986 [DIRS 131519]). However, the amount of moisture available will cause a negligible amount of corrosion as shown above, and the potential for degradation of the waste form containers is expected to be very remote (Kohli and Pasupathi 1986 [DIRS 131519]). Consequently, significant corrosion damage to the internal surface of the Stainless Steel Type 316 inner vessel is not expected to occur and is even less probable for the inner surface of the waste package outer barrier.

The amount of residual water in the commercial SNF, DOE SNF, and HLW glass waste packages will be very small due to drying and inerting the waste packages (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-04). Consequently, due to scarcity of water, corrosion in the commercial SNF, DOE SNF, and HLW waste packages prior to breach will be insignificant. If any DOE SNF-containing waste packages, such as those containing N Reactor fuel (i.e., uranium metal-based fuel), have more water, this water would be scavenged by the waste form due to the rapid corrosion rate of the metallic uranium that is the matrix of N Reactor SNF compared with other SNF (BSC 2004 [DIRS 172453], Table 6-9; Gray and Einziger 1998 [DIRS 109691], Section 4). DSNF waste packages containing N Reactor SNF may have residual free and chemically bound water at the time of sealing prior to placement in storage. If the N Reactor SNF cladding is significantly damaged, it could expose chemically reactive uranium metal surfaces to residual water, producing uranium oxide and uranium hydride. This chemically scavenged water is not available for corrosion of the waste package inner vessel or the waste package outer barrier. Other forms of DOE SNF are less damaged, and will contain much lower quantities of residual water due to drying prior to sealing for storage.

No credit is taken in the TSPA for the ability of DOE SNF canisters (within the waste package) to delay fuel degradation and radionuclide mobilization because the canisters will be constructed of stainless steel, which will degrade relatively fast once the waste package fails. Therefore, mechanisms that might enhance canister degradation prior to breach do not impact the predicted radionuclide releases from waste packages containing DOE SNF. The effects of radiolytically produced gases and other impacts owing to waste package internal pressurizations are discussed in excluded FEPs 2.1.13.01.0A (Radiolysis) and 2.1.03.07.0A (Mechanical Impacts on Waste Package).

Based on above discussion, insignificant corrosion damage of DOE SNF waste packages, defense HLW waste packages, and commercial SNF waste packages will occur due to drying of the waste form before loading, and backfilling of the waste packages with an inert gas. Omission

of FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.07.0A

FEP NAME:

Mechanical Impact on Waste Package

FEP DESCRIPTION:

Mechanical impact (dynamic loading) on the waste package may be caused by internal and external forces such as internal gas pressure, forces caused by swelling corrosion products, rockfall, and possible waste package or drip shield movement. Seismic-induced impacts are addressed in included FEP 1.2.03.02.0A, Seismic Ground Motion Damages EBS Components.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Mechanical loads may be exerted on waste packages through a variety of external or internal phenomena, as listed in the FEP description. These phenomena are discussed below, beginning with the mechanisms that can lead to internal gas pressurization of a waste package.

Mechanisms leading to internal gas pressurization—A number of mechanisms may lead to internal pressurization of a waste package from gas generation and/or temperature increases. The relevant mechanisms potentially leading to gas generation include:

- Pyrophoricity. Pyrophoricity of DOE SNF could occur because of exothermic reactions of uranium hydride and uranium metal in the DOE SNF with any oxygen and water that is present inside the waste package. Pyrophoricity is analyzed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF).

- Production of organic flammable gases. The only fuel waste types capable of producing organic flammable gases, such as methane and ethane, are the uranium-thorium carbide and plutonium-uranium carbide in DOE SNF. The volume of combustible gases from DSNF is analyzed in excluded FEP 2.1.02.29.0A (Flammable Gas Generation from DSNF).

- Decay-derived helium gas. Alpha particles are generated by the decay of actinide isotopes within the fuel pellets, and a fraction of the resulting helium gas may be released into the gap between the pellets and cladding and ultimately into the waste package if the fuel rod cladding fails. The production of decay-derived helium gas is analyzed in excluded FEP 2.1.12.02.0A (Gas Generation (He) from Waste Form Decay).

- Prepressurization and gaseous fission products in fuel rods. The fission products krypton and xenon are generated during in-reactor operation and may be released from the spent-fuel matrix. Total internal pressures of fuel pins upon removal from reactor due to the combined effects of prepressurization (with helium) and in-reactor production

of these gaseous fission products is analyzed by Rothman (1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins") and discussed in this FEP.

- Prepressurization of the waste packages. Waste packages will be cold vacuum dried and pre-pressurized with helium, as discussed below. The impact of temperature change on this initial pressurization is analyzed in this FEP.

- Residual moisture. Residual moisture contained on DOE SNF or on commercial SNF at the time of emplacement could generate or consume gases from corrosion on the internal surface of the waste package inner vessel. Gas generation from corrosion processes is analyzed in excluded FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach).

- Radiolysis. The potential pressurization caused by gases generated from radiolytic decomposition of free or chemically bound water inside a waste package is excluded on the basis of low consequence in excluded FEP 2.1.13.01.0A (Radiolysis). The potential for radiolysis to increase the pressure from water vapor in the waste package is also considered in this FEP.

- Microbial degradation. In-drift gas generation from microbial degradation is excluded on the basis of low consequence in excluded FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation), and is not considered further. Gas generation within the waste packages will be insignificant because of the high radiation environment and the lack of nutrients within the waste packages.

Waste package temperature increases after ventilation ceases because the spent fuel continues to generate heat. Peak waste package temperature occurs within the first 100 years after ventilation ceases at repository closure (SNL 2008 [DIRS 184433], Figure 6.3-76[a]). The maximum value of the peak waste package temperature varies between 174.7°C and 211°C for the hottest waste package (SNL 2008 [DIRS 184433], Table 6.3-49[a]). At 10,000 years after repository closure waste package temperatures range from approximately 25°C to 60°C (SNL 2008 [DIRS 184433], Figures 6.3-76[a]). These temperatures are for an intact drift; the thermal effects from drift collapse are discussed later.

The combined impacts of gas generation and temperature increase on internal pressurization of a waste package with commercial SNF contained in a TAD canister are discussed next, followed by an analysis of internal pressurization for codisposal waste packages with DOE SNF and HLW glass canisters or with DOE SNF and MCOs.

Internal pressurization of waste packages with CSNF in TAD canisters—The individual sources of gas generation or gas pressure in the TAD canister-bearing waste packages are as follows:

- Pyrophoricity cannot occur in commercial SNF because this fuel type does not contain uranium hydride or uranium metal.

- Organic flammable gases are not produced by commercial SNF because this fuel type does not contain uranium-thorium carbide fuel or plutonium-uranium carbide fuel.

- Helium from prepressurization of the fuel rods, fission-derived gases, and decay-derived helium may be released from failed commercial SNF fuel rods within the TAD canister. The radionuclides that are the major sources of decay-derived helium in SNF are: ^{244}Cm, ^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Am (Piron 2001 [DIRS 162396], Section 5.1.2). The decay-derived helium will accumulate in the solid matrix of the fuel pellets because the radionuclides are embedded in the fuel matrix and because most of the alpha particles from their decay are stopped within the fuel matrix. The contribution to fuel rod pressure from decay-derived helium is small in the first 100 years (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"). Because of the long half lives of some of these radionuclides, the decay-derived helium will continue to accumulate in the fuel matrix for a long time after disposal. However, the potential pressure increase in the waste package is within the waste package design limit at all times after repository closure, as demonstrated here.

  Pressure in the fuel rods results from prepressurization of the rods with helium and from release of fission-derived gases and decay-derived helium from the fuel matrix. A pressure of 5.5 MPa is suggested as the 99th percentile end-of-reactor-life gas pressure for PWR SNF rods (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"). Similarly, a pressure of 2 MPa is recommended for the end-of-life gas pressure for the BWR SNF rods (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"). The following discussion focuses on the PWR fuel rods because they bound the response of the BWR fuel rods with respect to gas pressure.

  If the fuel rod cladding fails, helium and fission gases will be released into the void volume within the waste package. The resulting pressure is estimated from the ideal gas law, based on the gap volume per fuel rod, the void volume inside the waste package, and the gap pressure. These three parameters are defined as follows:

  - The gap volume or free volume per fuel rod is given as 13 cm^3 for a fuel rod with a burnup of 47.5 GWd/MTU (Piron and Pelletier 2001 [DIRS 165318], Section 5.3.2.4.1), 30 cm^3 for a fuel rod with a burnup of 36 MWd/kg-U (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"), and an average value of 35 cm^3 (BSC 2006 [DIRS 181534], Section 6). The value of 35 cm^3 is used in this analysis because it maximizes the internal pressure in the waste package. The total initial gap volume inside all of the fuel rods is calculated as 153 liters, based on 21-PWR fuel assemblies with 208 fuel rods per assembly and a 35 cm^3 gap volume per rod (i.e., $21 \times 208 \times 35 = 152{,}900$ $cm^3 \approx 153$ liters).

  - The free volume inside the waste package is 4,737 liters (SNL 2007 [DIRS 180506], Table 6-3[a]).

  - The gap pressure is 5.5 MPa at 25°C, the 99th percentile pressure from Rothman (1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"). This analysis is based on the 99th percentile gap pressure because each TAD canister will be loaded at a single reactor and the 4,368 SNF rods from a single reactor may not represent a statistical sampling of all SNF rods. Note that the gap

pressure of 8.3 MPa is not considered here because it is referred to as "rare" (Johnson 1977 [DIRS 101687]), corresponding to unique conditions in the fuel rods for the Maine Yankee reactor (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins").

The resulting waste package pressure increase if the cladding on every fuel rod fails is estimated from a simplification of the ideal gas law, $P_2 = (P_1V_1)/V_2$, where the subscripts 1 and 2 denote conditions in the gap and in the waste package, respectively, and P and V denote pressure and volume, respectively. Numerically:

$$P_2 = (5.5 \text{ MPa})(153 \text{ liters})/(4{,}737 \text{ liters} + 153 \text{ liters}) = 0.172 \text{ MPa} \approx 25 \text{ psi}$$

at 25°C.

The maximum value of the peak waste package temperature for the hottest waste package with low percolation flux and low thermal conductivity of the host rock is 211.0°C (SNL 2008 [DIRS 184433], Table 6.3-49[a]). The resulting waste package pressure increase is estimated from a simplification of the ideal gas law, $P_3 = P_2(T_3/T_2)$, where the subscripts 2 and 3 denote conditions at 25°C and 211°C, respectively, and P and T denote pressure and temperature, respectively. Numerically, the waste package pressure increase is:

$$P_3 = (0.172 \text{ MPa})(211 + 273.15)(\text{K})/(25 + 273.15)(\text{K}) = 0.279 \text{ MPa} \approx 41 \text{ psi}$$

at the peak waste package temperature of 211°C. As a reminder, this peak temperature occurs within the first 100 years after repository closure, so the end-of-reactor-life gap pressure is an appropriate starting point for the analysis of waste package pressure at peak temperature. The pressure at 10,000 years is about 28 psi based on a similar calculation with a temperature of 65°C.

Decay-derived helium will continue to accumulate in the fuel matrix. Excluded FEP 2.1.12.02.0A (Gas Generation (He) from Waste Form Decay) provides a bounding estimate for the pressure resulting from the long-term buildup of helium in the gap. If the helium that accumulated for 10,000 years from alpha decay in a fuel rod with a burnup of 47.5 GWd/MTU is assumed to be completely released from the fuel matrix into the gap region between the fuel pellets and cladding, the pressure increase in the gap would be 90 bars at 20°C using a void volume of 13 cm^3/fuel rod (Piron and Pelletier 2001 [DIRS 165318], Section 5.3.2.4.1). This is an extreme upper bound because the release of fission gases from the fuel pellets into the gap is typically 3% or less for most fuel rods (Rothman 1984 [DIRS 100417], subsection: "Pressures and Stresses in Fuel Pins"). The total gap volume that would be estimated based on Piron and Pelletier (2001 [DIRS 165318], Section 5.3.2.4.1) is calculated as 57 liters (i.e., 21-PWR fuel assemblies with 208 fuel rods per assembly and a 13 cm^3 gap volume per rod ($21 \times 208 \times 13 = 56{,}784$ $cm^3 \approx 57$ liters)). The corresponding pressure inside the waste package for a temperature of 65°C at 10,000 years (with a total gap volume of 57 liters) is then given by a simplification of the ideal gas law, $P_5 = P_4(V_4T_5)/(V_5T_4)$, where the subscripts 4 and 5 denote conditions at 20°C for the gap volume and at 65°C for the void volume in the

waste package, respectively, and P, V, and T denote pressure, volume, and temperature, respectively. Numerically:

$$P_5 = (9\ \text{MPa})(57\ \text{liters})(65 + 273.15\ \text{K})/(4{,}737\ \text{liters} + 57\ \text{liters})/(20 + 273.15\ \text{K}) = 0.123\ \text{MPa} \approx 18\ \text{psi}.$$

Thus, at 65°C, the pressure inside a waste package from fission gases, helium from fuel rod prepressurization, and decay-derived helium is about 46 psi (28 psi + 18 psi). The total pressure from the fill gas, decay-derived helium, and the fission gas (mainly krypton and xenon) is analyzed by Rothman (1984 [DIRS 100417], Table 6), based on the assumption of a fill gas pressure of 500 psi at 20°C, 100% release of helium and 20% release of other gaseous fission products from the fuel pellets. The last three lines in the referenced table are relevant to the present analysis because the temperature at 100 years is 194°C, similar to the peak temperature of 211°C for this analysis, and because the temperature at 10,000 years is 30°C, similar to the temperature range used in TSPA for mean percolation flux and mean rock conductivity of 40°C to 55°C for this analysis. The total pressure increases by 2%, from 1,500 psi at 100 years to 1,530 psi at 10,000 years (Rothman 1984 [DIRS 100417], Table 6). The last line in the referenced table gives the total pressure inside a fuel rod at 10,000 years and 30°C as 1530 psi, assuming a gap volume of 30 cm^3 per fuel rod. Performing the same kind of calculation as done above (e.g., calculation of P_3) to calculate the pressure at 65°C yields a pressure inside a fuel rod of 1,707 psi. The total gap volume from all fuel rods inside a waste package (using the gap volume of 30 cm^3 given by Rothman (1984 [DIRS 100417, Table 6)) is about 131 liters ($21 \times 208 \times 30\ cm^3 = 131{,}040\ cm^3 \approx 131$ liters). Once again, performing the same kind of calculation as done above (e.g., calculation of P_2) to calculate the pressure at 65°C in a waste package that would result if every fuel rod failed yields a pressure of about 46 psi. This is the same as the pressure calculated above (46 psi) that used a measured gap pressure from fission gases and from helium from rod prepressurization of 5.5 MPa from Rothman (1984 [DIRS 100417], section: "Pressures and Stresses in Fuel Pins") and the calculated pressure from decay-derived helium of 90 bars (Piron and Pelletier 2001 [DIRS 165318], Section 5.3.2.4.1).

- The current waste package design requires the TAD canister-bearing waste packages to be dried and backfilled with helium gas (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04): "All TAD canisters and waste packages shall be dried and backfilled with Helium to achieve less than 0.43 moles (7.7 g) of H_2O in a 7 m^3 TAD canister after drying in a manner similar to NUREG-1536, *Standard Review Plan for Dry Cask Storage Systems*" (NRC 1997 [DIRS 101903], Section 8.V.1). The procedure described in NUREG-1567, *Standard Review Plan for Spent Fuel Dry Storage Facilities* (NRC 2007 [DIRS 149756], Section 9.5.4.1) is equivalent to NUREG-1536, for moisture removal and is therefore acceptable. Some chemically bound and adsorbed water will also remain in the waste package, and may be converted to gases by radiolysis. The impact of radiolysis on emplaced water is discussed in excluded FEP 2.1.13.01.0A (Radiolysis).

  Based on the drying process, corrosion within a sealed TAD canister-bearing waste package is not expected to be significant for gas production, based on the analysis in excluded FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach). The

0.43 mol of residual water can only cause a negligible amount of corrosion, generating a uniform layer of corrosion product (Fe_3O_4) that is approximately 0.13-μm thick. The thickness of this corrosion layer is insignificant compared to the initial thicknesses of the waste package outer corrosion barrier and inner vessel. In addition, the presence of the inert helium atmosphere inside the waste packages and TAD canisters will severely limit oxidization by any oxygen gas and water vapor within waste packages, thereby preserving the chemical and physical stability of the waste form. The presence of an inert helium atmosphere will also ensure negligible corrosion degradation prior to breach of the waste packages (i.e., breach of both the outer barrier and inner vessel).

In the unexpected event that the free water remains unreacted by corrosion, it could generate gas pressure as water vapor. Assuming a maximum temperature of 211°C and an available void volume for gas in the waste package of 4,737 liters (SNL 2007 [DIRS 180506], Table 6-3[a]), the pressure of water vapor is estimated using the ideal gas law as 0.051 psi:

$$
\begin{aligned}
p &= \frac{n\mathrm{R}T}{V}, \\
&= \frac{(0.43\,\mathrm{mol})\left(8.3143\,\frac{\mathrm{N\cdot m}}{\mathrm{mol\cdot K}}\right)(273.15+211)(\mathrm{K})}{(4{,}737\,\mathrm{L})\left(\frac{1{,}000\,\mathrm{cc}}{\mathrm{L}}\right)\left(\frac{1\,\mathrm{m}^3}{10^6\,\mathrm{cc}}\right)}, \\
&= 365\,\mathrm{N/m^2}, \\
&= 365\,\mathrm{Pa}, \\
&= 0.051\,\mathrm{psi}.
\end{aligned}
$$

This pressure could increase by 50%, to 0.08 psi, if radiolysis splits each mole of water vapor into one mole of hydrogen gas and 0.5 mole of oxygen gas.

All waste packages will be cold vacuum dried and initially prepressurized with 1 to 2 atmospheres of helium, as noted earlier. Using the upper bound of 2 atmospheres, the resulting waste package prepressurization is defined by the Gay-Lussac's law, $P_7 = P_6(T_7/T_6)$, where the subscripts 6 and 7 denote conditions at 25°C and 211°C, respectively. Numerically, the waste package prepressurization is:

$$P_7 = 2(14.7\text{ psi})(211 + 273.15)(\mathrm{K})/(25 + 273.15)(\mathrm{K}) = 47.7\text{ psi} \approx 48\text{ psi}$$

at the peak waste package temperature of 211°C. The pressure at 10,000 years from prepressurization is 33 psi, based on a similar calculation for a maximum temperature of 65°C.

In summary, the time-dependent pressure increases within the TAD canister-bearing waste package with commercial SNF in an intact drift are bounded by the following sources:

- No contribution from pyrophoricity

- No contribution from organic flammable gases
- Within the first 100 years after closure, 41 psi from fuel rod prepressurization, fission product gases, and decay-derived helium plus 48 psi from waste package prepressurization for a total internal pressurization of 89 psi at a peak waste package temperature of 211°C
- At 10,000 years after closure, 28 psi from fuel rod prepressurization and fission product gases, 18 psi from 10,000 years of decay-derived helium plus 33 psi from waste package prepressurization for a total internal pressurization of 79 psi at a waste package temperature of 65°C
- The internal pressurization from residual moisture is 0.08 psi, including radiolysis. The pressure from residual moisture is very small in comparison to the pressurization from decay-derived helium, fission product gases, and prepressurization of the fuel rods and waste package.

These predictions are based on a number of bounding assumptions, including (1) failure of all cladding, (2) release of all decay-derived helium from the fuel matrix at 10,000 years, (3) an initial prepressurization pressure of 2 atm in the waste packages, and (4) maximum temperatures from the thermohydraulic analyses for waste package temperature.

The maximum value of the peak waste package temperature can be significantly greater than 211°C if a drift collapses from a high intensity seismic event during the first 100 years after repository closure. In a collapsed drift with rubble surrounding the drip shield, the peak waste package internal temperature may be conservatively bounded by adding 50°C to the maximum waste package surface temperature of 300°C (i.e., 350°C) (SNL 2008 [DIRS 179962], Sections 6.1.6 and 6.5.1). A maximum value of 350°C increases the pressure from prepressurization of the fuel rods, fission gases, and decay-derived helium from 41 psi at a temperature of 211°C to:

$$(41 \text{ psi})(350 + 273.15)(\text{K})/(211 + 273.15)(\text{K}) = 52.8 \approx 53 \text{ psi},$$

and increases the pressure from prepressurization of the waste package from 29.4 psi at 25°C to:

$$2(14.7 \text{ psi})(350 + 273.15)(\text{K})/(25 + 273.15)(\text{K}) = 61.4 \text{ psi} \approx 61 \text{ psi},$$

for a total pressurization of 114 psi within the first 100 years after closure. The pressure from fuel rod prepressurization, fission gases, decay-derived helium and waste package prepressurization at 10,000 years is unchanged from 79 psi because the waste package temperature for a collapsed drift at 10,000 years is essentially equal to the value for an intact drift (SNL 2008 [DIRS 184433], Figures 6.3-82[a]and 6.3-83[a]).

The waste package will be designed to meet applicable requirements in *2001 ASME Boiler and Pressure Vessel Code* (ASME 2001 [DIRS 158115]). The inner vessel of the waste package is designed to withstand internal pressures of up to 140 psia at 707°F (375°C) (BSC 2007

[DIRS 180190], Appendix B, B4.2.2). These same design requirements will be imposed on TAD canister-bearing waste packages.

The internal pressurization of the TAD canister-bearing waste package with commercial SNF is bounded by a pressure change of 114 psi for an intact or collapsed drift, as explained earlier. This pressure change is based on bounding assumptions and is less than the design pressure of 140 psia, so the processes that can result in internal pressurization of the TAD canister-bearing waste package are excluded based on low consequence.

CDSP Waste Packages with DSNF and high level glass waste canisters—The individual sources of gas generation or gas pressure in the codisposal waste packages with DOE SNF and HLW glass canisters are discussed here. The response for a codisposal waste package loaded with DOE SNF and two MCOs is discussed in the following section.

- A pyrophoric material is capable of igniting spontaneously under temperature, chemical, or physical/mechanical conditions specific to the storage, handling, or transportation environments (ASTM C 1454-00 [DIRS 152779], Section 3.2). Uranium metal-based fuel, such as Hanford's N Reactor SNF, is a pyrophoric material that accounts for about 85% by weight MTHM of the total DOE SNF inventory (DOE 2002 [DIRS 158405], Appendix D). The N Reactor SNF has been loaded into MCOs, so the effects of pyrophoricity are discussed in the next section. Pyrophoricity is not considered a significant source for gas generation or temperature increase that could lead to internal pressurization of the codisposal waste package with other DOE SNF and high level glass waste canisters.

- The only fuel waste types capable of producing organic flammable gases, such as methane and ethane, are the uranium-thorium carbide and the plutonium-uranium carbide DOE SNF because they are the only spent nuclear fuels containing more than trace quantities of carbon. These gases are formed by the reaction of the carbides with liquid water or water vapor.

  As documented in excluded FEP 2.1.02.29.0A (Flammable Gas Generation from DSNF), an analysis of degradation and hydrocarbon production from graphite-matrix carbide fuels was conducted (Propp 1998 [DIRS 149395]). This study assessed the vulnerability of graphite-matrix SNF to oxidation by the ambient atmosphere in a geologic repository after fuel canister breach and examined the gases generated due to carbide combustion. Thermochemical and kinetic data were scrutinized for potential reactions between the graphite and the H_2O/O_2 system over the temperature range of 200°C to 400°C. This evaluation led to the conclusion that, even at 400°C, the reaction rate is "so small as to be of no practical consequence." Therefore, oxidation of the carbide-bearing SNF upon waste package breach is not anticipated to be a concern (Propp 1998 [DIRS 149395], Summary), and should not be a significant source for gas generation within the waste package.

- Decay-derived helium may be released from the DOE SNF within codisposal waste packages. However, the codisposal waste packages containing HLW glass canisters and DOE SNF have a much smaller inventory of the radionuclides that can produce

decay-derived helium in comparison to the commercial SNF waste packages (SNL 2007 [DIRS 180472], Table 7-1[a]). It follows that the potential pressurization effects of decay-derived helium on the codisposal waste packages are bounded by the internal pressurization of the commercial SNF in a TAD canister-bearing waste package, and can therefore be excluded based on the low consequence justification given above.

- The current waste package design requires all waste packages to be dried and backfilled with helium gas (SNL 2007 [DIRS 179567], Table 4-1, Parameter Numbers 03-26 and 04-04): "All TAD canisters and waste packages shall be dried and backfilled with Helium to achieve less than 0.43 moles (7.7 g) of H_2O in a 7 m^3 TAD canister after drying in a manner similar to Standard Review Plan for Dry Cask Storage systems" (NRC 1997 [DIRS 101903], Section 8.V.1). The amount of residual water in the codisposal waste packages with DOE SNF and HLW glass canister waste will therefore be very small due to the process for drying and inerting the waste packages. Consequently, gas production from corrosion in the codisposal waste packages prior to breach will be insignificant because of the scarcity of water. If any DOE SNF-containing waste packages have excess water, this water would be at least partly scavenged by corrosion of the waste form. This chemically scavenged water is not available for corrosion of the waste package inner vessel or the waste package outer corrosion barrier.

  The cold vacuum drying process results in approximately 0.0004 to 0.0005 liters of free water in a 15-ft-long canister containing high level waste or DOE SNF (Wachs 2004 [DIRS 184624], Section 6). The free water in a codisposal waste package with six canisters is less than 6(0.0005 liters) = 0.003 liters = 3 grams = 0.17 moles of water. The void volume inside a long DOE SNF codisposal waste package (containing 5 DHLW canisters and 1 DOE SNF canister) is 6,430 liters (DTN: MO0705GEOMODEL.000 [DIRS 181798], folder: FFTF, file: *CDSP_Long WP_FFTF_REV02.xls*, tab: Void Volume). This does not include the void inside the six canisters. The maximum gas pressure from water vapor at the peak temperature of 211°C is given by:

$$
\begin{aligned}
p &= \frac{nRT}{V}, \\
&= \frac{(0.17\,\text{mol})\left(8.3143\,\frac{\text{N}\cdot\text{m}}{\text{mol}\cdot\text{K}}\right)(273.15+211)(\text{K})}{(6{,}430\,\text{L})\left(\frac{1{,}000\,\text{cc}}{\text{L}}\right)\left(\frac{1\,\text{m}^3}{10^6\,\text{cc}}\right)}, \\
&= 106\,\text{N/m}^2, \\
&= 106\,\text{Pa}, \\
&= 0.015\,\text{psi}.
\end{aligned}
$$

  This pressure increase is less than the corresponding value for the TAD canister-bearing waste package with codisposal, 0.051 psi.

  All waste packages will be cold vacuum dried and initially prepressurized with 1 to 2 atmospheres of helium, as noted above. Using the upper bound of 2 atmospheres for

prepressurization, the resulting waste package pressures within the first 100 years and at 10,000 years after closure are identical to those calculated for the TAD canister-bearing waste package.

In summary, the combined pressure increases within a codisposal waste package with DOE SNF and HLW glass should be no more than the pressure increase for a TAD canister-bearing waste package with commercial SNF. The total pressure increase for the commercial SNF waste package, 114 psi, is within the design pressure limit (140 psia) of the waste package inner vessel (BSC 2007 [DIRS 180190], Appendix B, B4.2.2), so the processes leading to internal pressurization of the codisposal waste package can also be excluded based on low consequence.

CDSP Waste Packages with DSNF and Multicanister Overpacks (MCOs)—The individual sources of gas generation or gas pressure in the codisposal waste packages with DOE SNF and MCOs are discussed here.

- A pyrophoric material is capable of igniting spontaneously under temperature, chemical, or physical/mechanical conditions specific to the storage, handling, or transportation environments (ASTM C 1454-00 [DIRS 152779], Section 3.2). Uranium metal-based fuel, such as Hanford's N Reactor SNF, is a pyrophoric material that accounts for about 85% by weight MTHM of the total DOE SNF inventory (DOE 2002 [DIRS 158405], Appendix D)). The incidence and consequences from a pyrophoric event are evaluated in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF). Based on that FEP, the associated increase in the overall waste package temperature is expected to be small and would therefore not lead to further degradation of the waste package outer corrosion barrier that might increase the rate of oxygen ingress. These results are confirmed by a quantitative analysis for the response of the contents of a single MCO to hypothetical breaches and material/energy flow from the MCO (DOE 2004 [DIRS 173188]). The results of this analysis provide additional corroborating evidence that pyrophoric events that are limited by the rate of oxygen ingress will not be highly energetic and will not lead to temperature increases in the waste package container that will cause the area of the container breaches to increase as the event unfolds. Based on these results, pyrophoricity is not considered a significant source for gas generation or temperature increase that could lead to internal pressurization of the waste package.

- The only fuel waste types capable of producing organic flammable gases, such as methane, and ethane, are the uranium-thorium carbide and the plutonium-uranium carbide DOE SNF because they are the only spent nuclear fuels containing more than trace quantities of carbon. These gases are formed by the reaction of the carbides with liquid water or water vapor.

  As documented in excluded FEP 2.1.02.29.0A (Flammable Gas Generation from DSNF), an analysis of the degradation and hydrocarbon production from graphite-matrix carbide fuels was conducted (Propp 1998 [DIRS 149395]). This study assessed the vulnerability of graphite-matrix SNF to oxidation by the ambient atmosphere in a geologic repository after fuel canister breach and examined the gases generated due to carbide combustion. Thermochemical and kinetic data were scrutinized for potential reactions between the graphite and the H_2O/O_2 system over the temperature range of 200°C to 400°C. This

evaluation led to the conclusion that, even at 400°C, the reaction rate is "so small as to be of no practical consequence." Therefore, oxidation of the carbide-bearing SNF upon waste package breach is not anticipated to be a concern (Propp 1998 [DIRS 149395], Summary), and should not be a significant source for gas generation within the waste package.

- Decay-derived helium may be released from the DOE SNF within codisposal waste packages. However, the codisposal waste packages containing two MCOs and DOE SNF have a much smaller inventory of the radionuclides that can produce decay-derived helium in comparison to the commercial SNF waste packages (SNL 2007 [DIRS 180472], Table 7-1[a]). It follows that the potential pressurization effects of decay-derived helium on the codisposal waste packages are bounded by the internal pressurization of the commercial SNF in a TAD canister-bearing waste package, and can therefore be excluded based on the low consequence justification given above.

- The maximum pressure inside an MCO in the absence of a hydrogen deflagration has been estimated in excluded FEP 2.1.13.01.0A (Radiolysis). This analysis is based on the maximum amount of free and bound (hydrated) water that has been reported for all MCOs loaded to date. The pressure from release of all bound water and from prepressurization with 1.5 atm of helium gas is estimated to be 38 atmospheres (559 psia) at 211°C, the maximum value for the peak waste package temperature (SNL 2008 [DIRS 184433], Table 6.3-49[a]). This pressure is well beyond the design pressure for the MCO, 450 psig at 132°C (Garvin 2002 [DIRS 169141], Section 2.2.6.2). If an MCO fails from overpressurization, it will vent into the void volume inside the codisposal waste package. The resulting pressure is at most 104 psia at 211°C (see excluded FEP 2.1.13.01.0A (Radiolysis)), which is less than the design pressure of the waste package, 140 psia at 707°F (375°C) (BSC 2007 [DIRS 180190], Appendix B, B4.2.2).

  The maximum pressure in the event of a hydrogen deflagration is also analyzed in excluded FEP 2.1.13.01.0A (Radiolysis). The maximum pressure from a hydrogen deflagration is estimated to be about 16 atmospheres, or 235 psia, well below the MCO design pressure of 450 psig at 132°C (Garvin 2002 [DIRS 169141], Section 2.2.6.2). If the MCO canister fails from the hydrogen deflagration, the pressure is vented into the larger void volume inside the codisposal waste package, further reducing the pressure.

- The effects of radiolysis on the free water that remains inside an MCO and on the water that is bound in hydrides on the N reactor fuel in the MCO are analyzed in excluded FEP 2.1.13.01.0A (Radiolysis). The effects of radiolysis on the free and bound water are reflected in the predicted gas pressure inside an MCO in the absence of a hydrogen deflagration and in the event of a hydrogen deflagration, as discussed earlier.

In summary, the pressure increases within an MCO should be within the design pressure for the MCO or within the design pressure for the codisposal waste package containing the MCOs. The processes leading to internal pressurization of the codisposal waste package with two MCOs and DOE SNF can be excluded based on low consequence.

Swelling of corrosion products: As discussed in excluded FEP 2.1.09.03.0B (Volume Increase of Corrosion Products Impacts Waste Package), volume changes due to the corrosion of waste package internals from dry oxidation and from breaches in the waste package outer corrosion barrier caused by seismic events or the residual stresses in the waste package closure lid regions are excluded from the TSPA model based on low consequence under the exposure conditions in the repository.

Nominal Rockfall: The term "rockfall" as used in this discussion refers to the dislodging of relatively few, generally large blocks of rock from the sides or crown of an emplacement drift. Nominal rockfall may result from in situ conditions of gravitational stresses, excavation-induced stresses, and thermally induced stresses, as described in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6). Nominal rockfall does not include dynamic loading caused by seismic events.

Mechanical damage to the waste package by nominal rockfall that occurs as a result of gravitational-, excavation-, thermal- or corrosion-induced stresses, or weathering, is discussed in greater detail under excluded FEP 2.1.07.01.0A (Rockfall). Based on this discussion, the effects of nominal rockfall on the waste package are excluded from consideration on the basis of low consequence to the TSPA model for 10,000 years.

Seismic: Mechanical damage to the waste packages and drip shields by ground motion and rockfall during seismic events is discussed separately in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components), and in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components).

The effects of mechanical impact on waste packages (except those resulting from seismic events) are therefore excluded from the TSPA based on the low consequence justifications given above.

Based on the previous discussion, omission of FEP 2.1.03.07.0A (Mechanical Impact on Waste Package) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.07.0B

FEP NAME:

Mechanical Impact on Drip Shield

FEP DESCRIPTION:

Mechanical impact (dynamic loading) on the drip shield may be caused by forces such as rockfall and possible waste package or drip shield movement. Seismic-induced impacts are addressed in separate FEPs.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The function of the drip shield is to prevent or reduce water flow that could contact the waste package (thus reducing waste package corrosion) and to prevent damage to the waste package from rockfall. The drip shield protects the waste package from rockfall during the first 10,000 years of the postclosure period (see excluded FEP 2.1.07.01.0A Rockfall). This FEP pertains specifically to the potential mechanical effects of non-seismic-induced rockfall (resulting from in situ conditions of gravitational stresses, excavation-induced stresses, thermally induced stresses, or time-dependent strength degradation of the rock mass) on the drip shield, and focuses on the potential for drip shield displacements that result in contact with the waste package, subsequently damaging the waste package (see also excluded FEP 2.1.03.07.0A (Mechanical Impact on Waste Package)). In the absence of seismic ground motion, mechanical impact on the drip shield from either waste package or drip shield movement is not expected. The effect of uneven invert settlement on drip shield stability as a result of seismic ground motion was analyzed in *Mechanical Assessment of Degraded Waste Packages and Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Section 6.4.6). It was determined that the settlement of the invert is not expected to materially alter the drip shield function.

The effects of rockfall are discussed in more detail under excluded FEP 2.1.07.01.0A (Rockfall). The effects of seismic events on drip shield and waste package integrity are not considered here, but are discussed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components), and included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). Static loading to the drip shield resulting from either partial or complete collapse of the drifts is discussed in excluded FEP 2.1.07.02.0A (Drift Collapse).

Calculations of potential rockfall for the nonlithophysal and lithophysal layers of the repository for nominal and seismic loading conditions are described in detail in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4). In the absence of seismic events, rockfall may result from in situ conditions of gravitational stresses, excavation-induced stresses, and thermally induced stresses. Varying degrees of drift collapse can be expected in the lithophysal rock resulting from in situ conditions of gravitational stresses, excavation-induced stresses,

thermally induced stresses, and time-dependent strength degradation of the rock mass. However, the rock block sizes are predicted to be small (i.e., only a few centimeters to decimeters on a side) due to the ubiquitous fracture fabric found in the Tptpll unit (BSC 2004 [DIRS 166107], Sections 6.1.4.1 and 8.1). Minor amounts of rockfall are expected in nonlithophysal rock units for the non-seismic case that considers thermally induced stresses and time-dependent strength degradation of the rock mass (BSC 2004 [DIRS 166107], Section 8.1). However, static fatigue failure of asperities along fracture surfaces is possible and would result in gravitationally induced failure of large blocks. Hence, potential rockfalls in nonlithophysal units will consist of much larger blocks than in the lithophysal units (SNL 2007 [DIRS 178851], Section 6.4.7.1), and are therefore more capable of causing significant damage to the drip shield.

The analysis of high-energy rock blocks due to seismic events is discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). These results provide an upper bound to the expected mechanical effects of rockfall during the nominal scenario. Any SCC induced by non-seismic rockfall is of low consequence, as discussed in excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields).

In conclusion, mechanical impacts on the drip shield have no effect on repository performance for 10,000 years after repository closure. Omission of FEP 2.1.03.07.0B (Mechanical Impact on Drip Shield) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.08.0A

FEP NAME:

Early Failure of Waste Packages

FEP DESCRIPTION:

Waste packages may fail prematurely because of manufacturing defects, improper sealing, or other factors related to quality control during manufacture and emplacement.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The type and rate of occurrence of potential manufacturing defects in waste packages and drip shields is based on information from analogous surrogate industrial operations. The various processes that could potentially lead to early failure of either a waste package or drip shield were reviewed, and eleven generic types of defects were identified from a literature search (SNL 2007 [DIRS 178765], Section 6.1.6). A complementary type of defect is added to the list of eleven, i.e., base metal flaw (improper material selection). This type of defect was not identified in the literature search; only instances of improper weld material were found. This particular defect mode is combined with those associated with base-metal flaws for the analysis report (SNL 2007 [DIRS 178765], Section 6.1.6). Planned repository design and operations (DOE 2006 [DIRS 176937]) indicated that the generic list should also include defects introduced by improper stress relief of the waste package outer corrosion barrier closure weld with a low-plasticity burnishing process and recognize that the drip shield or waste packages might be improperly emplaced. Thus, 13 processes or conditions were evaluated in the analysis of early waste package and drip shield failure. Note that early failure of drip shields is addressed in included FEP 2.1.03.08.0B. These processes are listed follows:

- Weld flaws
- Improper heat treatment
  - outer corrosion barrier shell
  - outer corrosion barrier closure lid
- Improper stress relief of outer corrosion barrier lid (low plasticity burnishing)
- Improper base metal selection
- Improper weld filler material
- Improper weld-flux material
- Poor weld-joint design
- Contaminants
- Improperly located welds
- Missing welds
- Waste package mishandling damage

- Emplacement errors
- Administrative or operational errors.

Of these 13 flaws or processes, six processes were screened from further analysis with respect to the waste package outer corrosion barrier on the basis of either very low likelihood of occurrence or low consequences. A seventh process, administrative or operational errors, was included within the analysis methodology. Six were identified as significant for the waste package outer corrosion barrier, requiring further analysis. The six processes retained for further analyses with respect to mechanisms for potential early failures of a waste package outer corrosion barrier are listed below. Heat treatment of the outer corrosion barrier involves two processes (SNL 2007 [DIRS 178765], Section 6.1.6).

- Weld flaws
- Improper heat treatment
  - outer corrosion barrier shell
  - outer corrosion barrier closure lid
- Improper stress relief of outer corrosion barrier lid (low plasticity burnishing)
- Waste package mishandling damage
- Improper base metal selection
- Improper weld filler material.

Information from the literature search cited in *Analysis of Mechanisms for Early Waste Package / Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.1) on the rate and causes of manufacturing defects in welded metallic containers indicated that weld flaws (e.g., slag inclusions, porosity, lack of fusion, or hydrogen-induced cracking) have been a dominant contributor to early failure but usually required an external stimulus (e.g., cyclic fatigue) or environmental conditions to cause the flaw to propagate to failure. In many cases, components with unidentified defects entered service, not because the defect was missed by an inspection, but because no inspection for that type of defect was required at the time they were fabricated.

The weld flaw analysis applies only to the waste package outer corrosion barrier closure welds (SNL 2007 [DIRS 178765], Section 6.3). Other welds in the waste package outer corrosion barrier are heat treated for stress relief during the solution annealing of the outer corrosion barrier for phase control. In addition, these latter welds are examined with ultrasonic testing, radiographic testing, and visual penetrant testing methods that result in a lower (non-quantified) probability of non-detection.

Because the development of early failure modes from material defects is closely connected to the long-term environmental conditions, *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765]) addressed the probability that such defects exist, not the likelihood of failures due to defects. Accordingly, the information from the literature search on the fraction of components that experienced defect-related failure during their intended lifetime is not directly applicable to waste packages or drip shields. In addition, these population-based failure rates do not provide any insight into the time distribution of early failures. However, in some cases, information on the occurrence rate of particular types of defects was obtained from the literature search (SNL 2007 [DIRS 178765], Section 6.1).

Results from an uncertainty analysis of the six processes applicable to the waste package outer corrosion barrier evaluated by event tree/fault tree methods (SNL 2007 [DIRS 178765], Figure 6-9) were collected into individual and comprehensive entities. The comprehensive probability distribution for the presence of undetected defects per waste package was developed by running a large number of realizations for these various entities with Monte Carlo sampling of the individual distributions. A CDF from this information was developed for the waste package outer corrosion barrier (SNL 2007 [DIRS 178765], Figure 6-20).

A realistic estimate of when components with defects will fail would be difficult to develop and justify given the nature of the problem:

- Physical failure of highly corrosion resistant metallic structures with very small loads under nominal conditions
- The time frames involved—centuries to millennia or longer
- The lack of long-term experience with such engineered systems in standard industrial or engineering practice.

Because of such considerations, performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) assume a complete loss of function of the waste package barriers with respect to radionuclide containment at the time of repository closure for waste packages characterized as having defects.

However, an early failed waste package would only have an increased susceptibility to SCC (SNL 2007 [DIRS 178765], Section 6.5.2). Even with a network of stress corrosion cracks, the mechanical performance of the early failed waste package would be similar to an intact package and would not have degraded sufficiently that a human intrusion could occur without recognition by the drillers. Therefore, FEP 2.1.03.08.0A (Early Failure of Waste Packages) is not included in the performance assessment for the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) on the basis of low consequence.

FEP: 2.1.03.08.0B

FEP NAME:

Early Failure of Drip Shields

FEP DESCRIPTION:

Drip shields may fail prematurely because of manufacturing defects, improper sealing, or other factors related to quality control during manufacture and emplacement.

SCREENING DECISION:

Included

TSPA DISPOSITION:

While intact, the titanium drip shields divert any moisture that might seep from the drift walls, including condensed water vapor, around the waste packages to the drift floor. Because of the low corrosion rates of titanium and the 15 mm thickness of the drip shields, breaches of the drip shields due to corrosion degradation processes are not expected to occur until at least 35,000 years after closure of the repository as discussed in *General and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 1.3). Included FEP 2.1.03.01.0B (General Corrosion of Drip Shields) and excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields) describe the potential causes of failure that are not related to flaws and errors in manufacturing and emplacement.

The various processes that could potentially lead to early failure of either a waste package or drip shield were reviewed, and eleven generic types of defects were identified from a literature search (SNL 2007 [DIRS 178765], Section 6.1.6). A complementary type of defect is added to the list of eleven, i.e., out-of-specification (improper) base metal. This type of defect was not identified in the literature search; only instances of improper weld material were found. This particular defect mode is combined with those associated with base-metal flaws for the analysis report (SNL 2007 [DIRS 178765]). Planned repository design and operations (DOE 2006 [DIRS 176937]) indicated that the generic list should also include defects introduced by stress annealing of the waste package outer corrosion barrier closure weld with a low-plasticity burnishing process and recognize that the drip shield or waste packages might be improperly installed. Thus, 13 processes or conditions were evaluated in the analysis of early waste package and drip shield failure. Early waste package failure is addressed in included FEP 2.1.03.08.0A (Early Failure of Waste Packages). The processes discussed are as follows:

- Weld flaws
- Base metal flaws
- Improper weld filler material
- Improper stress relief for lid (low plasticity burnishing)
- Improper heat treatment of outer corrosion barrier and closure lid
- Improper weld-flux material

- Poor weld-joint design
- Contaminants
- Improperly located welds
- Missing welds
- Handling-induced defects
- Emplacement errors
- Administrative or operational errors.

Of these 13 flaws or processes, four were identified as significant with respect to the drip shields, requiring further analysis. The remaining nine processes were screened from further analysis with respect to the drip shield on the basis of either being applicable only to the waste package outer corrosion barrier, or very low likelihood of occurrence, or low consequences, or for administrative or operational errors, because they are addressed within the analysis methodology. The four processes retained for further analyses with respect to mechanisms for potential early failures of a drip shield are as follows from *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.1.6):

- Improper heat treatment
- Base metal selection flaws
- Improper weld filler material
- Emplacement damage.

Because the development of early failure modes from material defects is closely connected to the long-term postclosure environmental conditions conducive to SCC, *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765]) addresses the probability that such defects exist, not the likelihood of failures due to defects. Failure is dependent on multiple factors and is anticipated to occur after degradation takes place, which may happen hundreds of years after emplacement.

Results from an uncertainty analysis of the four processes applicable to the drip shield evaluated by event tree/fault tree methods (SNL 2007 [DIRS 178765], Figure 6-15) were collected into a single uncertainty distribution. The comprehensive probability distribution for the presence of undetected defects per drip shield was developed by running a large number of realizations for these end states with Monte Carlo sampling of the distributions. A CDF from this information was developed for the drip shield (SNL 2007 [DIRS 178765], Figure 6-21).

A realistic estimate of when components with defects will fail would be difficult to develop and justify given the nature of the problem:

- Physical failure of highly corrosion resistant metallic structures with very small loads under nominal conditions

- The time frames involved—centuries to millennia or longer

- The lack of long-term experience with such engineered systems in standard industrial or engineering practice.

Because of such considerations, performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) assume complete loss of function of the drip shield with respect to seepage at the time of repository closure for drip shields characterized as having defects.

Because early failed drip shields will not result in changes in drip shield mechanical properties, the earliest time after disposal that the drip shield would degrade sufficiently that a human intrusion could occur without recognition by the drillers (SNL 2008 [DIRS 183478], Section 6.7.2) would not be affected. Therefore, FEP 2.1.03.08.0B (Early Failure of the Drip Shield) is not included in the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) on the basis of low consequence.

FEP: 2.1.03.09.0A

FEP NAME:

Copper Corrosion in EBS

FEP DESCRIPTION:

Chemical reactions involving copper corrosion have been identified as being of potential interest for repository programs considering the use of copper containers.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The repository does not use copper containers (SNL 2007 [DIRS 179567], Tables 4-6 through 4-10; SNL 2007 [DIRS 179394], Table 4-3); however, consideration of copper effects may be appropriate since a small amount of copper may be present in the emplacement drifts as part of the gantry rail system. The total mass of elemental copper per meter of emplacement drift is less than 5.0 kg/meter (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-06). Copper, when oxidized to copper oxide or copper sulfide, is a potentially significant sorbent for iodine and technetium. Copper in the invert could retard transport of iodine and technetium released from the waste packages (SNL 2008 [DIRS 177407], Sections 6.3.4.2.1 and 6.3.4.2.2), but the presence of copper is highly localized, so that the probability of iodine or technetium contacting the copper is low. Therefore, iodine and technetium are assumed not to sorb onto copper corrosion products in the invert.

Copper will have no adverse effects on the performance of the Alloy 22 waste package outer barrier or Titanium Grade 7 or Grade 29 drip shield material in the absence of seismic activity because the waste package or the drip shield will not come into contact with copper. The waste package is designed to rest on a pallet (SNL 2007 [DIRS 179354], Section 4.1.3) constructed of Alloy 22 bearing surfaces and stainless steel connector tubes. The pallet is designed to keep the waste package from contacting other dissimilar metals in the absence of seismic activity (SNL 2007 [DIRS 179354], Section 4.1.3 and Table 4-3). Similarly, the drip shields are designed to contact no other material except the Alloy 22 base (SNL 2007 [DIRS 179354], Table 4-2), which is attached to the bottom of the drip shields. Therefore, the effect of copper corrosion is of low consequence to the performance and integrity of the waste package and the drip shield.

If, however, the drip shield were to come into contact with copper due to the failure of the gantry system, there is a potential for galvanic interaction between the titanium and copper. If hydrogen generation were to result from galvanic coupling between copper and titanium, the potential for hydrogen absorption, or hydrogen-induced cracking, is considered low. This is because an oxide film forms on the surfaces of the Titanium Grade 7 drip shield plate material, which hinders hydrogen absorption (SNL 2007 [DIRS 181339], Section 6.1.5). When Titanium Grade 7 is cathodically polarized at −1.14 V (versus saturated calomel electrode), a more severe condition

than galvanically coupling to copper, the hydrogen absorption efficiency was found to be 0.015 and the resulting hydrogen absorption insignificant (SNL 2007 [DIRS 181339], Section 6.1.5). The Titanium Grade 29 drip shield support material is, for the same reasons as the Titanium Grade 7 drip shield plate material, also highly resistant to hydrogen embrittlement (SNL 2007 [DIRS 181339], Section 6.2[a]). Therefore, the potential for hydrogen-induced cracking of the Titanium Grade 29 drip shield support material, due to galvanic coupling with the limited amounts of copper in the emplacement drifts, is also considered to be low.

Based on the above discussion, omission of FEP 2.1.03.09.0A (Copper Corrosion in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.10.0A

FEP NAME:

Advection of Liquids and Solids Through Cracks in the Waste Package

FEP DESCRIPTION:

The presence of one or more cracks or other small openings of sufficient size in a waste package may provide a pathway for the advective flow of water (e.g., thin films or droplets) or solid material into the waste package. The resulting presence of sufficient water or solid material in the waste package may affect in-package chemistry and/or criticality. Partial or full plugging of the waste package cracks by chemical or physical reactions after their formation (i.e., healing) could also affect water flow and radionuclide transport through the waste package. Passivation by corrosion products is a potential mechanism for waste package healing.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The waste packages may be subject to SCC under repository conditions. The potential sources of stress that could result in SCC in the Alloy 22 WPOB include: (1) weld-induced residual stress, and (2) plasticity-induced residual stress caused by small-probability severe seismic events, as discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.5.3.1).

Residual stresses in all regions of the waste package (including the fabrication welds), except the closure lid welds, are to be fully relieved by annealing before the waste packages are loaded with waste (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-16); therefore, the waste packages will not develop residual stress high enough for SCC to occur (SNL 2007 [DIRS 181953], Section 6.5.3). According to the current waste package design, the stress mitigation of the outer lid closure weld will be by low-plasticity burnishing (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-17; SNL 2007 [DIRS 181953], Section 6.5.5), which imparts a layer of compressive residual stress to a minimum depth of 3 mm (0.12 in.) (SNL 2007 [DIRS 181953], Section 6.5.3.3). Upon removal of the compressive stress layer by general corrosion, the closure-lid weld region may be subject to SCC (SNL 2007 [DIRS 181953], Sections 6.5.5 and 8.4.2.1). However, removal of the stress-mitigated layer by general corrosion is not expected in the first 10,000 years. Therefore, as discussed below, damage from seismic ground motion is the only significant potential cause for SCC breach in the WPOB within the first 10,000 years.

Waste packages could be subject to SCC under the action of seismic-induced loading and seismic-induced rockfall. Rockfall/seismic effects on waste package degradation are discussed in excluded FEPs 2.1.07.01.0A (Rockfall), and FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). Damage to the waste packages from seismic-induced ground motion could occur in response to the impact of waste packages on the emplacement pallets, and

from end-to-end impacts between adjacent waste packages. Seismic-induced damage could result in deformation and resultant sustained residual stresses that may initiate SCC cracks, depending on the corrosion environment. Through-wall cracks could develop if the residual tensile stress exceeds the residual threshold stress (i.e., 90% to 105% of the yield strength of Alloy 22), as discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.1.4). The potential for the seismic-induced damage is discussed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components).

This FEP analyzes the potential for advective flow of liquid water into the waste package through SCC cracks; it does not address transport of water vapor through the cracks, which is included in the TSPA (SNL 2008 [DIRS 177407], Sections 1 and 6.4.2). The analysis considers SCC damage to the waste package subject to seismic-induced loading and rockfall impacts at the 1.05 m/s PGV level in the first 10,000 years of the repository. This PGV level corresponds to a mean annual exceedance frequency of approximately 10^{-5}/yr (DTN: MO0501BPVELEMP.001 [DIRS 172682], file: *Bounded Horizontal Peak Ground Velocity Hazard at the Repository Waste Emplacement Level.xls*, cells: A5 and B5), and was selected as representative.

This analysis provides quantitative estimates of the attenuation of seepage rates, when seepage contacts the surface of a waste package that has SCC damage. Seepage may contact the waste package surface as macroscopic "sheet" or rivulet flow, and as impinging drip ("falling drop") conditions. The analysis does not consider microscopic film flow along solid surfaces, under the impetus of gravity or in response to gradients of thermodynamic water potential, because such flows are considered to be much smaller than other modes of moisture movement such as gas-phase diffusion and condensation.

In addition, condensation on the underside of the drip shield, or directly on cooler waste packages, can provide a source of liquid water that could flow into SCC-damaged waste packages, but is excluded on low consequence as discussed in excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield).

This analysis shows that the potential for advective flow of liquids through waste package cracks caused by SCC damage is insignificant, following the logic below:

- As discussed in excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield), SCC-damaged drip shields still divert seepage so that water flow through the drip shield, if any occurs, will be negligibly small. Using bounding values for the uncertain parameters of drip shield damage and flow, the analysis for that FEP shows that a damaged drip shield can still reduce the rate of seepage that contacts the underlying waste package by more than six orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell B25).

- The size of the damaged area in the waste package from seismic-induced loading and ground motion is small relative to the surface area of the waste package (0.377 m^2, or 0.95% of the waste package surface; Section C.2.3.1).

- If through-wall SCC cracks were to develop in the WPOB, plugging of the tight, tortuous cracks by agglomerated mineral precipitates and corrosion products will limit the amount of water inside the cracks and the potential for advective water flow.

- If through-wall SCC cracks were to develop in the damaged waste package, only a small fraction of the through-wall cracks are expected to be spatially aligned with impinging seepage drips from the SCC-damaged drip shield.

Summary discussions for the factors listed above are presented below.

SCC Crack Morphology in Passive Alloys

As discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (BSC 2007 [DIRS 181953], Section 6.7.1.1), SCC cracks in passive alloys such as Alloy 22 tend to be tight (i.e., small crack-opening displacement), and highly tortuous often with many branches. Figure 2.1.03.10.0A-1 shows typical examples of transgranular and intergranular SCC cracks in stainless steel. SCC crack morphology in Alloy 22 is expected to be similar to that in stainless steel because of the crystalline granular structure of these alloys (BSC 2007 [DIRS 181953], Section 6.7.1.1).

Bounding Analysis for the Geometry and Number of Through-Wall SCC Cracks in Waste Package

As discussed in Section C.2.1, an SCC crack in the WPOB can be treated as a semi-elliptical crack. An initially semi-elliptical crack becomes a semi-circular crack as it grows to a through-wall crack (SNL 2007 [DIRS 181953], Section 6.6.2). See Figure C-1 for the simplified geometry of a through-wall crack in this analysis. The expected maximum length ($2c$) of the cracks is at least two times the wall thickness (SNL 2007 [DIRS 181953], Sections 6.6.2 and

6.8.5.2). The crack width and opening area are assumed to be the same through the wall thickness. Note that for an actual SCC crack propagating through the wall thickness, the crack width and opening area are expected to decrease with depth because of residual stress redistribution and relaxation near the crack tip as the crack grows. For waste packages that are damaged by seismic-induced events, the residual tensile stress in the WPOB tends to decrease from the outer surface (where the seismic impact occurs) to the inner surface of the WPOB (SNL 2007 [DIRS 181953], Sections 6.7.1.2 and 7.5.1.2). Therefore, the expected configuration of through-wall cracks that result from seismic damage is one with a larger opening at the outer surface and a much smaller opening at the penetration point on the inner surface. Those effects can be amplified when neighboring cracks propagate in parallel through the wall thickness (SNL 2007 [DIRS 181953], Section 6.7.1.3).

If SCC breach occurs during the first 10,000 years after repository closure when the WPOB maintains most of the design wall thickness of 25 mm (i.e., $2c$ = 50 mm), a reasonable upper-bound width for a through-wall crack in the WPOB is calculated to be approximately 195 μm, and the corresponding crack mouth area is approximately 7.68 mm^2 (Section C.2.1).

The seismic consequence abstraction analysis provides estimates of the damaged area on waste packages damaged by seismic ground motion (SNL 2007 [DIRS 176828]). The seismic-induced damaged area on a waste package is defined as the total area in which the residual tensile stress exceeds an uncertain threshold that varies from 90% to 105% of at-temperature yield strength of Alloy 22 (SNL 2007 [DIRS 181953], Section 8.1.1). This analysis assumes that seismic-induced damage to waste packages is distributed randomly over the package surface. As described in detail in Section C.2.3.1, the waste package with 23-mm thick WPOB was selected as appropriate for the first 10,000 years of the repository because degradation (or thinning) of the WPOB by general corrosion will be insignificant during this time period. A reasonably conservative estimate of the general corrosion penetration depth for the first 10,000 years is only 0.3 mm using the 50th percentile general corrosion rate (30.8 nm/yr) at 100°C for the expected case (the medium uncertainty level for R_o and the mean apparent activation energy of 40.78 kJ/mol) (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*, worksheet: "Data," cell: M71). An intact state of the waste package internals was selected as appropriate because earthquakes of sufficient magnitude to cause significant SCC damage to the WPOB occur relatively infrequently during this time period, and the internals will not undergo substantial degradation by corrosion until after the waste package experiences an extensive breach. The TAD canister-bearing waste package and 5-DHLW/DOE SNF codisposal waste package are the most abundant waste package types in the repository, and are considered in this analysis (Section C.2.3.1).

TAD canister-bearing waste packages with 23-mm-thick WPOB and intact internals are not subject to SCC damage from ground motion at the 1.05 m/s PGV level (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *Kinematic Damage Abstraction 23-mm Intact.xls*, worksheet: "WP Total"). Codisposal waste packages are subject to SCC damage from the same PGV level, and the 95th percentile of damaged area for this condition (0.377 m^2), conditioned on damage occurring, was selected as a reasonably conservative upper-bound value for the damage area of the waste package (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *CDSP Kinematic Damage Abstraction 23-mm Intact.xls*, worksheet: "Gamma for 90%_i23," cell I172). The probability of damage to the codisposal waste package occurring for the 1.05 m/s

PGV level is 0.559 at the RST of 90%, and significantly less at greater RST values (SNL 2007 [DIRS 176828], Section 6.6.1, Table 6-14). This codisposal waste package damaged area is used as a representative value for the waste package in the analysis (Section C.2.3.1). The damaged area is greater than the 50th percentile damaged area (0.253 m^2) at 2.44 m/s PGV (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *CDSP Kinematic Damage Abstraction 23-mm Intact.xls*, worksheet: "Gamma for 90%_i23," cell H178).

As discussed in Section C.2.3.1, the selected damage area corresponds to 0.95% of the total surface area of a codisposal waste package (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow WP flow rate," cell B13). The upper-bound total number of through-wall SCC cracks per damaged waste package is then estimated to be 697 cracks, and the corresponding total crack-mouth opening area of through-wall SCC cracks per damaged waste package is approximately 5,351 mm^2 (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, cells B17 and B16).

Laboratory Drip Tests

An analogue to the residual stress states and stress profiles from the stress calculation (BSC 2005 [DIRS 174052], Section 7) was created in stainless steel plates to evaluate the potential for such stresses to propagate through-wall cracks (Andresen et al. 2005 [DIRS 176653], Section 5). A series of stress corrosion crack tests was performed in which a simulated, rockfall-dented stainless steel plate was exposed to a boiling saturated aqueous solution of magnesium chloride. This is a highly corrosive environment that will initiate and propagate stress corrosion cracks in stainless steels even at low levels of residual tensile stress down to about 70 MPa (approximately 10 ksi) (ASM International 1987 [DIRS 101992], p. 272, Figure 54). The stress state in stainless steel was tested as an analogue to that of Alloy 22, which is extremely resistant to SCC and for which SCC is difficult to initiate under test conditions.

A series of tests was conducted to examine the potential for water flow through cracks (DTN: SN0506F4104405.003 [DIRS 174472]). These tests were designed to determine if water could penetrate real SCC cracks in the stainless steel plates described above, as well as simulated cracks formed between precision-ground blocks of Titanium Grade 7 and stainless steel. The simulated cracks had no tortuous pathways (i.e., machined internal surfaces), were empty, and free of any plugging matter. Flow testing was performed with the simulated, parallel-wall cracks, and with the real SCC cracks. Water was dripped onto both the simulated and real cracks from a height of 2.2 m (the maximum distance from the emplacement drift crown to the drip shield crown), and 0.4 m (the maximum distance between the drip shield crown and top of the waste package). The plates were held at different angles relative to the dripping water. A "sheet flow" test was also performed in which the water was dripped onto the plates a few inches above the cracks and allowed to flow over the cracks as a "sheet" flow.

For the real cracks in the stainless steel plate, the largest nominal aperture size (observed by inspection) in one location was approximately 381 μm, and that in the other location was approximately 127 μm; effective aperture sizes could be inferred from flow measurements, but were not characterized directly (Walton 2005 [DIRS 175407], pp. 110 and 145). The test results are summarized in DTN: SN0506F4104405.003 ([DIRS 174472], files: *Dynamic_Drop_Test_*

Summary_SCC_4-15-05.doc and *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*). The largest aperture used for simulated cracks with both the titanium and stainless steel blocks was 50.8 μm.

For the impinging drip ("falling drop") tests with real SCC cracks, two locations were identified as potential flow paths; one location did not yield any sign of water penetration, and the other yielded water flow through cracks in amounts ranging from 0.03% to 1.82% of the total amount of impinging water (with one exception, a test that yielded 4.02%) (DTN: SN0506F4104405.003 [DIRS 174472], file: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc*). Results from flow testing of the real SCC cracks are used to estimate potential leakage from the impinging-drip flow mode in Appendix C. Results from testing of the simulated cracks were used only to investigate behaviors such as the dependence on tilt angle and drop height and on material interactions. For the largest simulated crack aperture (50.8 μm) with the titanium blocks, less than 3% of the impinging drip water penetrated the crack when dripped from a height of 2.2 m (DTN: SN0506F4104405.003 [DIRS 174472], file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

A total of six test runs were conducted for the sheet flow condition, two runs for the titanium test blocks and four runs for the stainless steel test blocks. The titanium block test runs (both tilted at a 5° angle from horizontal) did not yield water penetration, and two (both tilted at a 5° angle) of the four stainless steel block test runs yielded water penetration (0.04% and 1.03%, respectively, of the total water dripped) (DTN: SN0506F4104405.003 [DIRS 174472], file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

The laboratory test results support the conclusion that only a small fraction of seepage flow is expected to penetrate cracks for both sheet flow and dripping conditions, even if dripping impinges directly on a crack. The results also demonstrate that the tilt angle of the block containing cracks strongly attenuates potential for water flow through the cracks under both sheet flow and impinging drip conditions.

Sustained dripping of seepage directly on the same cracks in the repository environment is not expected because the alignment of the drip impact location with the crack will vary. The tests also show that the tilt angle of the surface containing cracks strongly attenuates water flow through the cracks, for both sheet flow and impinging drip conditions. Furthermore, it is expected that these flow rates through actual SCC cracks will decrease significantly as a result of the plugging mechanisms discussed below and in Appendix C. Figure 2.1.03.10.0A-1 shows typical SCC cracks in stainless steel with highly branched (for transgranular crack) and tortuous crack morphology.

Crack Plugging with Mineral Precipitates and Corrosion Products

Stress corrosion cracking is a corrosion process that requires the presence of a corrosive environment (i.e., water with dissolved species such as chloride or fluoride) inside the crack and around the crack mouth for sustained operation. The SCC process will result in accumulation of corrosion products from associated corrosion reactions and mineral precipitates from evaporation (or evaporative equilibration) of water filling the crack. Detailed studies using high-resolution analytical electron microscopy have demonstrated the accumulation of corrosion products and

intrusion of the external environment water deep inside very fine SCC cracks of stainless steels and nickel-based alloys (Bruemmer and Thomas 2001 [DIRS 183685]).

As discussed in Section C.3, propagation of SCC cracks through the 25-mm thick WPOB could take a few hundreds years in the repository-relevant conditions. As SCC cracks grow through the WPOB wall, intermittent humidity cycles resulting from atmospheric fluctuations in the repository, or from variability in dripping rate and location (BSC 2004 [DIRS 169734], Sections 7.3.2 and 7.4.1), will promote mineral precipitation and accumulation of corrosion products inside the cracks.

Stress corrosion cracking cracks for corrosion-resistant materials like Alloy 22 are typically very tight and tortuous (BSC 2007 [DIRS 181953], Section 6.7.1.1; Bruemmer and Thomas 2001 [DIRS 183685]), and therefore require only small amounts of corrosion products and mineral precipitates to become filled. The corrosion product oxides tend to cement and agglomerate (Ishikawa et al. 2006 [DIRS 183682]; Ishikawa et al. 2007 [DIRS 181136]), especially in the presence of other minerals such as silica minerals (Milnes and Fitzpatrick 1995 [DIRS 105911], pp. 1,180 to 1,183). In addition, because of the larger molar volumes of the corrosion products than the base metal (e.g., nickel and chromium oxides from corrosion of Alloy 22), cracks will eventually be plugged by compacted corrosion products. The SCC cracks in the WPOB are expected to be continuously filled with compact cemented agglomerates of corrosion products and mineral precipitates as the cracks grow through the wall thickness.

A summary of the calculation of the expected rate of SCC plugging due to calcite precipitation from seepage is documented in *Plugging of Stress Corrosion Cracks by Precipitation* (BSC 2001 [DIRS 156807], Section 6.3). The calculation shows that water originating either as condensate or seepage, or water-dust mixtures that enter SCC cracks, will warm because of its closer proximity to the heat of the waste packages. This will cause enhanced precipitation of minerals such as calcite with retrograde solubility (depending on the availability of solutes). Over time, corrosion products, precipitated minerals, and particles of dust and rock in the environment will plug the cracks. The calculation employs a simplifying assumption that no corrosion products or mineral precipitates form inside a crack until the crack fully penetrates the wall thickness. Actually, as discussed earlier, SCC cracks will be continuously filled with corrosion products and mineral precipitates as they grow through the wall thickness. Dust on the waste package surface and CO_2 in the drift air will provide dissolved constituents for calcite and other minerals to form in water contacting the waste package surface. If there is fluctuation in humidity conditions on the waste package surface, more precipitation and faster plugging could occur (BSC 2001 [DIRS 156807], Section 6.3). Other assumptions of the calculation include: (1) that the corrosion products generated on the crack wall, as well as colloids, particulates, and any precipitated minerals, do not participate in resisting the water flow through the crack; and (2) that there is a uniform water seepage flow in space and time. It is concluded that, under these assumptions, the cracks will be sealed in a few hundred years at most when seepage water is allowed to flow at low sheet-flow rates. If the cracks are bridged by water, plugging may take thousands of years (limited by the delivery of solute), but no advective flow may occur if capillary forces hold the water.

Flow Rates in Through-Wall SCC Cracks Under Impinging Drips

For excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield) estimated flow rates through a SCC-damaged drip shield in the sheet flow condition are found to be negligibly small (0.05 to 3.42 cm^3/yr; Section C.3.1). This range of flow rates is not sufficient to create sheet-flow conditions on the underlying waste package surface. Therefore, the potential for water flow through SCC cracks in the WPOB for sheet-flow conditions is not considered further in this FEP.

Analysis was conducted to evaluate the potential for the water flow in through-wall SCC cracks in the waste package, under impinging-drip conditions, below an SCC-damaged drip shield (Section C.5). The analysis assumes that waste packages are damaged from seismic-induced ground motion at the 1.05 m/s PGV level in the first 10,000 years of the repository, and that through-wall SCC cracks from the seismic damages are distributed randomly over the waste package surface. The analysis for the seismic-induced SCC damage to waste packages is detailed in Section C.2.3.1.

Using bounding values for the uncertain parameters, and the waste package damage from seismic-induced ground motion at the 1.05 m/s PGV level (Section C.2.3.1), analysis shows that the damaged waste package diverts the seepage from the SCC-damaged drip shield, reducing the seepage flux by more than five orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell H25) (Section C.5). Combining diversion by the SCC-damaged drip shield and the SCC-damaged waste package, the drift seepage flux is reduced by at least ten orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell H27). For comparison, the estimated upper-bound advective flow into a damaged waste package is negligible compared to the minimum advective liquid influx rate (100 mL/yr) into a breached waste package (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or the threshold seepage rate per waste package (100 mL/yr; SNL 2007 [DIRS 181244], Section 6.4[a], p. 6-29[a]), that are defined for TSPA. Also, the TSPA model basis allows formation of corrosion products on the internal surfaces of the waste package to begin immediately after breach (SNL 2008 [DIRS 177407], Section 6.5.2.2.1), and the amount of water that is retained in those corrosion reactions greatly exceeds the potential advective leakage through a damaged waste package (e.g., SNL 2008 [DIRS 177407], Figure 6.5-8). Whereas gaseous diffusion of water vapor is the assumed mechanism that supplies this water, a small addition from advective flow would be inconsequential.

Screening Justification Summary

TAD canister-bearing waste packages are not subject to SCC damage in the first 10,000 years of the repository. Codisposal waste packages are subject to such damage, and the associated damaged area estimates are used in this analysis to represent potential waste package damage. Advective flow of water (and by inference, solids) in through-wall cracks in the SCC-damaged waste package is excluded on the basis of low consequence because the amount of advective water flow through the cracks will be severely limited by the combined effects of: (1) protection by drip shields (even damaged ones) against drift seepage; (2) limitations on the extent of waste

package damage from to seismic events; (3) tight and highly tortuous crack pathways for advective liquid flow; and (4) plugging of cracks by compact cemented agglomerates of corrosion products and mineral precipitates. The amount of liquid water that could flow advectively through cracks in the WPOB is small compared to the ingress of moisture by other modes such as diffusion, and the rates of moisture uptake by in-package degradation processes, as represented in TSPA.

Based on the above discussion, omission of FEP 2.1.03.10.0A (Advection of Liquids and Solids through Cracks in the Waste Package) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.10.0B

FEP NAME:

Advection of Liquids and Solids Through Cracks in the Drip Shield

FEP DESCRIPTION:

The presence of one or more cracks or other small openings of sufficient size in a drip shield may provide a pathway for the advective flow of water (e.g., thin films or droplets) or solid material through the drip shield. The resulting flux may affect drip shield performance and/or subsequent dripping onto the waste packages. Partial or full plugging of the drip shield cracks by chemical or physical reactions after their formation (i.e., healing) could also affect water flow through the drip shield.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Drip shields may be subject to SCC under repository conditions. The sources of stress that could result in SCC in the Titanium Grade 7 drip shields include: (1) welding-induced residual stress, (2) plasticity-induced residual stress from seismic-induced impacts, and (3) residual stress produced by rockfall impacts (SNL 2007 [DIRS 181953], Section 6.8, Introduction). Welding-induced residual stress in the drip shields will be relieved by heat treatment before placement in the drifts (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-13). Therefore, drip shields will not be subject to SCC on emplacement. However, the drip shields may be subject to SCC from damage induced by seismic and rockfall impacts. Rockfall/seismic effects on drip shield degradation are discussed in excluded FEPs 2.1.07.01.0A (Rockfall) and 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). These FEPs are excluded from the TSPA on the basis of low-consequence for the first 10,000 years; exclusion of this FEP is used as one of the bases to support exclusion of the above two FEPs.

This FEP finds that residual stresses in the drip shield plates, made from Titanium Grade 7, will relax because of creep so that through-wall SCC cracks are not expected to result. For the unexpected situation in which through-wall cracks develop, this analysis also evaluates the potential for advective water flow through an SCC-damaged drip shield. The analysis considers SCC damage to drip shields subject to seismic-induced loading and reasonably bounding rock block size and energy at the 1.05 m/s PGV level in the first 10,000 years of the repository. This PGV level corresponds to a mean annual exceedance frequency of approximately 10^{-5}/yr (DTN: MO0501BPVELEMP.001 [DIRS 172682], file: *Bounded Horizontal Peak Ground Velocity Hazard at the Repository Waste Emplacement Level.xls*, cells: A5 and B5), and was selected as representative seismic ground motion in the first 10,000 years of the repository. The bounding block size used in this analysis (7.49 MT with an impact velocity of 4.81 m/s; SNL 2007 [DIRS 178851], Table 6-153) corresponds to greater than the 99th percentile of block size at PGV levels of 1.05 and 2.44 m/s (SNL 2007 [DIRS 178851], Table 6-154); these PGV levels correspond to mean annual exceedance frequencies of approximately 10^{-5} and

4.5×10^{-7} m/yr, respectively (DTN: MO0501BPVELEMP.001 [DIRS 172682]). The analysis of drip shield denting by rockfall (Appendix B) considers higher PGV levels.

This analysis provides quantitative estimates of the attenuation of seepage rates, when seepage contacts the surface of a drip shield that has SCC damage. Seepage may contact the drip shield surface as macroscopic "sheet" or rivulet flow, and impinging drip ("falling drop") conditions. The analysis does not consider microscopic film flow along solid surfaces, under the impetus of gravity or in response to gradients of thermodynamic water potential, because such flows are considered to be smaller than the minimum advective liquid inflow rate into a breached waste package (100 mL/yr; SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or the minimum seepage rate per waste package location (100 mL/yr; SNL 2007 [DIRS 181244], Section 6.4[a]), that are defined for TSPA. Below these low thresholds, the contribution to water availability at the waste package is not significant because other modes of moisture transport such as gaseous diffusion and condensation are more important.

This analysis shows that the potential for advective flow of liquids (and by analogy, solids) through drip shield cracks caused by SCC damage is insignificant, as follows:

- Much of the repository (80% to 85% of the repository emplacement area) will be in lithophysal rock zone (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03) that does not produce rock blocks capable of causing sufficient SCC damage or denting of the drip shield (Section B.1), so the number of drip shields that could be affected by rockfall is small relative to the total number of drip shields in the repository. The impact of drift collapse (i.e., the en masse fall of rock fragments) on the drip shield is discussed in included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components).

- Relatively few rock blocks can fall in the nonlithophysal host rock that could damage drip shields or create dents that could act to funnel seepage. The probability for large rock blocks to fall in the nonlithophysal tuff is shown to be small due to the low probability of seismic events of sufficient magnitude (Section B.2.3). As discussed in detail in Appendix B, significant conservatisms were employed in the probability analysis.

- The size of the damaged area in the drip shield from seismic-induced rockfall is small relative to the surface area of the drip shield (0.064 m^2, or 0.48% of the drip shield topside surface; Section C.2.2.1).

- Residual stresses from seismic-induced rockfall are not expected to result in through-wall SCC cracks in the drip shield due to stress relaxation and low-temperature creep of Titanium Grade 7.

- If through-wall SCC cracks were to develop in the drip shield plate, only a small fraction of the through-wall cracks are expected to be spatially aligned with impinging seepage drips from the drift wall.

- If through-wall SCC cracks were to develop in the drip shield, plugging of the tight and highly tortuous cracks by mineral precipitates and corrosion products will limit the amount of water inside the cracks and the potential for advective water flow (a reasonable upper-bound volumetric flow rate of 4 mL/yr per damaged drip shield is estimated; Sections C.3.1 and C.4).

- The localized corrosion initiation uncertainty analysis for the WPOB shows that for the assumed condition that drip shields are completely removed and waste packages are exposed to the occurrence of drift seepage, only a fraction (approximately 10% or less at any point in time) of the waste packages are exposed to conditions that initiate localized corrosion (SNL 2008 [DIRS 183478], Appendix O).

- Even if leakage through a crack-damaged drip shield was to cause localized corrosion that penetrated the WPOB, and the 4 mL/yr leakage flowed directly into the waste package, the impact would be insignificant to repository performance.

In summary, the advection of liquids and solids through cracks in the drip shield is excluded on the basis of low consequence because: (1) SCC cracks resulting from damage by seismic-induced rockfall and/or ground motions at the 1.05 m/s PGV level are not expected to form or to fully penetrate the drip shield; and (2) if through-wall cracks develop, the additional factors described above and in Appendix C will limit the amount of advective water flow to amounts much less than the minimum liquid influx rate (100 mL/yr) into a breached waste package that is important in TSPA. A separate excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking of Drip Shields) is also excluded on the basis of low consequence; exclusion of this FEP is used as one of the bases to support exclusion of that FEP. Summary discussions for each of those factors listed above are presented below.

Rockfall Damage Analysis

During a seismic event, large-block rockfall is predicted to occur in the nonlithophysal units only (BSC 2004 [DIRS 166107], Section 6.3). In the lithophysal units, large blocks are not expected to form due to the presence of lithophysal voids interconnected by densely spaced fractures (BSC 2004 [DIRS 166107], Sections 6.4.1.1 and 8.1). Approximately 80% to 85% of the repository emplacement area will be in lithophysal rock (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03), so most drip shields will not be subject to large-block rockfall impacts that could lead to SCC. Some rock blocks released in the nonlithophysal tuff will have sufficient mass and energy to cause plastic deformation in the drip shield plates, and if the resulting residual tensile stress is sufficiently high and is not relaxed by creep, then the damaged area could be subject to SCC depending on the corrosion environment (SNL 2007 [DIRS 181953], Section 6.8).

Appendix B evaluates the potential for dents to occur to the drip shield that could impact its flow diversion function. The analysis in Appendix B evaluates the frequency of such rockfall events as a function of seismic event recurrence probability, and the consequences to the drip shields from rock block impacts. The results indicate that such damage will be rare, and additional confidence is assured because reasonable conservatisms are used in the consequence analysis, including:

- A large rock block is partly fractured and may break or crumble on impact with the drip shield, thus dispersing energy and attenuating the intensity of impact. However, the potential for block failure is not included in the structural response calculations.

- The orientation and shape of rock blocks are chosen to calculate an upper-bound damage to the drip shield by locating the center of mass directly above the impact point. Blocks have a cubic shape for the LS-DYNA calculations, with the center of mass directly above an edge that contacts the crown of the drip shield.

As shown in Appendix B, there are no blocks at the 1.05 and 2.44 m/s PGV levels that cause a significant dent (i.e., a dent that has a concave shape that can retain standing seepage liquid in the dent) to form on the drip shield crown (although residual stresses from these impacts may lead to SCC). The potential for SCC in the drip shield resulting from the damage areas associated with denting is addressed in subsequent sections within this FEP screening justification and in Appendix C. The tearing or rupture of drip shield plates from large block impacts is excluded from the TSPA model because of low consequence as discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). For blocks simulated using seismic events with PGV levels greater than 2.44 m/s, the risk to performance is insignificant considering the low probability of occurrence, and the reasonable conservatisms in the consequence analysis (Section B.2.3). Based on the rockfall calculations, impacts by the highest energy blocks will be mitigated by the tendency toward shoulder impacts rather than crown impacts and by the irregular block shape, wherein the center of mass is not directly over the impact point.

The potential for SCC in the drip shield to result from the damage areas associated with denting is addressed in subsequent sections within this FEP screening justification and in Appendix C. Tearing or rupture of drip shield plates from large block impacts is excluded from the TSPA model because of low consequence as discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components).

Stress Mitigation by Low Temperature Creep of Titanium Alloy

In response to stresses induced by rockfall deformations, stress relief will occur via creep mechanisms or SCC of the drip shield. Unlike most metals and alloys, titanium and many of its alloys are susceptible to creep at lower temperatures, down to room temperature (ASM 1961 [DIRS 170284], pp. 537 to 539). Since stress relaxation is directly related to creep, relaxation of plasticity-induced residual stresses is expected and has been measured for titanium alloys. For example, titanium exhibits room temperature stress relaxation even after five minutes when held at a range of stresses from less than half of the yield strength to stresses in excess of the yield strength (Sargent and Conrad 1969 [DIRS 174054], Figure 3). Thus, even though residual stresses near the yield strength are calculated to be present following large-block rockfalls, these displacement-controlled stresses are expected to relax over time to stresses below the SCC initiation threshold of 80% of yield strength (SNL 2007 [DIRS 181953], Section 8.1.5) without initiation of cracking, or if cracks initiate, without propagation of cracks through the thickness.

This expectation is best corroborated by tests conducted on 182 U-bend test specimens of Titanium Grades 7 and 16, and welded Titanium Grade 12 (SNL 2007 [DIRS 181953],

Section 6.8.3.1.2). These U-bend specimens were bent approximately 180 degrees and then the legs were restrained to give an apex strain (cold-work level) of approximately 12%. Approximately half the specimens were exposed to liquid of representative composition, and half to vapor, for a range of relevant environments at 60°C and 90°C. These test conditions produced stress levels near or slightly above the yield strength. The exposure time was approximately 5 years for Titanium Grades 12 and 16 and approximately 2.5 years for Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 6.8.3.1.2). Stress corrosion cracking initiation was not detected in any of the Titanium Grade 7 and 16 specimens. In all, only three of the welded Titanium Grade 12 specimens demonstrated cracking. These results show that the Titanium Grade 7 plates that serve as the flow diversion elements of the drip shield design are not expected to sustain any SCC damage at all, and that consideration of flow through such cracks is a conservative presumption.

The plastic deformation associated with the dented regions caused by rockfall will create residual stress gradients in the dented regions. An analysis of the resultant residual stress states is evaluated in *Drip Shield Structural Response to Rock Fall Supplemental Calculation* (BSC 2005 [DIRS 174052]). An evaluation of the time histories associated with these impacts shows that the stresses decrease as the material rebounds from the impact. The largest block of 28.29 MT, which is associated with unbounded ground motions with a PGV level of 5.35 m/s, leaves a residual first principal tensile stress of 140 MPa on the outer surface (also referred to as "top" surface) of the drip shield and a residual first principal tensile stress of 10 MPa on the inner surface (also referred to as "underside" surface) of the drip shield (BSC 2005 [DIRS 174052], Figure 7-60 and Table 7-9). The smaller block of 11.87 MT, which is associated with unbounded ground motions with a PGV level of 2.44 m/s, yields residual first principal tensile stresses of 125 MPa and 15 Mpa on the upper and lower surfaces of the drip, shield respectively (BSC 2005 [DIRS 174052], Figure 7-57 and Table 7-9).

These residual stress are well below the 209-MPa yield strength of Titanium Grade 7 at 150°C (the temperature for which the analysis was performed; BSC 2005 [DIRS 174052], Table 7-9). Because SCC also requires a corrosion environment (i.e., stable water to support corrosion reactions) in addition to sufficient tensile residual stress, the drip shield plate temperature has to decrease below approximately 100°C before SCC can initiate. Since the residual stress on the outer surface of the drip shield does not exceed the stress corrosion crack initiation threshold of 80% of yield strength (for example, 225 MPa at 90°C or 221 MPa at room temperature; SNL 2007 [DIRS 181953], Table 8-2), it is expected that cracks will not initiate in the dented regions. Because of the low temperature creep and resulting stress relief associated with Titanium Grade 7 discussed above, it is logical to expect gradual relief of these residual first principal stresses as the alloy undergoes creep.

Laboratory Tests

An analogue to the residual stress states and stress profiles from the stress calculation (BSC 2005 [DIRS 174052], Section 7) was created in stainless steel plates to evaluate the potential for such stresses to propagate through-wall cracks (Andresen et al. 2005 [DIRS 176653], Section 5). A series of stress corrosion crack tests was performed in which a simulated, rockfall-dented stainless steel plate was exposed to a boiling saturated aqueous solution of magnesium chloride. This is a highly corrosive environment that will initiate and propagate stress corrosion cracks in

stainless steels even at low levels of residual tensile stress down to about 70 MPa (approximately 10 ksi) (ASM International 1987 [DIRS 101992], p. 272, Figure 54). The stress state in stainless steel was tested as an analogue to that of Titanium Grade 7 because the titanium alloy is extremely resistant to SCC and it is difficult to initiate SCC under the test conditions.

A series of tests was conducted to examine the potential for water flow through cracks (DTN: SN0506F4104405.003 [DIRS 174472]). These tests were designed to determine if water could penetrate real SCC cracks formed in a stainless steel plate subject to point-loading and a boiling electrolyte, as well as simulated cracks formed between precision-ground blocks of Titanium Grade 7 and stainless steel. The simulated cracks had no tortuous pathways (i.e., machined internal surfaces), were empty, and free of any plugging matter. Flow testing was performed with the simulated, parallel-wall cracks, and with the real SCC cracks. Water was dripped onto both the simulated and real cracks from a height of 2.2 m (the maximum distance from the emplacement drift crown to the drip shield crown), and 0.4 m (the maximum distance between the drip shield crown and top of the waste package). The plates were held at different angles relative to the dripping water. A "sheet flow" test was also performed in which the water was dripped onto the plates a few inches above the cracks and allowed to flow over the cracks as a "sheet" flow.

The largest aperture used for the simulated cracks with both the titanium and stainless steel blocks was 50.8 μm. For the real cracks in the stainless steel plate, the largest nominal aperture size (observed by inspection) in one location was approximately 381 μm, and that in the other location was approximately 127 μm; effective aperture sizes could be inferred from flow measurements, but were not characterized directly (Walton 2005 [DIRS 175407], pp. 110 and 145). The test results are summarized in DTN: SN0506F4104405.003 ([DIRS 174472], files: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc* and *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

For the impinging drip ("falling drop") tests with real SCC cracks, two locations were identified as potential flow paths; one location did not yield any sign of water penetration, and the other yielded water flow through cracks in amounts ranging from 0.03% to 1.82% of the total amount of impinging water (with one exception, a test that yielded 4.02%) (DTN: SN0506F4104405.003 [DIRS 174472], file: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc*). Results from flow testing of the real SCC cracks are used to estimate potential leakage from the impinging-drip flow mode in Appendix C. Results from testing of the simulated cracks were used only to investigate behaviors such as the dependence on tilt angle and drop height and on material interactions. For the largest simulated crack aperture (50.8 μm) with the titanium blocks, less than 3% of the impinging drip water penetrated the crack when dripped from a height of 2.2 m (DTN: SN0506F4104405.003 [DIRS 174472], file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

A total of six test runs were conducted for the sheet flow condition, two runs for the titanium test blocks and four runs for the stainless steel test blocks. The titanium block test runs (both tilted at 5° angle from horizontal) did not yield water penetration, and two (both tilted at 5° angle) of the four stainless steel block test runs yielded water penetration (0.04% and 1.03%, respectively, of the total water dripped) (DTN: SN0506F4104405.003 [DIRS 174472], file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

The laboratory test results support the conclusion that only a small fraction of seepage flow is expected to penetrate cracks for sheet flow and dripping conditions, even if dripping impinges directly on a crack. Sustained dripping of seepage directly on the same cracks in the repository environment is not expected because the alignment of the drip impact location with the crack will vary. The tests also show that the tilt angle of the surface containing cracks strongly attenuates water flow through the cracks, for both sheet flow and impinging drip conditions. Furthermore, it is expected that these flow rates through actual SCC cracks will decrease significantly as a result of the plugging mechanisms discussed below and in Appendix C. Typical SCC cracks in stainless steel are highly branched (for transgranular cracks) and exhibit tortuous morphology (Figure 2.1.03.10.0B-1). It is expected that SCC morphology in Titanium Grade 7 is similar to that in stainless steel because of similarity in the crystalline granular structure of these alloys. Evidence of tight, highly branching intergranular and transgranular SCC cracks was observed from some Titanium Grade 7 U-bend samples tested in highly aggressive conditions with elevated dissolved fluoride and chloride concentrations (SNL 2007 [DIRS 181953], Section 6.8.2).

NOTE: This figure also appears in SNL 2007 [DIRS 181953], Figure 6-61.

Figure 2.1.03.10.0B-1. Typical Examples of (a) Transgranular SCC and (b) Intergranular SCC Cracks in Stainless Steel

Crack Plugging with Mineral Precipitates and Corrosion Products

SCC is a corrosion process that requires the presence of a corrosive environment (i.e., water with dissolved species such as chloride or fluoride) inside the crack and around the crack mouth for sustained operation. The SCC process will result in accumulation of corrosion products from associated corrosion reactions and mineral precipitates from evaporation (or evaporative equilibration) of water filling the crack. Detailed studies using high-resolution analytical electron microscopy have demonstrated the accumulation of corrosion products and intrusion of the external environment water deep inside very fine SCC cracks of stainless steels and nickel-based alloys (Bruemmer and Thomas 2001 [DIRS 183685]). Corrosion product particles are expected to be a few tens of nanometers in size as shown from electron microscope studies of

corrosion products formed on Titanium Grade 7 samples (He et al. 2007 [DIRS 183687], p. 789 and Figure 14-b).

As discussed in Section C.3, propagation of SCC cracks through the 15-mm-thick drip shield plates could take a few tens of years to thousands years in the repository environment. As SCC cracks grow through the drip shield plate thickness, intermittent humidity cycles resulting from atmospheric fluctuations in the repository, or from variability in dripping rate and location (BSC 2004 [DIRS 169734], Sections 7.3.2 and 7.4.1), will promote mineral precipitation and accumulation of corrosion products inside the cracks.

SCC cracks for corrosion resistant materials like Titanium Grade 7 are typically very tight and tortuous (SNL 2007 [DIRS 181953], Section 6.8.2), and therefore require only small amounts of corrosion products and/or mineral precipitates to become filled. The corrosion product oxides tend to cement and agglomerate (Ishikawa et al. 2006 [DIRS 183682]; Ishikawa et al. 2007 [DIRS 181136]), especially in the presence of other minerals such as silica minerals (Milnes and Fitzpatrick 1995 [DIRS 105911], pp. 1,180 to 1,183). In addition, because of greater molar volumes of corrosion product compounds compared to the base metal (e.g., titanium oxide from corrosion of Titanium Grade 7), cracks will eventually be plugged by compacted corrosion products in the presence of mineral precipitates. Any SCC cracks that form in the drip shield are expected to be filled with compact cemented agglomerates of corrosion products and mineral precipitates as the cracks grow through the plate wall thickness.

A summary of the calculation of the expected rate of SCC plugging due to calcite precipitation from seepage water is documented in *Plugging of Stress Corrosion Cracks by Precipitation* (BSC 2001 [DIRS 156807], Section 6.3). The calculation employs a simplifying assumption that no corrosion products or mineral precipitates form inside the crack until it fully penetrates the wall thickness. In reality, as discussed earlier, the SCC cracks will be continuously filled with corrosion products and mineral precipitates as they grow through the wall thickness. Other assumptions include: (1) that the corrosion products generated on the crack walls, as well as colloids, particulates, and any precipitated minerals, do not participate in resisting the water flow through the crack; and (2) that there is a uniform water seepage flow in space and time. It is concluded that, under these assumptions, the cracks will be sealed in a few hundred years at most when water is allowed to flow at low sheet-flow rates. If the cracks are bridged by water, plugging may take thousands of years (limited by the delivery of solute), but no flow will occur if capillary forces hold the water. In a more realistic case of nonuniform flow onto the drip shield, more precipitation and faster plugging could occur (BSC 2001 [DIRS 156807], Section 6.3).

Bounding Analysis for the Geometry and Number of Through-Wall SCC Cracks in Drip Shield

As discussed in Appendix C, an SCC crack in the drip shield can be treated as a semi-elliptical crack (SNL 2007 [DIRS 181953], Sections 6.6.2 and 6.8.5.2). An initially semi-elliptical crack becomes a semi-circular crack as it grows to a through-wall crack (SNL 2007 [DIRS 181953], Section 6.6.2). Figure C-1 presents the simplified geometry of a through-wall crack in this analysis. The expected maximum length ($2c$) of the cracks is at least two times the wall thickness (SNL 2007 [DIRS 181953], Sections 6.6.2 and 6.8.5.2). The crack width and opening

area are assumed to be the same through the wall thickness. Note that for an actual SCC crack propagating through the wall thickness, the crack width and opening area are expected to decrease with depth because of the residual stress redistribution and relaxation at the crack tip as the crack grows. For the drip shields that are damaged by seismic-induced events, the residual tensile stress tends to decrease from the outer surface (where the seismic impact occurs) to the inner surface of the drip shield (SNL 2007 [DIRS 181953], Sections 6.7.1.2 and 7.5.1.2). The expected configuration of through-wall cracks that result from seismic damage is one with a larger opening at the outer surface and a much smaller opening at the penetration point on the inner surface. Those effects can be amplified when neighboring cracks propagate in parallel through the wall thickness (SNL 2007 [DIRS 181953], Sections 6.7.1.2 and 6.7.1.3).

If SCC breach of the drip shield were to occur during the first 10,000 years after repository closure when the drip shields maintain most of the design wall thickness of 15 mm (i.e., $2c$ = 30 mm), a reasonable upper-bound width of a through-wall crack in the drip shield is calculated to be approximately 155 μm (Equation C-1), and the corresponding crack mouth area is approximately 3.65 mm^2 (Equation C-2), using the room temperature yield strength and modulus of elasticity of Titanium Grade 7 (Section C.2.1).

Seismic-induced SCC of the drip shield plates would require that the resultant residual tensile stress is greater than 80% of the yield strength of Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 8.1.5). As described in detail in Section C.2.2.1, no damage to the drip shield with the 15-mm plate thickness is estimated in the lithophysal rock zone (also see DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *DS Damaged Area with Rubble.xls*, worksheet: "1.05 ms PGV - Case 2 BCs," cells: M57 to M68, and worksheet: "1.05 ms PGV - Case 1 BCs," cells: M54 to M65). In the nonlithophysal zone, the upper-bound impact damage area in the drip shield with 15-mm thick plate by the largest rock block (the 99.9th percentile for all blocks ejected under the 1.05 m/s PGV) is estimated to be 0.064 m^2, which corresponds to 0.43% of the total upper surface area of the drip shield (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cell: B12)) (see Section C.2.2.1 for details). The seismic damage areas are assumed to be distributed randomly over the drip shield surface. A reasonable upper-bound total number of through-wall SCC cracks per damaged drip shield is estimated to be 326 cracks, and the corresponding upper-bound total crack-mouth opening area of through-wall SCC cracks per damaged drip shield is approximately 1,190 mm^2 (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cells: B16 and B17.

Water Flow Rates from Through-Wall SCC Cracks in Sheet Flow Condition

This analysis was conducted to bound the potential rate of gravity driven, liquid water flow through SCC cracks in a damaged drip shield in the sheet flow condition. The impinging drip ("falling drop") condition is discussed in the next section. The analysis assumes liquid-saturated conditions within a porous medium that fills the cracks in the path of sheet flow, bounding the potential flow rate. Note that 18 (about 6%) of 326 through-wall cracks (discussed earlier) are located on the top of the drip shield above the waste package, where leakage is potentially significant (Section C.3.1). The other through-wall cracks will not be fully saturated with water,

and thus will be more permeable to gases and water vapor (addressed in more detail for excluded FEP 2.1.03.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package)).

The Kozeny-Carman equation is a widely used derivation for permeability in granular media (Bear 1972 [DIRS 156269], pp. 165 to 167) and is used to estimate the saturated permeability of the porous filling for any SCC cracks that form in the drip shields (Section C.3). The Kozeny-Carman equation is based on a theory that treats a porous medium as a bundle of capillary tubes of equal length (Bear 1972 [DIRS 156269], p. 166) and this simplifying conceptual model gives rise to uncertainty in the estimation of permeability. An assumption is made that the porous medium inside a crack consists primarily of titanium oxide (TiO_2), a corrosion product of Titanium Grade 7. The corrosion product particles are expected to be a few tens of nanometers in size as shown from an electron microscopic study of corrosion products formed on Titanium Grade 7 samples (He et al. 2007 [DIRS 183687], p. 789 and Figure 14-b). Titanium oxide particles of the size have been estimated to have specific surface area on the order of 100 m^2/g (Yao and Zhang 1999 [DIRS 184766], Tables I and II (excluding those heat treated at 500°C and 600°C)). Compaction or cementation of the particles of corrosion products and mineral precipitates will further limit permeability. The density of natural rutile (4.26 g/cm^3; Lide 2000 [DIRS 131202], p. 4-108) and specific surface area of commercial-grade crystalline rutile and anatase (6 to 50 m^2/g; Siriwardane and Wightman 1983 [DIRS 183688], p. 504) are used in the analysis; the specific surface area used is conservative because, as discussed earlier, the surface area of titanium oxide corrosion product particles may be much higher.

The saturated hydraulic conductivity (calculated from permeability) of the titanium oxide particles filling cracks is estimated to be in a range of 7.44×10^{-4} m/yr (or 2.36×10^{-11} m/s for the lower bound of the specific surface area) to 5.17×10^{-2} m/yr (or 1.64×10^{-9} m/s for the upper bound of the specific surface area) (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cells B29 and D29). The estimated hydraulic conductivity values fall in the range for clay, which range from 1.0×10^{-11} to 4.7×10^{-9} m/s (Domenico and Schwartz 1990 [DIRS 100569], Table 3-2, p. 65). Considering the high specific surface area of the corrosion products, the comparison with clays corroborates the estimated range for hydraulic conductivity. Clays typically have very fine particle sizes, rugged platy surface morphology, and high specific surface area. When settled or compacted, clays retain their high porosity but have very low permeability.

Applying a unit head gradient in the flowing cracks, the total volumetric flow rate through the SCC through-wall cracks in the drip shield is estimated to be in a range of 0.05 to 3.42 mL/yr (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cells B31 and D31). The estimated flow rates through the damaged drip shield are negligibly small, so that no advective flow condition is expected on the waste package surface (Section C.3.1). These estimated flow rates are much smaller than the minimum advective liquid influx rate (100 mL/yr) into a breached waste package (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or the threshold seepage rate per waste package (100 mL/yr; SNL 2007 [DIRS 181244], Section 6.4[a]), that are defined for TSPA.

Flow Rates in Through-Wall SCC Cracks Under Impinging Drips

This analysis was conducted to bound the potential rate of liquid flow through SCC cracks in a damaged drip shield, by impinging drips (Section C.4). As discussed earlier, the analysis considers that seismic damage area is distributed randomly over the drip shield surface. Twenty-five percent (82 cracks) of 326 through-wall cracks (reasonable upper-bound number of through-wall cracks per seismic-damaged drip shield) are estimated to potentially flow water under impinging drip conditions (Section C.3.1). The other through-wall cracks will not be fully saturated with water, and thus will be more permeable to gases and water vapor (addressed in more detail for excluded FEP 2.1.01.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package)).

Even for the bounding values for the uncertain parameters of the impinging drip condition analysis, the analysis shows that the SCC-damaged drip shield can still divert most of the drift seepage, reducing the seepage by more than six orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell B25). For example, if the damaged drip shield were subject to a reasonable upper-bound drift seepage flux of 500 L/yr (DTN: MO0705TSPASEEP.000 [DIRS 183008], file: *v5.005_Seismic-FD_1Myr_CDSP_SeepRate_Bin5_stats.txt*; based on the mean drift seepage rate of approximately 460 L/yr from percolation subregion 5 (highest percolation rate subregion) at 10,000 years), a reasonable upper-bound volumetric flow rate through the damaged drip shield under impinging drip condition is estimated to be only 0.4 mL/yr, which is negligibly small (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell B24). Combining the sheet flow and impinging-drip modes for flow through cracks, the bounding estimate is approximately 4 mL/yr. As discussed above, this estimated upper-bound flow rate is much smaller than the minimum liquid influx rate (100 mL/yr) into a breached waste package, or the threshold seepage rate per waste package location (100 mL/yr) that are defined for TSPA (SNL 2007 [DIRS 181244], Section 6.4[a]).

Impact of Leakage through Crack-Damaged Drip Shield on the Waste Package

The effects from small rates of leakage through a crack-damaged drip shield on the potential for localized corrosion of the underlying WPOB are insignificant to repository performance because:

- Crack-damage is spatially distributed on the surface of the drip shield, so the leakage is also spatially distributed on the surface of the underlying waste package. In addition, much of the leakage would flow down the underside of the drip shield and not fall onto the waste package. These effects would combine to limit the salt load deposited on the waste package surface, so that the potential for localized corrosion initiation in the outer barrier is limited. This type of limitation is the same as that described for the effects of dust deliquescence (SNL 2007 [DIRS 181267], Section 6.5).

- Because only through-wall cracks in the upper surface of drip shield have the potential to flow seepage water, leakage, if any occurs, from an SCC-damaged drip shield is expected to fall onto the upper surface of the underlying waste package. Creviced conditions are not expected on the upper-surface area of the waste package, which will

be "boldly exposed" Alloy 22. Localized corrosion of boldly exposed Alloy 22 (i.e., pitting corrosion) requires much more aggressive corrosion conditions than the creviced conditions that are adopted in the localized corrosion initiation model for Alloy 22 for TSPA (SNL 2007 [DIRS 178519], Section 6.4.4.1). The small flow rates (4 mL/yr, reasonably conservative upper-bound) that are projected to result from leakage of a SCC-damaged drip shield are not expected to produce such aggressive corrosion environments on the upper surface of the waste package.

- The localized corrosion initiation uncertainty analysis for the WPOB shows that for the assumed condition that drip shields are completely removed and waste packages are exposed to the occurrence of drift seepage, only a fraction (approximately 10% or less at any point in time) of the waste packages are exposed to conditions that initiate localized corrosion (SNL 2008 [DIRS 183478], Appendix O).

Even if leakage through a crack-damaged drip shield were to cause localized corrosion that penetrated the WPOB, and the 4 mL/yr leakage flowed directly into the waste package, the impact would be insignificant to repository performance. The estimated upper-bound flow rate is much smaller than the minimum liquid influx rate (100 mL/yr) into a breached waste package that is important to the in-package chemistry for TSPA (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or the threshold seepage rate per waste package location that is used to define the presence of seepage for TSPA (100 mL/yr; SNL 2007 [DIRS 181244], Section 6.4[a]). In addition, the TSPA model basis allows formation of corrosion products on the internal surfaces of the waste package to begin immediately after breach (SNL 2008 [DIRS 177407], Section 6.5.2.2.1), and the amount of water that is consumed by those corrosion reactions greatly exceeds 4 mL/yr (e.g., SNL 2008 [DIRS 177407], Figure 6.5-8). Whereas gaseous diffusion of water vapor is the assumed mechanism that supplies this water, a small addition from advective flow would be inconsequential. Thus even if localized corrosion under a crack-damaged drip shield were to penetrate the waste package, the amount of additional water that would be added to the in-package environment is negligible.

Screening Justification Summary

This FEP finds that residual stresses in the drip shield plates will relax because of creep so that through-wall SCC cracks are not expected to result. Stress relaxation is directly related to creep, so relaxation of rockfall-induced, displacement-controlled residual stresses will occur over time to stresses near or below the stress corrosion crack initiation threshold of 80% of the yield strength. For the unexpected situation in which through-wall cracks develop, this analysis shows that the impact to performance from SCC damage, leading to small amounts of seepage leaking through cracks, is insignificant.

A relatively small number of rock blocks are expected to fall in the repository in the first 10,000 years that could damage drip shields and create dents that could funnel seepage to through-wall cracks in the drip shield. The size of the SCC-damage area in the drip shield plate from seismic-induced rockfall will be small relative to the surface area of the drip shield. As shown in Appendix B, there are no blocks at the 1.05 and 2.44 m/s PGV levels that cause a significant dent to form on the drip shield. For blocks simulated using seismic events with PGV levels greater

than 2.44 m/s, the risk to performance is insignificant considering the low probability of occurrence, and the conservatisms in the consequence analysis (Section B.2.3).

Analysis detailed in Appendix C shows that, if through-wall SCC cracks were to develop in the drip shield, plugging of the tight and highly tortuous cracks by compact cemented agglomerates of mineral precipitates and corrosion products will limit the potential for advective water flow under sheet flow and impinging drip conditions to negligibly small levels. A reasonable upper-bound volumetric flow rate through a seismically damaged drip shield under these flow conditions combined is approximately 4 mL/yr. This rate is much smaller than the minimum liquid influx rate (100 mL/yr) into a breached waste package (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or the threshold seepage rate per waste package (100 mL/yr; SNL 2007 [DIRS 181244], Section 6.4[a]) that are defined for TSPA.

The combined effects of: (1) few damaging rockfall events, (2) creep/stress relaxation in drip shield, (3) evaporation of seepage water contacting the drip shield, and (4) plugging of tight tortuous cracks will limit the amount of seepage water that can flow through cracks in the drip shields, to insignificant levels.

Based on this discussion, omission of FEP 2.1.03.10.0B (Advection of Liquids and Solids through Cracks in the Drip Shield) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.03.11.0A

FEP NAME:

Physical Form of Waste Package and Drip Shield

FEP DESCRIPTION:

The specific forms of the various drip shields, waste packages, and internal waste containers that are proposed for the Yucca Mountain repository can affect long-term performance. Waste package form may affect container strength through the shape and dimensions of the waste package and affect heat dissipation through waste package volume and surface area. Waste package and drip shield materials may affect physical and chemical behavior of the disposal area environment. Waste package and drip shield integrity will affect the releases of radionuclides from the disposal system. Waste packages may have both local effects and repository-scale effects. All types of waste packages and containers, including CSNF, DSNF, and DHLW, should be considered.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The waste package, drip shield, and repository design configurations for the Yucca Mountain Project are shown in *Total System Performance Assessment Data Input Package for Requirements Analysis for Transportation Aging and Disposal Canister and Related Waste Package Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179394]), *Total System Performance Assessment Data Input Package for Requirements Analysis for DOE SNF/HLW and Naval SNF Waste Package Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179567]), and *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354]). Only one drip shield configuration is used in the repository (SNL 2007 [DIRS 179354], Section 4.1.2), so the potential impacts from different drip shield configurations are not considered further. While different waste package configurations will be used in the repository, they are generally similar in their design and fabrication methodology. Dimensions and nominal quantities for the six major waste package configurations expected to be emplaced in the repository are shown in Table 2.1.03.11.0A-1.

Many analyses and models address the performance and characteristics of the waste package and drip shield as part of the performance assessment. For example, analyses that consider material properties, strength of the waste package, and shape and dimension of the waste package and drip shield are discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]), *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953]), and *Analysis for Mechanisms of Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765]). The effects of heat dissipation through the waste package are discussed in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]) and *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]). The effect of waste package

and drip shield materials on the physical and chemical behavior of the disposal area environment is discussed in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]) and *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407]). The behavior of the waste package and drip shield materials is described in *General Corrosion and Localized Corrosion of the Waste Package Outer Barrier* (SNL 2007 [DIRS 178519]) and *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778]). For additional information, see included FEP 1.1.07.00.0A (Repository Design).

FEP: 2.1.04.01.0A

FEP NAME:

Flow in the Backfill

FEP DESCRIPTION:

Preferential pathways for flow and diffusion may exist within the backfill and may affect long-term performance of the waste packages. Backfill may not preclude hydrological, chemical, and thermal interactions between waste packages within a drift.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Backfill is not part of the design for the waste emplacement regions of the repository. Specifically, engineered backfill shall not be present in the space between the drip shield and the drift wall (SNL 2007 [DIRS 179354], Table 4-4, Parameter Number 05-04). Closure of shafts and ramps shall include backfill of the opening (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01); however, because backfill in shafts and ramps will not be in close proximity to the waste emplacement region, flow and diffusion in the backfill will have a negligble impact on long-term performance. Based on the above discussion, omission of FEP 2.1.04.01.0A (Flow in the Backfill) will not result in significant adverse change in the magnitude of time or radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.04.02.0A

FEP NAME:

Chemical Properties and Evolution of Backfill

FEP DESCRIPTION:

The chemical properties of the backfill may affect groundwater flow, waste package and drip shield durability, and radionuclide transport in the waste disposal region. Properties of the backfill may change through time, due to processes such as alteration of minerals.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Backfill is not part of the design for the waste emplacement regions of the repository. Specifically, engineered backfill shall not be present in the space between the drip shield and the drift wall (SNL 2007 [DIRS 179354], Table 4-4, Parameter Number 05-04). Closure of shafts and ramps shall include backfill of the opening (SNL 2007]DIRS 179466], Table 4-3, Parameter Number 09-01); however, because backfill in shafts and ramps will not be in close proximity to the waste emplacement region, chemical properties of the backfill will have a negligible impact on long-term performance.

Backfill material is derived from the excavation and construction of the invert within the repository host horizon, and therefore would exhibit the same or similar chemical properties of the excavated invert material. Chemical degradation of the invert material (crushed tuff) has been excluded from the TSPA calculations (excluded FEP 2.1.06.05.0D (Chemical Degradation of Invert)), because it would not lead to significant changes in the hydrologic properties of the crushed tuff material. Thus the evolution of the backfill material is of little significance to the hydrologic properties in the access main and ventilation shaft openings.

Based on the this discussion, omission of FEP 2.1.04.02.0A (Chemical Properties and Evolution of Backfill) will not result in significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.05.01.0A

FEP NAME:

Flow Through Seals (Access Ramps and Ventilation Shafts)

FEP DESCRIPTION:

Long-term fluid flow through the shaft seal system, and uncertainty about long-term properties of the shaft seal system, may influence cumulative radionuclide releases from the disposal system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is very similar to FEP 2.1.05.02.0A (Radionuclide Transport through Seals), which is excluded on the basis of low consequence.

Closure of shafts and ramps shall include backfill of the opening (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01). Deviations from backfill design are not relevant to the emplacement drift environment and would have no impact on repository performance as discussed in excluded FEP 1.1.03.01.0B (Error in Backfill Emplacement).

During construction of the emplacement drifts, and operation and closure of the repository, administrative controls will be imposed to prevent impact on waste isolation from materials used, lost, or left in the repository. These controls will be supported by technical evaluation. The entries for Parameter Number 02-03 (SNL 2007 [DIRS 179354], Table 4-1) point to the most recent documents that list committed materials (i.e., materials that are intended to be present in the repository at closure). The committed materials have been found to be acceptable by analysis.

Two justifications demonstrate that fluid flow through the seals, in the access ramps and ventilation shafts, will be of little consequence for the flow and transport of radionuclides. The first justification below shows that the flow through shafts and ramps is not expected to affect the flow and transport of water in the repository in any significant way. The second justification shows that long-term changes in the backfill material are not expected to impact repository performance.

First, the flow through the repository is expected to be predominantly vertical; water influx at the land surface percolates dominantly downward, with little lateral spread. *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], p. 6-18) states, "Computations have shown that the average flux flowing to the repository is within three percent of the average flux specified at the ground surface over the projected repository area." Therefore, any flow down the ventilation shafts, which do not abut the emplacement drifts, should have little effect on flow into and through the emplacement drifts. Furthermore, the surface expressions of the ventilation shafts are such that the shafts should not be water-collection areas. The shafts will be positioned and

engineered to prevent flooding (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-19) (i.e., the shafts will not be in topographic lows expected to collect water).

Lateral drainage from perched-water zones is also not expected to impact flow through the repository via access ramps or the ventilation shafts (which only extend from the surface down to the repository). The North Construction Ramp is expected to intersect the Tptpv2, Tptpv1 and Tpbt1 (BSC 2003 [DIRS 165572], file: *subsurfaceladesign_i.dxf*; *Geologic Framework Model (GFM2000),* DTN: MO0012MWDGFM02.002 [DIRS 153777]). Two of these units have the potential for perched water, the Tptpv2 and the Tptpv1 (tsw38 = Tptpv3, tsw39 = Tptpv3, ch1z = Tptpv1 and Tpbt1, and ch2z is a component of Tac) (SNL 2007 [DIRS 184614], Sections 6.2.2, 6.2.3, 6.2.5). This study also indicates that there is evidence of perched water bodies along the base of the TSw in the northern region of the repository footprint (SNL 2007 [DIRS 184614], Sections 6.2.2.2 and 6.6.2.2). Perched waters that intersect a ramp could result in water being directed into the ramp and toward the emplacement drifts. However, drainage of perched water into the North Construction Ramp is not expected to significantly alter water flow to the emplacement drifts. The repository nonemplacement openings (such as access ramps) are designed to provide a repository grade so overall water drainage and accumulation travels away from waste package emplacement areas, as stated in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02). Any water that enters the ramp and accumulates will eventually drain into the rock below before it can reach the emplacement drifts. A bounding analysis may be used to demonstrate this behavior.

First, consider the amount of lateral drainage that may occur into the North Construction Ramp in the perched water zone. The North Construction Ramp enters and exits the perched water zone near the curve where this ramp turns from a northerly heading to a southerly heading towards the repository. The portion of the turn within the potential perched-water zone is approximately 500 m (BSC 2003 [DIRS 165572], file: *subsurfaceladesign_i.dxf*; DTN: MO0012MWDGFM02.002 [DIRS 153777]). The maximum drainage may be estimated by the potential catchment area north of this segment of the ramp. The potential perched water zone is intercepted by other faults about 4,000 m north of the location of the North Construction Ramp (DTN: GS010908314221.001 [DIRS 162874]; BSC 2003 [DIRS 165572], file: *subsurfaceladesign_i.dxf*). Therefore, a maximum catchment area of about 500 m × 4,000 m = 2×10^6 m^2 is estimated for lateral flow into the 500-m segment of the North Construction Ramp. From infiltration maps for future climates (SNL 2008 [DIRS 182145], Figures 6.5.7.2-5[a] and 6.5.7.3-5[a]), a maximum infiltration rate of 100 mm/yr may be used. This infiltration rate is derived from the monsoon and glacial-transition climates using the 90th-percentile infiltration maps, which have about a 6% chance of occurrence in TSPA models (SNL 2007 [DIRS 184614], Table 6.8-1). Combining this rate with the catchment area gives a bounding value of 2×10^5 m^3/yr. This water will flow south from the North Construction Ramp to the Panel 3 Exhaust and Intake Mains (BSC 2003 [DIRS 165572], Section 8.4.3). From there, the water will move downward to Exhaust Shaft #2, the lowest point connecting these mains (BSC 2003 [DIRS 165572], Section 8.4.3). The Exhaust Shaft #2 East and West Access tunnels and a portion of the Panel 3 Exhaust Main are connected to Exhaust Shaft #2, and these three sections are at the lowest elevation in Panel 3 (BSC 2003 [DIRS 165572], file: *subsurfaceladesign_i.dxf*). The combined length of these tunnels is greater than 300 m, and the approximate width of each tunnel available for downward drainage is 8 m (BSC 2003

[DIRS 165572], Table 5 and Figure 8). Thus, the minimal area available for drainage of any accumulated water in these sections is 300 m × 8 m = 2,400 m^2.

Next, consider the area required to drain a continuous inflow of 2×10^5 m^3/yr (or 6.3×10^{-3} m^3/s) from the North Construction Ramp (calculated above). The fractured rock in these locations has a bulk permeability on the order of 10^{-12} m^2 (model units tsw35 through tsw38; SNL 2007 [DIRS 184614], Appendix B), which is equivalent to a hydraulic conductivity of about 9.8×10^{-6} m/s (bulk permeability is multiplied by the product of the liquid water density (1,000 kg/m^3) and the gravitational constant (9.81 m/s^2 and divided by the dynamic viscosity (10^{-3} kg/m-s). The required area to drain the inflow is therefore equal to 6.3×10^{-3} m^3/s ÷ 9.8×10^{-6} m/s = 640 m^2. Because the available area for downward drainage in the Exhaust Shaft #2 East and West Access tunnels and the lowest section of the Panel 3 Exhaust Main is significantly larger (2,400 m^2), any inflow from lateral drainage induced by perched water zones into the North Construction Ramp will eventually drain into the fractured rock near Exhaust Shaft #2 before entering the emplacement drifts.

Second, long-term changes in the backfill material are not expected to impact repository performance. There are no performance attributes assigned to backfill other than limiting ingress of animals (excluded FEP 2.3.09.01.0A (Animal Burrowing/Intrusion)). Therefore, any degradation of backfill material and subsequent change in hydraulic characteristics is not relevant to repository performance.

The conclusion of these two justifications is that the seals, and any long-term alteration of the seals, are not expected to have a significant effect on fluid flow through the repository.

Based on the previous discussion, omission of FEP 2.1.05.01.0A (Flow through Seals (Access Ramps and Ventilation Shafts)) from the performance assessment calculations will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.05.02.0A

FEP NAME:

Radionuclide Transport Through Seals

FEP DESCRIPTION:

Groundwater flow through seals in the access ramps, ventilation shafts, and exploratory boreholes could affect long-term performance of the disposal system. Radionuclide transport through seals should be considered.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is analogous in content to FEP 1.1.01.01.0A (Open Site Investigation Boreholes) and FEP 2.1.05.01.0A (Flow through Seals (Access Ramps and Ventilation Shafts)), both of which are excluded on the basis of low consequence and address the closure of shafts and ramps with backfill of the opening (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01).

Therefore, omission of FEP 2.1.05.02.0A (Radionuclide Transport through Seals) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.05.03.0A

FEP NAME:

Degradation of Seals

FEP DESCRIPTION:

Degradation of seals in the access ramps, ventilation shafts, and exploratory boreholes could modify flow and transport properties. Physical properties of the seals emplaced in the access ramps, ventilation shafts, and exploratory boreholes may affect the long-term performance of the disposal system. These properties include the location of the seals (and the openings they seal), and the physical and chemical characteristics of the sealing materials. Possible mechanisms for seal degradation include: chemical alteration from water interactions, wetting associated with condensation, and thermally-induced stress-strain changes.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

There are three other closely related excluded FEPs. The basis for excluding flow and radionuclide transport through seals is provided in FEP 2.1.05.01.0A (Flow through Seals (Access Ramps and Ventilation Shafts)) and FEP 2.1.05.02.0A (Radionuclide Transport through Seals). The degradation of seals in exploratory boreholes is discussed in FEP 1.1.01.01.0A (Open Site Investigation Boreholes), and is excluded on the basis of low consequence.

Closure of shafts and ramps shall include backfill of the opening (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01). Deviations from backfill design are not relevant to the emplacement drift environment and would have no impact on repository performance as discussed in excluded FEP 1.1.03.01.0B (Error in Backfill Emplacement). Degradation of the seal material is not expected to increase permeability. Degradation of crushed tuff backfill will parallel that of the host rock and may lead to formation of clays and zeolites. These minerals have greater molar volumes than the initial, dominantly anhydrous minerals, and should be even less permeable than the initial material. In general, low-temperature alteration of primary phases in backfill results in higher volume hydrated alteration products. Condensation wetting would favor this. In the shorter term, the backfill may self-compact in the ventilation shafts under gravity; this physical degradation process should lower the permeability. If the backfill compacts to provide local, open pockets, such open spaces would act as capillary barriers to flow. Since the backfill is not brittle, it will respond to stress with granular flow or plastic deformation, and will not shatter or crack.

In conclusion, the effects of degradation of seals are considered to be negligible.

Based on the previous discussion, omission of FEP 2.1.05.03.0A (Degradation of Seals) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is

excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.01.0A

FEP NAME:

Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS

FEP DESCRIPTION:

Degradation of ground support material (e.g., cement, rock bolts, wire mesh) used for any purpose in the disposal region may affect long-term performance through both chemical and physical processes. Degradation may occur by physical, chemical, and microbial processes.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The discussion presented here focuses on potential impacts that ground support materials, left in the repository after closure, might have on the chemistry of seepage waters in the drifts, the transport of radionuclides, and the permeability of the surrounding rocks. The location and quantity of cemetitious materials and steels is obtainable from the design basis documents for TSPA (SNL 2007 [DIRS 179466]; SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-15 and 02-03). These documents point to the most recent specifications, drawings and tables for the quantities of cementitious materials and steels used in the support materials. After closure of the repository, the vast majority of cementitious materials will be in the turnout intersections, exhaust air (ventilation) turnouts, and access ramps (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). Cementitious materials are specifically excluded from the emplacement drifts, but it is possible that cement leachates from other areas will disperse and interact with materials in the emplacement drifts. Excavation effects on chemistry of the near-field are addressed in excluded FEP 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near-Field). The steel used in the emplacement drifts will be in the form of 3-mm-thick perforated sheets and friction-type rock bolts, both composed of Stainless Steel Type 316 or the equivalent; there will be no wire mesh in the emplacement drifts (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-15).

Corrosion of steel in the drift support materials could potentially affect performance in two ways: first, the degradation could alter the pH and general chemistry of the aqueous phase and second, the galvanic interaction of the perforated stainless steel plates, should they fall onto the drip shields, might cause galvanic corrosion. The first effect is evaluated in *Engineered Barrier System: Physical and Chemical Environment* (P&CE) (SNL 2007 [DIRS 177412], Section 6.8.4.1). The P&CE report (SNL 2007 [DIRS 177412]) demonstrates that wide variations in the available masses of Stainless Steel Type 316L merely result in the precipitation of more corrosion products and do not impact the aqueous phase chemistry significantly. These calculations were specifically designed to be corrosion-rate independent by adding masses of steels well beyond what would be expected for reasonable products of time, corrosion rate, and surface area. The second is discussed in excluded FEP 2.1.03.04.0B (Hydride Cracking of Drip Shields), and the potential galvanic action from contact with support materials is insufficient to

compromise the drip shields. Corrosion products from the ground support materials might also accumulate in the drift. Should radionuclides encounter these corrosion products, transport might be hindered.

Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry (BSC 2004 [DIRS 169991], Section 7.1) discusses rock reinforcement materials and other introduced materials in the context of environmental constraints on in-drift microbial activity as sources of energy and nutrients. Microbial impacts on in-drift chemistry are expected to be minimal, as discussed in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS). For this reason, microbes are not expected to accelerate degradation of ground support materials.

Two principal effects of cementitious materials on repository performance were identified by Ziegler (2004 [DIRS 171694], Section D.3). The first is an enhancement of transport that might result from an alkaline plume. This plume would result from leaching of the cementitious material and could enhance radionuclide transport to the accessible environment, either through the complexation of radionuclides or through the presence of pseudocolloids (i.e., radionuclides sorbed to preexisting solid phase colloids). Initially, any alkaline plume will be spatially separate from radionuclide-bearing plumes, because the principal locations of cementitious materials (the turnouts and ventilation shafts) are distant from the waste-bearing parts of the emplacement drifts. Standoff distances are established in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-18). Hence, the greatest possibility of radionuclide transport enhancement will come from potential overlapping of the plumes below the repository. For example, an increase in the pH of the radionuclide plume, from mixing with an alkaline plume, could conceivably lower sorption of radionuclides onto minerals in the saturated zone, simply because sorption coefficients are dependent on pH. The second effect is a potential porosity and permeability change in the surrounding rock due to calcite precipitation or caustic leaching of silicate phases in the tuff. Calcite precipitation is due to the addition of ambient CO_2 to the abundant CaO component of cements. Alkaline dissolution of silicates may occur if the pH stays high because most silicates are more soluble and dissolve faster at high pH. These changes would occur in the host rock near cementitious materials, particularly the shotcrete supporting the turnout intersections in the main access drifts and the intersections of the exhaust main drifts with the emplacement drifts. Such changes in hydrologic properties of the surrounding rock might alter the flow of water into and out of the drifts, and down to the saturated zone.

Before evaluating the two potential effects described above, it is necessary to establish the basic nature of the predicted flow near the repository. Water is expected to move in a generally vertical flow pattern through the waste emplacement horizon relative to the length scale of these drifts, with significant flow diversion around the drifts resulting from the capillary barrier effect. Water influx at the land surface percolates dominantly downward, with little lateral spread near the repository. *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], p. 6-18) states, "Computations have shown that the average flux flowing to the repository is within three percent of the average flux specified at the ground surface over the projected repository area." Standoffs from the shotcrete portions of the turnouts and exhaust drift intersections are established (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-18) and will prevent contact between shotcrete or leachate, and waste packages in the emplacement drifts. As discussed

below, the rapid neutralization of the alkaline plumes combined with the calcium available in equilibrium with cement phases will result in rapid precipitation of calcite in close proximity to the location of the cement. Thus, there should be little chance for alkaline plumes to interact with the waste, at or below the repository horizon. However, flow below the repository horizon may be diverted laterally at the TSw–CHn contact or into a few fracture zones, with potential for mixing of the plumes.

The first effect, transport enhancement by alkaline plumes, will be negligible for long-term repository performance, for two reasons. First, as indicated above, there will be little opportunity for mixing of the alkaline plumes with the fluids in the EBS, hence, the plumes will have no effect on the generation of a mobile radionuclide source term. Second, any high-pH plumes in the unsaturated zone are expected to be short-lived and rapidly neutralized. The unsaturated zone is open to gas circulation; particularly, ambient CO_2 will dissolve into the plume and neutralize pH. The rapid neutralization of cement leachates by CO_2 gas is indicated by experiment (DTN: LL030211523125.006 [DIRS 172021], file: *LiquidCarbonationEQ36Modeling.doc*). These findings are consistent with the analysis reported by Ziegler (2004 [DIRS 171694], Table D-12). As discussed in Appendix J, the Ziegler data provide solubility values for portlandite. The solubility of portlandite is used in the assessment of the alkaline cement leachate stability. Exposure of the cement leachate to CO_2 leads to plume carbonation and thus its neutralization. It is assumed that the leachate is saturated with respect to portlandite and the total calcium concentration in solution is sufficient to allow for calcite precipitation as a result of the plume neutralization. The rapid rate of this reaction indicates that the generation of an alkaline plume which could effect radionuclide transport is not expected. Even in the northwestern end of the repository footprint, where the TSw–CHn contact is at its highest elevation, approximately 80 m below the repository horizon as read from a contour plot (source for the elevation of the top of the CHn: DTN: MO0610MWDHFM06.002 [DIRS 179352], file: *H06_18chvu_X.dat*; source for the repository outline and elevations: SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01) where lateral flow may occur, the flow path from the emplaced cement to that contact is more than sufficient to neutralize the potential plumes. Details regarding the impact of an alkaline plume in the unsaturated zone are considered as part of excluded FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ).

For the reasons discussed above, calcite precipitation will not lead to changes in host-rock hydrologic properties that are sufficiently large or extensive enough to divert the dominantly vertical flow beneath the turnouts towards the emplacement drifts because it is expected to occur in close proximity to where the cement is located.

As stated earlier, cement will not be used in emplacement drifts, but will be used in turnout intersections, exhaust air (ventilation) turnouts, and access ramps. Resuspension of cement dust from these areas, prior to and during the ventilation period, could result in deposition of cement dust onto waste package surfaces. This could affect the dust composition, and in turn, the composition of brines that form by dust deliquescence on the waste package surface.

In general, dust deposited on the waste packages is anticipated to be similar to atmospheric dust collected at Yucca Mountain, or to dust collected from the Exploratory Studies Facility. Brines formed by deliquescence of these dusts is benign with respect to localized corrosion of Alloy 22 (excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to

Deliquescence)). The effects of an added component of cement dust on deliquescent brine composition are uncertain. However, other aspects of the exclusion argument presented in excluded FEP 2.1.9.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence) (e.g., capillary retention of brine in the dust inhibiting initiation of localized corrosion; limited extent of damage due to the limited mass of chloride) remain valid. Therefore, the cement dust is not expected to result in waste package failure due to localized corrosion. Also, the potential for deposition of cement dust on waste packages will be minimized by design requirements that limit the generation of concrete dust through the use of surface coatings and the use of dust suppression and ventilation control during concrete installation and removal (BSC 2008 [DIRS 183627], Parameter Number 02-03).

Based on this discussion, omission of FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Material in EBS) will not result in significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.02.0A

FEP NAME:

Mechanical Effects of Rock Reinforcement Materials in EBS

FEP DESCRIPTION:

Degradation of rock bolts, wire mesh, and other materials used in ground control may affect the long-term performance of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Rock reinforcement, also called ground support, mitigates the potential for rockfall into repository emplacement drifts during construction and operations. After repository closure, ground support will continue to serve this function until it degrades and eventually fails (BSC 2004 [DIRS 166107], Section 1.1). Postclosure modeling of rock mechanical response to heating and ground motion, which estimates the amount of rockfall, takes no credit for the presence of functioning ground support (BSC 2004 [DIRS 166107], Section 6). This assumption is a bounding approach that simplifies the modeling and increases the extent of predicted drift degradation during preclosure and postclosure periods. The introduction of other materials will be governed by *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-15 and 02-03). Preclosure degradation that might affect postclosure conditions will also be addressed (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-17 and 02-03).

Analyses of multiple rockfall impacts (BSC 2004 [DIRS 171756]) suggest that the drip shield can withstand two 2-metric ton blocks hitting the same spot. The Bernold sheets will have a mass of approximately 40 kg (BSC 2007 [DIRS 181645]). Rock bolts will weigh roughly a third of that. Rock blocks falling onto the drip shield are calculated to acquire a kinetic energy approximately that gained by falling through a distance of 2.5 m (SNL 2007 [DIRS 176828], Section 6.10.2.2), reaching a maximum velocity of 7 m/s (SNL 2007 [DIRS 176828], Table 6-50). The energy imparted to the drip shield by rockfall, a Bernold sheet, or a rock bolt will be proportional to the mass of the falling object. Because the ground support material will possess less than one tenth the mass of a 2-metric ton rockfall it will impose less than a tenth the force of the non-damaging 2-ton rockfall onto the drip shield. The yield strength of the ground support material is expected to be marginally larger than that of the rock (roughly a factor of two greater), so falling ground support material will be expected to withstand an impact with the drip shield. Yet, the much larger difference between rock block mass and ground support mass outweighs this difference in material yield strength. It is therefore reasonable to expect falling ground support materials to not damage the drip shield.

Drift degradation (rockfall and ground support degradation) due to seismic, thermal, and time-dependent effects during the postclosure period is described in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.2 through 6.4). The impact of rockfall occurring during the postclosure period (when complete degradation of the ground support is assumed) is addressed in other FEPs: excluded FEP 1.2.03.02.0B (Seismic-induced Rockfall Damages EBS Components), included FEP 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components), excluded FEP 2.1.07.01.0A (Rockfall), and excluded FEP 2.1.07.02.0A (Drift Collapse).

It should be noted that this FEP does not address the chemical effects that degradation of rock bolts or other ground support materials may have on repository performance. Those effects are addressed in excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS). Also, as discussed in excluded FEP 2.1.06.04.0A (Flow through Rock Reinforcement Materials in EBS), the presence of rock bolts has minimal effect on seepage into the repository.

Based on the previous discussion, omission of FEP 2.1.06.02.0A (Mechanical Effects of Rock Reinforcement Materials in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 78394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.04.0A

FEP NAME:

Flow Through Rock Reinforcement Materials in EBS

FEP DESCRIPTION:

Groundwater flow may occur through the ground support materials (e.g., wire mesh, rock bolts, grout) and liner (if present).

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP refers to the potential for ground support or its degradation products to enhance or decrease seepage (groundwater flow) into emplacement drifts, or to divert water flow within the drifts. Notice that cementitious materials will not be used for ground support in the emplacement areas (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). The Bernold-type sheets, which are bolted to the emplacement drift walls and roof (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15), may be considered a liner. This FEP addresses groundwater flow and seepage; vapor transport and condensation are addressed by a separate included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts).

Groundwater flow into emplacement drifts (seepage) is modeled in the TSPA as being completely unhindered by any rock reinforcement materials. The impact of rock bolts on seepage was investigated using the predictive seepage model for performance assessment (BSC 2004 [DIRS 167652], Section 6.5). The results of these simulations are presented in Section 6.6.4 and Table 6-4 of that report (BSC 2004 [DIRS 167652]) and in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.4.2.5 and 6.5.1.6). These results indicate that the presence of rock bolts does not lead to significant seepage enhancement. This is understandable, considering that an open borehole without grout acts as a capillary barrier to unsaturated flow; that the cross-sectional area of the rock bolt borehole, onto which flow may be incident, is small; and that water that may have seeped into the borehole can imbibe back into the rock along its length (see excluded FEP 1.1.01.01.0B (Influx Through Holes Drilled in Drift Wall or Crown). Note that only ungrouted rock bolts will be used in emplacement drifts (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15).

The Bernold-type sheets, which are bolted to the emplacement drift walls and roof (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-15 and 01-16), may act to divert some seepage away from waste packages either before or after the sheet installations fail due to corrosion or ground motion. However, these sheets are well perforated, so the potential diversion effect on seepage is limited and therefore not included in TSPA (consistent with SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-16).

Friction-type carbon steel rock bolts with plates are planned for use as temporary ground support during construction of the emplacement drifts, and will be left in place between the rock and the permanent (Bernold-type) ground support (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). As discussed above, neither the rock bolts used as temporary ground support nor those holding the Berthold plates will have a significant effect on the seepage flow rate. Also, as discussed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6) the ground support system is expected to degrade following repository closure. Therefore, not including the temporary ground support in the representation of seepage for TSPA is a realistic representation of the system with respect to groundwater flow into the drift.

In light of the above discussion, omission of FEP 2.1.06.04.0A (Flow Through Rock Reinforcement Materials in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.05.0A

FEP NAME:

Mechanical Degradation of Emplacement Pallet

FEP DESCRIPTION:

Degradation of the materials used in the pallet supporting the waste package may occur by physical processes, and may affect the long-term performance of the repository. Degradation may be fast (e.g., from dynamic loading) or slow (e.g., from static loading).

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP considers the potential for mechanical degradation of the emplacement pallets to affect long-term performance of the repository. Each emplacement pallet supports the static load of a waste package during handling and emplacement. The emplacement pallets raise the waste packages above the invert during the preclosure and postclosure time periods (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-02). If a seismic event occurs, the emplacement pallets are subjected to the static load of the waste packages plus the dynamic loads from waste package-to-pallet impacts. Both of these loading conditions are considered in this FEP.

Undisturbed Conditions—The emplacement pallet design consists of two cradles or pedestals, fabricated from Alloy 22, that are connected by tubing fabricated from Stainless Steel Type 316 (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-01). The tubing provides structural stability for the pallet as a lifting fixture for a waste package. The two pedestals are free-standing structures that can support a waste package without the tubing in the emplaced configuration. The dimensions and thicknesses of the key parts of the emplacement pallets are summarized in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-01).

The load-bearing capacity of the pedestals will be virtually unaffected by general corrosion, and the pallets will continue to fulfill their function of supporting the waste packages during the 10,000-year period. General corrosion can reduce the thickness of the pedestals, but this is a very slow process. As an example, the median corrosion rate of Alloy 22 at 60°C is 6.35 nm/yr, based on a medium uncertainty level in the distributions for general corrosion rate (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*, worksheet: "Data," cell: L71). Over 10,000 years, the thickness reduction from double-sided corrosion on the pallets is estimated as (10,000 years)$(2 \times 7 \times 10^{-9}$ m/yr) = 1.4×10^{-4} m = 0.14 mm. This thickness reduction is not significant in comparison to the initial thicknesses of the sides, ends, or tops of the pallet, which are 17.5, 17.5, and 22.2 mm, respectively (SNL 2007 [DIRS 178851], Table 6-2). An average temperature of 100°C may be more appropriate for the first 10,000 years

after closure. The median corrosion rate increases by a factor of 4 to 5 between 60°C and 100°C (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*), equivalent to a thickness reduction of 0.56 mm to 0.70 mm after 10,000 years. In either case, the Alloy 22 pedestals remain structurally intact during the first 10,000 years after repository closure.

The pallet design requirements are also relevant to mechanical degradation of the pallets. The emplacement pallets provide structural support and isolation from the invert during the preclosure and postclosure repository periods (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-02). The pallet material thicknesses include allowance for specified corrosion rates for at least 10,000 years after repository closure (SNL 2007 [DIRS 179354], Table 4-3 Parameter Number 08-03). The fact that the pallet design provides a corrosion allowance for 10,000 years is confirmed by the median corrosion estimates calculated in a previous paragraph.

Possible impacts of thermal-mechanical stresses on in-drift EBS components are discussed under excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-drift EBS Components), which is excluded on the basis of low consequence.

Seismic-Induced Loads—Other FEPs evaluate the response of the engineered barrier system (EBS) components to seismic events. The EBS components are the waste package, drip shield, emplacement pallet, invert, waste form, cladding, and the emplacement drift. These FEPs generally focus on the response of the waste packages and drip shields because failure of these EBS components has the potential to form new transport pathways that release radionuclides and because TSPA does not take credit for the potential delay in radionuclide transport due to the presence of the emplacement pallets. However, two FEPs explicitly represent the chemical degradation of the pallets at the time of a seismic event. The effect of general corrosion of the Alloy 22 components of the emplacement pallet on the structural response to a seismic event is addressed in included FEP 2.1.06.05.0C (Chemical Degradation of Emplacement Pallet) and included FEP 1.2.03.02.0A (Seismic Induced Ground Motion Damages EBS Components). Included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components) discusses the potential for the emplacement pallets to change the clearance between the bottom of the drip shields and top of the waste packages in response to a fault displacement with an intact drip shield (SNL 2007 [DIRS 176828], Section 6.11.1.1).

A structural analysis of the pallets during seismic events is documented in *Structural Calculations of Waste Package Exposed to Vibratory Ground Motion* (BSC 2004 [DIRS 167083], Section 6.2.4). This analysis shows that the pallets will deform (bulge) but do not collapse under large dynamic loads imposed by waste package impacts during infrequent seismic events at the 5.35 m/s PGV level. This PGV level corresponds to less than the 10^{-8} annual exceedance frequency on the bounded hazard curve (SNL 2007 [DIRS 176828], Table 6-3). The dynamic deformation of the pallets reduces the damage to the waste packages from waste package-to-pallet/invert impacts (BSC 2004 [DIRS 167083], Section 6.2.4 and Figure 9). An additional assessment of the performance of the emplacement pallet connector tubes during seismic events with a PGV of 5.35 m/s, where the connector tube properties were those of 316 stainless steel instead of Alloy 22 as used in the original analysis, indicates that they will perform their function for at least 10,000 years (BSC 2005 [DIRS 173172], Attachment XI).

A complete suite of structural response calculations for waste package-to-pallet impacts during a seismic event has been performed with deformable pallets that are chemically degraded (SNL 2007 [DIRS 178851], Section 6.3.2.2). These calculations evaluate the damaged area on the waste packages' OCB for two OCB thicknesses, 23 and 17 mm, from the nominal 25.4-mm thickness (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-03), and for various impact velocities, impact locations, and impact angles between the pallet and the package. The corresponding thickness reduction for the Alloy 22 plates of the pallet is equal to the thickness reduction of the OCB for each analysis. The thickness reductions of 2.4 mm and 8.4 mm span the range of waste package structural response that is expected during the time frame for geologic stability (SNL 2007 [DIRS 176828], Sections 6.5.1.2 and 6.5.2.2). These calculations provide part of the basis for the seismic damage abstractions when the drip shields are intact and the waste packages and emplacement pallets can move kinematically beneath the drip shields (SNL 2007 [DIRS 176828], Sections 6.5 and 6.6).

Exclusion of the mechanical degradation of the pallets from the structural response calculations maximizes the plastic deformation of waste packages and maximizes the area with high residual stress that has the potential to form stress corrosion cracks in the OCB. For example, the presence of the stainless steel connector rods stiffens the pallets and maintains the pedestals in a vertical, as-emplaced configuration that maximizes plastic deformation from waste package-to-pallet impacts. As a second example, multiple waste package-to-pallet impacts will occur during many ground motions. However, the potential for damage to accumulate and reduce the mechanical stiffness of the pallets is excluded because an undamaged pallet maximizes the plastic deformation of a waste package. Finally, a severe ground motion could rupture the connector rods, allowing the individual pedestals to topple onto the invert. A toppled pedestal will lie flatter on the invert than a vertical pedestal, causing less plastic deformation of a waste package during waste package-to-pallet impacts than the pallets in their as-emplaced configuration. These examples show that screening out mechanical degradation of the pallets maximizes the damaged areas on the waste packages.

Based on the previous discussion, omission of FEP 2.1.06.05.0A (Mechanical Degradation of Emplacement Pallet) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.05.0B

FEP NAME:

Mechanical Degradation of Invert

FEP DESCRIPTION:

Degradation of the materials used in the invert may occur by physical processes, and may affect the long-term performance of the repository. Degradation may be fast (e.g., from dynamic loading) or slow (e.g., from static loading).

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The invert is composed of plain carbon steel components and crushed-tuff ballast (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). The invert provides structural support for other EBS components, namely the pallet, waste package, and drip shield (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-07). Degradation, bearing capacity, and long-term settlement properties are part of the design (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). Postclosure mechanical loads on the invert can result from thermal expansion of invert components (e.g., the steel structure), deformation of the host rock containing the invert, seismic loading, and loading from collapse-rubble. Postclosure thermal-mechanical effects on emplacement drift stability (i.e., rockfall) have been analyzed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3.1.3 and 6.4.2.3). EBS component responses to seismic events are discussed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components), and in included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). Invert damage due to drift collapse is also discussed in excluded FEP 2.1.07.02.0A (Drift Collapse).

Processes leading to postclosure mechanical loading, and the potential impacts of those processes on the EBS components, are summarized as follows:

- Thermal expansion of invert materials is accommodated in the invert design (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-04). Peak thermal deformation (e.g., of the invert steel) will occur when in-drift temperatures are at a maximum, within approximately 20 years after closure (SNL 2008 [DIRS 184433], Section 6.3.16[a]).

- The limited vertical displacement of the drift floor, as described in excluded FEP 2.1.07.06.0A (Floor Buckling), is not expected to result in invert degradation due to thermal-mechanical deformation of the host rock.

- Seismic ground motion could result in bulking and subsequent uneven settlement of the invert, potentially damaging the drip shield. This process is evaluated in *Mechanical*

Assessment of Degraded Waste Packages and Drip Shields Subject to Vibratory Ground Motion (SNL 2007 [DIRS 178851], Section 6.4.6). Stresses produced by uneven settlement of the invert do not exceed the drip shield tensile strength, and settlement of the invert is not expected to materially alter the drip shield function.

- In the absence of seismic ground motion, invert settlement is expected to be minor. The invert is graded and will be tightly compacted during placement, and most of the settlement will occur during construction. Further compaction is expected to be negligible (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08), resulting in displacements that produce only minor shifting in the drip shields, which will not compromise their integrity because the overlap between adjacent drip shields is approximately 320 mm (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-01). The effect of settling on the position of the waste packages and pallet is also expected to be minor in the non-seismic case.

In addition to the effects listed above, the invert is part of the transport pathway for radionuclides as represented in TSPA (SNL 2008 [DIRS 177407], Section 6.5). Radionuclide transport through the invert is not significantly affected by mechanical degradation for the following reasons:

- Mechanical degradation or settling of the invert ballast could result in changes in the intergranular porosity and permeability. Uncertainty with respect to hydrologic properties of the invert could affect the predicted in-drift thermal-hydrologic environment (temperature, relative humidity, and invert liquid-phase saturation), which, in turn, controls the chemical environment in the drift (SNL 2007 [DIRS 177412], Section 6.9). This uncertainty was evaluated over a range of particle sizes (0.317 mm to 20 mm) in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.11). The in-drift thermal-hydrologic environment is insensitive to the hydrologic properties of the intergranular porosity, indicating that mechanical degradation will have a negligible effect on predictions of in-drift chemistry.

- Consolidation of the invert ballast could change the hydrologic properties affecting advective radionuclide transport. Intragranular rewetting and degree of saturation are independent of grain size and intergranular hydrologic properties (SNL 2008 [DIRS 184433], Section 6.3.11); invert rewetting is largely a function of the capillary condensation in intragranular porosity as opposed to wicking, because the intergranular porosity has a negligible capillarity relative to that of fractures in the rock. Therefore, the invert provides little resistance to downward flow, regardless of grain size. The effects of hydrologic changes in the invert are discussed in excluded FEPs 2.1.08.09.0A (Saturated Flow in the EBS) and 2.1.08.12.0A (Induced Hydrologic Changes in Invert).

- Consolidation of the invert ballast could change the invert porosity and water content, affecting radionuclide diffusion rates. The uncertainty associated with the porosity of the invert is included in the uncertainty in the diffusion coefficient, which is based on measurements for a variety of geologic materials having a range of porosities. Thus, the porosity uncertainty can be considered to be accounted for in the effective diffusion coefficient. (SNL 2008 [DIRS 177407], Section 6.3.4.1.1). The anticipated porosity range of 0.27 to 0.39 (SNL 2008 [DIRS 177407], Equation 6.3.4.1.1-23) includes a

range of potential mechanical degradation effects. Therefore, small changes in invert porosity will not significantly affect calculation of the invert diffusion coefficient in TSPA.

Based on the previous discussion, omission of FEP 2.1.06.05.0B (Mechanical Degradation of Invert) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessment conducted to demonstrate compliance with proposed 10 CFR 63.311 and 633.21 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.05.0C

FEP NAME:

Chemical Degradation of Emplacement Pallet

FEP DESCRIPTION:

Degradation of the materials used in the pallet supporting the waste package may occur by chemical or microbial processes, and may affect the long-term performance of the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Mechanical degradation of the emplacement pallet is discussed in excluded FEP 2.1.06.05.0A (Mechanical Degradation of Emplacement Pallet). In addition, microbial activity in the EBS is of low consequence with respect to potential chemical degradation of EBS components, including emplacement pallets (see excluded FEP 2.1.10.01.0A (Microbial Activity in EBS)). Chemical degradation of the emplacement pallet is included by performing structural analyses with thinned emplacement pallet components.

The waste package emplacement pallet supports the waste package during handling, emplacement, preclosure, and postclosure periods. In the first 10,000 years after emplacement, in the absence of seismic or igneous activity, the emplacement pallet maintains a waste package in a nominally horizontal position (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-02). The emplacement pallet waste package supports are fabricated from Alloy 22 and the emplacement pallet connector tubes are fabricated from Stainless Steel Type 316 (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-01). The stainless steel tubes connect to the Alloy 22 waste package supports. Galvanic coupling between Alloy 22 and Stainless Steel Type 316 is discussed in excluded FEP 2.1.09.09.0A (Electrochemical Effects in EBS).

The Alloy 22 emplacement pallet supports are the main load-bearing members because the geometry of the emplacement pallet prevents direct contact between the waste package and non-Alloy 22 drift components (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). The emplacement pallet is designed with margins accounting for corrosion such that it meets the requirements to support the waste package (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03) during the first 10,000 years after closure. The corrosion allowance for both the Alloy 22 and stainless steel components shall be at least 2 mm (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). As discussed below, the corrosion of the connector tubes over the first 10,000 years after closure is low enough that the connector tubes retain their structural integrity. The structural integrity of the connector tubes is only important in the case of a seismic event of sufficient acceleration to cause the waste package to separate from the emplacement pallet.

When the drip shield is intact, seepage water is prevented from contacting the emplacement pallet connector tubes. A bounding estimate of the drip shield failure time by general corrosion can be obtained by using the upper 97.5% uncertainty bound, 0.999 probability general corrosion rate for the outer surface of the Titanium Grade 7 drip shield plate material (DTN: SN0704PADSGCMT.001 [DIRS 182122], file: *DS GC Model Analysis_aggressive condition.xls*) and the upper 97.5% uncertainty bound, 0.999 probability general corrosion rate for the inner surface of the Titanium Grade 7 drip shield plate material (DTN: SN0704PADSGCMT.001 [DIRS 182122], file: *DS GC Model Analysis_benign condition.xls*). These general corrosion rates are about 58 nm/yr and 21 nm/yr, respectively. Using these general corrosion rates for the 15 mm drip shield plate material, the failure time by general corrosion is estimated to be about 190,000 years. Furthermore, drip shield localized corrosion is discussed in excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields). Thus, in the absence of seismic activity or igneous intrusion, the emplacement pallet will not experience seepage water contact during the first 10,000 years after closure. The potential for concentrated solutions formed as a result of dust deliquescence to materially influence localized corrosion is screened out for Alloy 22, as discussed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence). Since similar justifications (small brine volume, sublimation of salts, acid degassing, capillary retention of deliquescent brine within the dust, retention of deliquescent brines by corrosion products) also apply to localized corrosion of the stainless steel connector tubes, these components of the emplacement pallet are not expected to experience significant amounts of localized corrosion while the drip shield is performing its water diversion function. The stresses imposed in the Alloy 22 components of both the waste package and the emplacement pallet, in the as-emplaced configuration, shall be lower than the stress level necessary to cause SCC of Alloy 22 (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-05). Therefore, in the absence of seismic activity of sufficient magnitude to disturb the as emplaced waste package/emplacement pallet geometry, the Alloy 22 components of the emplacement pallet are not expected to develop stresses large enough to cause SCC of these components.

A reasonable estimate for the aqueous phase general corrosion rate for the Stainless Steel Type 316 emplacement pallet supports is 0.2 μm/yr. This estimate is corroborated by the general corrosion rates of Stainless Steel Type 316L measured in J-13 water after over one year of exposure reported by McCright et al. (1984 [DIRS 159336], Table 6). These values are appropriate for corroboration of the aqueous phase general corrosion rates of the emplacement pallet supports because Stainless Steel Type 316L is a low carbon version of Stainless Steel Type 316, which is, therefore, a suitable analogue material for Stainless Steel Type 316. Furthermore, the bulk water that may contact the emplacement pallet supports under an intact drip shield will result from condensation and have a dilute chemistry, as does J-13 well water (McCright et al. 1984 [DIRS 159336], Table 5). Aqueous phase corrosion rates of Stainless Steel Type 316L at temperatures of 50°C, 80°C, and 100°C, for samples exposed for longer than one year, have been measured to be 0.154±0.008, 0.109±0.005 , and 0.037±0.011 μm/yr, respectively (McCright et al. 1984 [DIRS 159336], Table 6). The estimated aqueous phase general corrosion rate for the Stainless Steel Type 316 emplacement pallet supports of 0.2 μm/yr sufficiently bounds these reported general corrosion rate values. Furthermore, studies have shown that there is a continual decrease of the degradation rate of stainless steel over time (Gdowski and Bullen 1988 [DIRS 100860], Figure 19; Larrabee 1953 [DIRS 159337], pp. 259 to 271; Southwell et al. 1976 [DIRS 100927], Table 4), and therefore the values of corrosion rate

resulting from these shorter-term corrosion tests (1.2 to 1.3 years) are higher than the corrosion rates expected when averaged over the design life of the emplacement pallet. The highest Stainless Steel Type 316 corrosion rate used in *In-Package Chemistry Abstraction* (14.8 μm/yr) (SNL 2007 [DIRS 180506], Table 4-8) is higher than the rate used in the current analysis. However, this higher general corrosion rate, derived from salt-water conditions, is a bounding rate applicable only in a seepage scenario when the drip shield is no longer intact.

Marine atmosphere corrosion rates for Stainless Steel Type 316L have been compiled and found to have a mean of 0.113 μm/yr for atmospheric conditions (DTN: MO0705OXYBALAN.000 [DIRS 185041], file: *atmospheric May2007.xls*, worksheet: "316"). Using this vapor phase corrosion rate for the first 2,000 years during the hot, dry period, and using the aqueous phase corrosion rate of 0.2 μm/yr at 50°C for the remaining 8,000 years, the depth of corrosion is calculated to be approximately 1.8 mm (rounded to two significant figures), which is about 19% of the 9.5-mm connector tube wall thickness. Because this calculation is based on short-term corrosion measurements, and because general corrosion rates tend to decrease with time, this is an upper limit of corrosion penetration that would be expected.

Corrosion of the stainless steel ground support in the drifts does not significantly influence the in-drift chemistry (SNL 2007 [DIRS 177412], Section 6.8). Therefore, corrosion of the stainless steel pallet tubes can be excluded as a factor influencing in-drift chemistry on the basis of low consequence. Additionally, *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 8.1) uses the conceptual model that all of the flux from the waste package flows directly into the invert, independent of the breach location on the waste package. The emplacement pallet could interfere with flow into the invert; however, no performance credit is taken for this process. *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 5.6) also assumes that no corrosion products exist in the invert. This assumption maximizes the potential transport of radionuclides through the invert as metal oxide corrosion products are capable of sorbing large amounts of radionuclides (SNL 2008 [DIRS 177407], Section 5.6). Although the text of the assumption discusses the corrosion products of the carbon steel invert materials, similar processes involving corrosion products resulting from degradation of the emplacement pallet are not credited in TSPA either.

In summary, chemical degradation of the emplacement pallet during the first 10,000 years of closure is determined mostly by the expected corrosion behavior of the stainless steel connector tubes, which does not significantly influence structural integrity of the emplacement pallets or in-drift chemistry.

The following discussion summarizes the effect of the emplacement pallet on repository performance after the first 10,000 years of closure. Mechanical degradation of the emplacement pallet (including the effects of seismic loadings) is discussed in excluded FEP 2.1.06.05.0A (Mechanical Degradation of Emplacement Pallet). The seismic analyses documented in *Mechanical Assessment of Degraded TAD Canisters and Degraded Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Section 6) are conducted on three degraded states: a 23-mm-thick WPOB with intact waste package internals; a 23-mm-thick WPOB with degraded waste package internals; and a 17-mm-thick WPOB with degraded waste package internals. The future states of the EBS components are represented by three conceptual configurations as discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828],

Section 6.1). These future configurations are defined largely by the physical condition of the drip shield and the presence of rubble in the drift. The first configuration represents the as-emplaced EBS configuration, with a substantially intact drip shield and minimal rockfall in the drifts. In this configuration, the waste packages can move freely beneath the drip shields. The second configuration represents an intermediate configuration of the system where the legs of the drip shield have buckled under combined rockfall/seismic load, but the drip shield plates remain intact. In this configuration, the drip shield may collapse onto the waste package, inhibiting free movement of the waste package and emplacement pallet during seismic events. When the waste package is free to move under the action of seismicity, analyses indicate that most of the damage to waste packages from vibratory ground motion is caused by waste package-to-pallet impacts as opposed to waste package-to-waste package impacts (SNL 2007 [DIRS 178851], Section 8). A thickness reduction equal to the WPOB thickness reduction is also applied to the Alloy 22 plates of the emplacement pallet for each analysis (SNL 2007 [DIRS 178851], Section 6.3.2.2.1). This approach is reasonable because there is no reason that the Alloy 22 components in the emplacement pallet should undergo corrosion rates that are significantly different from those of the WPOB. In this manner, chemical thinning of the emplacement pallet is included in these seismic analyses. In the third configuration of the system, rubble surrounds the waste package after failure of the drip shield plates. In the seismic analyses of this configuration, the emplacement pallet is as an elastic solid body with stiffness such that its deformability is negligible (SNL 2007 [DIRS 178851], Section 5.21). This treatment will result in overestimation of deformation and damage in the waste package (SNL 2007 [DIRS 178851], Section 5.21). The Alloy 22 waste packages and emplacement pallet supports are expected to last longer than the drip shields, which are fabricated from titanium, as explained in *Mechanical Assessment of Degraded TAD Canisters and Degraded Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Section 1.2). Once the drip shield has degraded, mechanical system response is governed by the rubble surrounding the waste package and emplacement pallet (SNL 2007 [DIRS 178851], Section 6.5). In this final configuration, the interactions between the waste package and the surrounding rubble are not affected significantly by the emplacement pallet (SNL 2007 [DIRS 178851], Section 6.5.1.2.1). Thus, in the long-term, degradation of the emplacement pallet is a relatively small contributor to seismic performance of the waste package.

In an analysis representative of the drift configuration during the first 10,000 years of the postclosure period and for normal condition loads, the emplacement pallet design was evaluated using a reduction in plate thickness to represent the effects of corrosion. The emplacement pallet design was found to perform satisfactorily (i.e., the waste package remains on the emplacement pallet) under seismic events with an annual frequency of occurrence of 1×10^{-6} per year (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 03-08). As stated above, the function of the emplacement pallet becomes less important to mechanical performance at later times when the drip shield is collapsed and rubble accumulates adjacent to waste packages.

At some time beyond the first 10,000 years after waste package emplacement, the emplacement pallet will fail by corrosion of its components and/or mechanical damage. From the above discussion, degradation of the emplacement pallet is not considered from the standpoint of radionuclide release nor does it have a significant impact on long-term seismic performance. When the emplacement pallet does fail, the waste package may come to rest on the invert. The invert structure contains a carbon steel structure that provides a framework that supports the

emplacement pallets and is covered by a layer of crushed tuff (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). It is expected that the carbon steel invert structure will have degraded significantly by the time the emplacement pallet has failed (particularly its Alloy 22 components). Even if the waste package contacts the metallic components of the invert structure, as discussed in excluded FEP 2.1.09.09.0A (Electrochemical Effects in EBS), these contacts are not expected to result in enhanced degradation of the more corrosion-resistant Alloy 22 WPOB.

In conclusion, thinning of the waste package emplacement pallet due to chemical degradation is included in seismic analyses; however, the effect of the emplacement pallet on radionuclide release is not considered.

FEP: 2.1.06.05.0D

FEP NAME:

Chemical Degradation of Invert

FEP DESCRIPTION:

Degradation of the materials used in the invert may occur by chemical or microbial processes, and may affect the long-term performance of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The invert is composed of plain carbon steel components and crushed-tuff ballast (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). The invert provides structural support for other EBS components, namely the pallet, waste package, and drip shield (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-07). Degradation, bearing capacity, and long-term settlement properties are part of the design (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08).

One consequence of chemical degradation of the invert could be the loss of mechanical integrity. Mechanical degradation of the invert is discussed in excluded FEP 2.1.06.05.0B (Mechanical Degradation of Invert), floor buckling, or heave, is excluded in FEP 2.1.07.06.0A (Floor Buckling).

Potential chemical degradation products in the invert include metal oxides and oxyhydroxides from the corrosion of steels. Invert corrosion products are expected to be localized and widely spaced, with the possibility that seepage from the waste package could completely miss corrosion products in the invert (SNL 2008 [DIRS 177407], Section 6.3.4.2.2.2). In this case, even small sorption coefficient values could overestimate the amount of retardation of radionuclides in the invert. Therefore although steel corrosion products have the potential to retard both iodine and technetium, no credit is taken for radionuclide sorption onto these materials, which are expected to be present locally in the invert (SNL 2008 [DIRS 177407], Section 6.3.4.2.2.2), through which radionuclides must be transported to reach the accessible environment.

The impact of steel corrosion on seepage water chemistry is evaluated in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.8.4.1). The P&CE report demonstrates that wide variations in the amount of low alloy steel that corrodes per liter of seepage (up to 0.1 mole per liter) merely result in differing amounts of corrosion products and do not impact the aqueous phase chemistry significantly. This conclusion is corrosion-rate independent, as the effect was evaluated for large masses of steel well beyond what would be expected for reasonable time scales, corrosion rates, and surface areas.

The lower part of the invert will be crushed tuff. Degradation of the crushed tuff can either result in increased porosity due to the dissolution of primary minerals or decrease in porosity through the precipitation secondary phases. Both scenarios would be limited by the availability of water. Increased porosity would increase repository performance by decreasing the likelihood of local ponding, and overall water availability. Reduced porosity might lead, at worst, to accumulation of water and an increase in the rate of radionuclide release by advection. However, as explained in excluded FEP 2.1.08.12.0A (Induced Hydrologic Changes in Invert), which is excluded on the basis of low consequence, the repository emplacement drift design will preclude wetting or ponding along the invert–rock interface. The effects of hydrologic changes in the invert are further discussed in excluded FEP 2.1.08.09.0A (Saturated Flow in the EBS).

In the absence of advective flow, radionuclide migration through the crushed tuff is evaluated as a diffusion-only process. The effects of variable porosity on radionuclide diffusion are captured in the range of values for the diffusion coefficient that are used in TSPA (SNL 2008 [DIRS 177407], Section 6.3.4.1.1). The anticipated porosity range of 0.27 to 0.39 (SNL 2008 [DIRS 177407], Equation 6.3.4.1.1-23) includes a range of potential invert degradation effects. Therefore, small changes in invert porosity will not significantly affect the magnitude of invert diffusion coefficients calculated by TSPA.

Chemical degradation of the crushed tuff ballast in the invert could lead to changes in the invert porewater chemistry. The thermally perturbed interactions between porewaters and tuff are evaluated by the near-field chemistry model as the water–rock interaction parameter (SNL 2007 [DIRS 177412], Section 6.3.2). The water–rock interaction parameter is utilized by the P&CE seepage dilution/evaporation abstraction model to provide a wide range of potential seepage water compositions to TSPA (SNL 2007 [DIRS 177412], Sections 6.3.3 and 6.9). Any additional chemical changes induced by pore water interactions with the invert are not expected to generate changes in chemistry that is outside the range of compositions already included in the TSPA. On this basis, the effects on invert water chemistry can be regarded as insignificant.

Carbon present as in-drift committed materials will be in a refractory, reduced state (e.g., graphite) as discussed in *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 6.4.5). Therefore, introduced carbon will not be biodegradable and can not participate in microbial reactions. *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 6.4.5) also evaluates the potential sources of carbon available as sources of energy and nutrients to bacteria and other microorganisms that might survive in the in-drift environment. Results of that analysis show that microbial activity is of low consequence with respect to the composition of the in-drift chemistry (BSC 2004 [DIRS 169991], Section 7.1; excluded FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation) and excluded FEP 2.1.10.01.0A (Microbial Activity in EBS)).

In conclusion, degradation of the invert by chemical or microbial processes will not alter (a) the hydrologic properties of the invert sufficiently to affect the transport of radionuclides through the invert, and (b) the chemical environment of emplacement drifts sufficiently to affect predictions of repository chemistry.

Based on this discussion, omission of FEP 2.1.06.05.0D (Chemical Degradation of Invert) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis or low consequence.

FEP: 2.1.06.06.0A

FEP NAME:

Effects of Drip Shield on Flow

FEP DESCRIPTION:

The drip shield will affect the amount of water reaching the waste package. Effects of the drip shield on the disposal region environment (for example, changes in relative humidity and temperature below the shield) should be considered for both intact and degraded conditions.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The EBS includes Titanium Grade 7 drip shield top and side plates supported by a Titanium Grade 29 framework, which is placed over the waste packages. The drip shield is a free-standing structure that sits on the invert transverse support beams and employs interlocking segments continually installed along the length of the drift. The drip shield design requirements and component details are summarized in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Section 4.1.2, Table 4-2). The effects of the drip shield on flow are included in TSPA models for in-drift natural convection and condensation as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]) for in-drift thermal hydrology as described in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]), and for EBS radionuclide transport as described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407]).

The role of the drip shield on flow processes in the in-drift environment is addressed in *In-Drift Natural Convection and Condensation Model* (SNL 2007 [DIRS 181648]), which develops a computational fluid dynamics model of natural convection during the postclosure period (SNL 2007 [DIRS 181648], Sections 6.1.5 and 6.2.5). Axial dispersion coefficients of water vapor are derived from the natural convection model, and implemented in a simplified model of evaporation and condensation in the in-drift environment (SNL 2007 [DIRS 181648], Section 6.3.3). Condensation on the drift walls is discussed in more detail in included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)). The results are included in the TSPA, as also described in included FEP 2.1.08.04.0A.

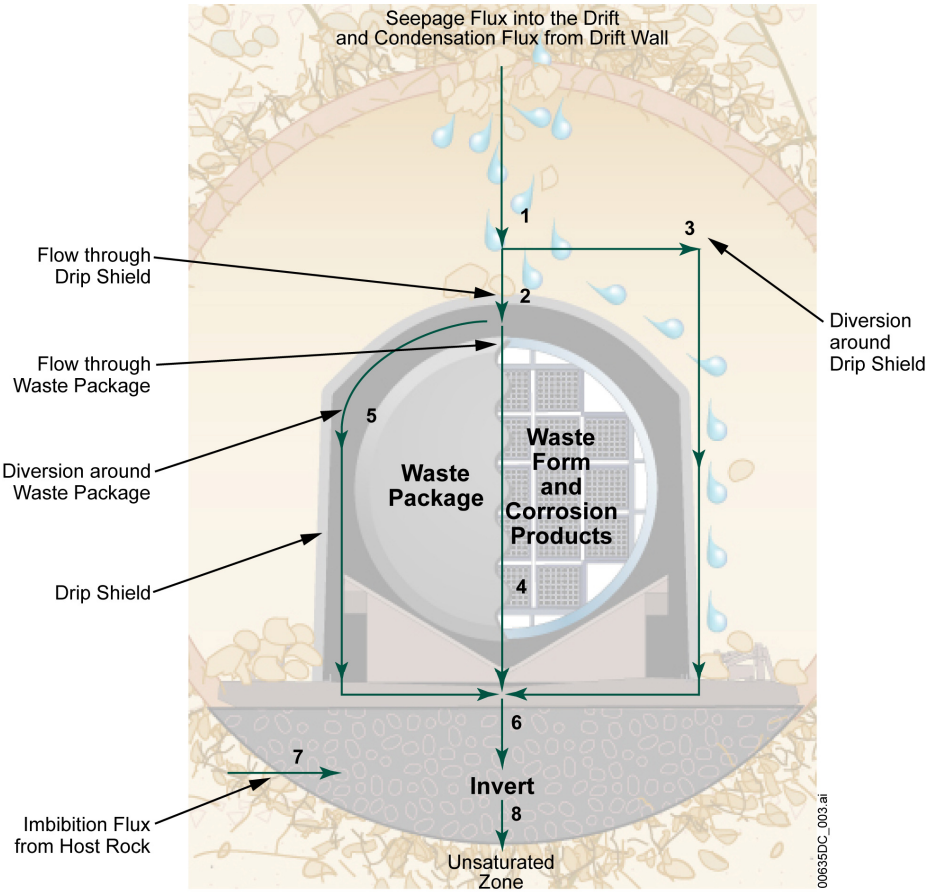
The drip shield limits the amount of water that contacts waste forms, and limit the rates of release of radionuclides from breached waste packages (as discussed for included FEP 2.1.08.07.0A (Unsaturated Flow in the EBS)).

Temperature and unsaturated relative humidity under intact drip shields are included in the multiscale model for TSPA (SNL 2008 [DIRS 184433], Sections 8.1 and 8.4). Diffusive vapor transport through gaps in the joints between drip shields, and through the invert ballast is

assumed to be rapid so that the partial pressure of water vapor is the same under and outside of the drip shield (SNL 2008 [DIRS 184433], Section 5.5). This is supported by results from scale-model testing to investigate condensation under the drip shield (as discussed for excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield)), in which water vapor readily migrated from inside to outside the drip shield, so that condensation was controlled by the cooler drift wall. In addition, the drip shield acts as a thermal radiation shield, causing the waste package to be warmer and thus drier than if no drip shield were present (SNL 2008 [DIRS 184433], Section 6.2.4). Similar behaviors are predicted in the event of seepage into collapsed drift openings, where coverage by collapse rubble increases the temperature of the drip shield and waste package, prolonging dryout. Seepage into collapse rubble will be diverted from contacting the drip shield until the waste package temperature cools to approximately 100°C or lower (SNL 2008 [DIRS 184433], Section 6.3.17[a]).

When seepage or drift wall condensation occurs, and the drip shield fails to perform its flow diversion function, liquid water may flow through breaches in the drip shield and contact the waste package (see included FEPs 2.2.07.20.0A (Flow Diversion Around Repository Drifts) and 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)). Flow of water through breaches in the drip shield is described by the EBS flow component, of the EBS radionuclide transport abstraction model (SNL 2008 [DIRS 177407], Section 6.3.1.1), which quantifies the time-dependent radionuclide releases from a failed waste package and the subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. Basic inputs to the EBS radionuclide transport abstraction model (SNL 2008 [DIRS 177407], Section 6.1) include the drift seepage and drift wall condensation rates, the environmental conditions in the drift (temperature, relative humidity, and water chemistry), and the degradation states of EBS components including the drip shield.

Water flow in the EBS comprises eight pathways (Figure 2.1.06.06.0A-1) and corresponding fluxes: total dripping flux, including any condensation on drift walls above the drip shield (F_1), flux through the failed drip shield (F_2), diversion around an intact drip shield (F_3), flux through the waste package (F_4), diversion around the waste package (F_5), flux from the waste package and drip shield into the invert (F_6), imbibition flux from the drift host-rock matrix to the invert (F_7), and flux from the invert to the unsaturated zone matrix and fractures (F_8). These pathways are time dependent, in that the total dripping flux and waste package penetrations will vary with time and local conditions in the repository. The primary source of inflow to the EBS is the dripping flux from the crown (roof) of the drift (F_1), and includes seepage flux and any condensation that may occur on the walls of the drift above the drip shield.



Source: SNL 2008 [DIRS 177407], Figure 6.3-1.

Figure 2.1.06.06.0A-1. Potential Flow Pathways in the EBS

Section 6.3.2 of *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407]) describes water flux through a failed drip shield (F_2) and around an intact drip shield (F_3). Once the drip shield has failed, all of the water flux ($F_2 = F_1$) will pass through the drip shield and have access to the waste package. Until the drip shield has failed, all of the flux is diverted around the drip shield ($F_3 = F_1$). Key assumptions include: (1) the dripping flux (seepage plus condensation) into the drift is assumed to fall as droplets from the top of the drift onto the crown of the drip shield; (2) droplets fall randomly along the length of the drip shield; (3) evaporation from the drip shield is assumed to be negligible; and (4) all water that flows through the failed drip shield flows onto or into the waste package.

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.06.06.0B

FEP NAME:

Oxygen Embrittlement of Drip Shields

FEP DESCRIPTION:

A potential failure mechanism for drip shields is oxygen embrittlement, resulting from the diffusion of interstitial oxygen in the titanium at high temperatures.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Oxygen embrittlement of a titanium alloy results from the diffusion of oxygen into the titanium metal occurring at temperatures greater than 340°C to 370°C (i.e., 645°F to 700°F) (ASM International 1987 [DIRS 103753], p. 681). During diffusion through a titanium alloy, oxygen atoms insert themselves at interstitial positions in the crystal lattice and thereby increase the resistance to sliding of one part of the crystal past another. This effect, in turn, can impact mechanical properties of the titanium alloy (e.g., it can increase the hardness and strength but decrease the ductility) promoting embrittlement (Leyens and Peters 2004 [DIRS 181560], p. 187).

Without drift collapse, the waste package temperature will be below 300°C (SNL 2008 [DIRS 184433], Figure 6.3-76[a]) and decrease with time after achieving a peak value. Due to greater distance of the drip shield from the heat source (i.e., the waste form) than the waste package, surface temperatures of the drip shields will be lower than those for the waste packages. In order for the waste package surface to exceed 300°C, a seismic event must occur within approximately 90 years after closure, result in drift collapse, and affect a waste package with an unfavorable combination of a high thermal output surrounded by a low conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about one in 10,000 within the first 10,000 years of disposal (SNL 2008 [DIRS 179962], Section 6.5.1). Therefore, a reasonably bounding drip shield exposure temperature in the repository is 300°C and is used in the analysis of oxygen embrittlement in this FEP.

To estimate the critical oxygen concentration below which oxygen embrittlement is not expected to occur, a reasonable approach is to use the maximum oxygen content specified for Titanium Grade 4, an oxygen-strengthened titanium metal, as the lower-bound value of this parameter for Titanium Grade 7 at 300°C. The specified maximum oxygen content in Titanium Grade 4 is 0.4 wt % (ASTM B265-02 [DIRS 162726], Table 2). Based on the above discussion, the lower-bound value of the critical oxygen concentration of Titanium Grade 7 could be considered as any value equal to or higher than the oxygen content of the oxygen-strengthened alloy Titanium Grade 4 (i.e., 0.4 wt %). Using this lower-bound value of the critical oxygen content, the amount of time required to increase the oxygen content of Titanium Grade 7 to 0.4 wt % at

300°C can be estimated if the oxygen diffusion coefficient at 300°C is known. The specified oxygen content in Titanium Grade 7 is 0.25 wt % (ASTM B265-02 [DIRS 162726], Table 2). The calculated time to reach the lower-bound oxygen content value of 0.4 wt % from 0.25 wt % represents the minimum period of time before oxygen embrittlement of titanium drip shield can occur.

The value of the oxygen diffusion coefficient in titanium at 300°C is 8.8×10^{-18} $cm^2 \cdot s^{-1}$ and has an uncertainty of 70% (Rogers et al. 1988 [DIRS 184108], Table 1 and p. 146). Using this value of the oxygen diffusion coefficient, the amount of time required to increase the oxygen content of Titanium Grade 7 to 0.4 wt % at 300°C at any depth, x, can be estimated from the following equation (Guy 1959 [DIRS 154917], p. 407):

$$\frac{C - C_0}{C_1 - C_0} = 1 - erf\left(\frac{x}{2\sqrt{Dt}}\right) \qquad \text{(Eq. 2.1.06.06.0B-1)}$$

Here, C is the oxygen concentration at a depth of x centimeters into the metal surface after diffusion has occurred for time t seconds, C_1 the surface oxygen concentration in wt %, C_0 the initial oxygen concentration in the metal plate in wt %, and D the diffusion coefficient of oxygen in the metal. A sensitivity analysis performed using various values of oxygen concentration on the drip shield surface (C_1 = 10 wt % to 40 wt %), the upper bound value of the diffusion coefficient of oxygen in titanium ($D = 1.7 \times 8.8 \times 10^{-18}$ $cm^2 \cdot s^{-1}$ at 300°C), a depth of 0.3 mm into the drip shield (x = 0.3 mm), the critical oxygen concentration beyond which oxygen embrittlement of drip shield could occur (C = 0.4 wt %), and the specified maximum oxygen concentration in Titanium Grade 7 (C_0 = 0.25 wt %), produced results as shown in Table 2.1.06.06.0B-1.

Table 2.1.06.06.0B-1. Results of Sensitivity Analysis for Oxygen Embrittlement of Drip Shield

C_1	Equation LHS Value	Required Time (Years)	Equation RHS Value
10%	1.54×10^{-2}	1.63×10^{5}	1.54×10^{-2}
20%	7.59×10^{-3}	1.34×10^{5}	7.59×10^{-3}
30%	5.04×10^{-3}	1.21×10^{5}	5.04×10^{-3}
40%	3.77×10^{-3}	1.14×10^{5}	3.77×10^{-3}

LHS = left-hand side; RHS = right-hand side.

As seen in Table 2.1.06.06.0B-1, a time on the order of 10^5 years would be required to increase the oxygen content of Titanium Grade 7 from 0.25 wt % to the critical oxygen content of 0.4 wt % at a depth of 0.3 mm into the drip shield. A thickness of 0.3 mm is very small compared to the intact drip shield total thickness of 15 mm. Thus, even if the mechanical properties of a 0.3 mm layer on each side of the drip shield were affected, there would be no significant impact on the mechanical properties of the drip shield. Therefore, the time needed to cause oxygen embrittlement of Titanium Grade 7 in the drip shield should be greater than 10^5 years even for a constant exposure temperature of 300°C. At temperatures below 300°C, the oxygen diffusivity in titanium would be lower so that the time needed to cause oxygen embrittlement of Titanium Grade 7 will be even longer. The value of the diffusion coefficient of

oxygen in titanium increases at higher temperatures (Rogers et al. 1988 [DIRS 184108], Table 1). As discussed earlier, the waste package temperature could possibly exceed 300°C due to a low probability drift collapse event. However, the waste package would be above 300°C only for a short time period and decrease at later times. Therefore, the drip shield temperature, which would be lower than the waste package temperature, could exceed 300°C for a short time period as well. Consequently, the use of a constant temperature of 300°C in this analysis is bounding.

Although a similar sensitivity analysis has not been performed for Titanium Grade 29, the drip shield structural support material, oxygen embrittlement of this material will not occur before 10^5 years for the following reasons:

- The drip shield surface temperature will be lower than 300°C except for the low-probability event of a drift collapse within the first approximately 90 years of emplacement (SNL 2008 [DIRS 184433], Figure 6.3-82[a]; SNL 2008 [DIRS 179962], Section 6.5.1).

- For drip shield surface temperatures below 300°C, the oxygen diffusivity in titanium, the base metal of Titanium Grade 29, is lower than that at 300°C. In light of the results of sensitivity analysis on Titanium Grade 7, the time required to cause oxygen embrittlement of Titanium Grade 29 at 300°C is expected to be approximately 1×10^5 years.

In conclusion, oxygen embrittlement of the titanium drip shields is not expected to occur under the relatively low temperature conditions of the drip shield in the repository.

According to 10 CFR 63.114(d) [DIRS 180319], only events that have at least one chance in 10,000 of occurring over 10,000 years need to be included in performance analysis.

Based on the previous discussion, FEP 2.1.06.06.0B (Oxygen Embrittlement of Drip Shields) will have less than one chance in 10,000 of occurring over 10,000 years based on the time required to achieve significant oxygen concentrations within the metal under repository thermal exposure conditions. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

Hydrogen embrittlement is discussed in excluded FEP 2.1.03.04.0B (Hydride Cracking of Drip Shields). The effects of potential acidification in creviced regions such as cracks are discussed in excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields).

FEP: 2.1.06.07.0A

FEP NAME:

Chemical Effects at EBS Component Interfaces

FEP DESCRIPTION:

Chemical effects that occur at the interfaces between materials in the drift may affect the performance of the system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The EBS component interfaces addressed in this FEP are those that may involve solid-solid interactions. Solid–liquid interactions of EBS components are addressed in included FEPs 2.1.03.01.0A (General Corrosion of Waste Packages) and 2.1.03.03.0A (Localized Corrosion of Waste Package) for general and localized corrosion of the waste package, respectively. In addition, included FEP 2.1.03.01.0B (General Corrosion of Drip Shields) and excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields) address general and localized corrosion of the drip shield, respectively. As described in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354]), the base plates of the drip shield are fabricated from Alloy 22 (SNL 2007 [DIRS 181339], Section 6.3) to prevent direct contact between the titanium and steel members in the invert, thus minimizing electrochemical effects at this interface (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-07). This configuration prevents contact between the titanium and invert steel, to avoid hydrogen diffusion into the titanium (SNL 2007 [DIRS 181339], Section 6.3). The pallet pedestals are fabricated of Alloy 22, as is the waste package outer shell (SNL 2007 [DIRS 179354], Table 4-3, Parameter Numbers 08-01 and 08-03), thus precluding galvanic reactions at this interface. It should be noted that the pallet connector rods are made of stainless steel and will be in contact with the Alloy 22 pallet pedestals. If galvanic corrosion occurs, it will attack the invert steel rather than the Alloy 22 in the pallet pedestal because of the former's lower resistance to corrosion. Further discussions on the potential effects of galvanic interactions between EBS components are given in excluded FEP 2.1.09.09.0A (Electrochemical Effects in EBS). This FEP also concludes that enhanced degradation as a result of galvanic interactions would be negligible due to similarities in the corrosion potentials of the considered metals and alloys in the EBS that may come into contact with one another.

Interactions between various types of EBS components as a result of extensive degradation and subsequent consolidation of these assemblies is discussed in excluded FEP 2.1.08.15.0A (Consolidation of EBS Components). The only exception is the case of drift collapse as a result of seismically induced ground motion. In this case, rockfall could damage the drip shield and possibly the outer shells of the waste packages (assuming drip shield failure) as discussed in included FEP 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components).

Included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) discusses the effects of ground motion damage on EBS components that mainly results in structural/mechanical interactions between adjacent waste packages. In-drift chemistry can be affected by modification of drift hydrological and thermal properties as a result of drift collapsed rock material and other related processes. These effects of rock collapsed on in-drift chemistry are discussed in excluded FEP 1.2.03.02.0E (Seismic-Induced Drift Collapse Alters In-Drift Chemistry). Mechanical effects at EBS component interfaces due to static loading are discussed in excluded FEP 2.1.06.07.0B (Mechanical Effects at EBS Component Interfaces). Interaction with magmatic fluids during an igneous intrusion is discussed in included FEPs 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components) and 1.2.04.04.0B (Chemical Effects of Magma and Magmatic Volatiles). According to that FEP, EBS components will be subjected to elevated temperatures diminishing the tensile strength of the metal components, making them susceptible to plastic deformation. Once the magma enters the drift, it will stagnate and magma flow would be insufficient to mobilize any of the waste packages. Excluded FEP 2.1.09.03.0B (Volume Increase of Corrosion Products Impacts Waste Packages) discusses the potential for mechanical damage as a result of volume change due to the formation of corrosion products relative to the metal. The lack of closely confined spaces in the EBS precludes any mechanical damage due to changes in corrosion product volume, and this process is therefore excluded on the basis of low consequence.

The effects of interactions of seepage waters with ground support materials (e.g., cement, rock bolts, wire mesh) remaining in the repository after closure were assessed by FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS); these effects were excluded on the basis of low consequence. Steel corrosion in the drift could potentially affect the pH and/or chemistry of aqueous solutions and the amount of precipitated steel corrosion products. The effect of steel corrosion on aqueous chemistry is examined in Section 6.8.4.1 of *Engineered Barrier System: Physical and Chemical Environment* (P&CE) (SNL 2007 [DIRS 177412]). This section of the P&CE model report indicates that significant changes in the masses of steel/alloy (Stainless Steel Type 316L and Carbon Steel Type A588) reacting with seepage essentially results in an increase of precipitated corrosion products and does not significantly affect aqueous solution chemistry. Therefore, the effect of these seepage-metal interactions on seepage chemistry in the drift is excluded on the basis of low consequence.

Telluric current flows induced by geomagnetic phenomena could result in the generation of significant electrical potentials and have been observed to cause corrosion of buried oil/gas pipelines. Enhancement of metal/alloy corrosion degradation in the EBS as a result of telluric currents is not expected. Both theoretical and measured pipe-to-soil potentials in buried pipelines indicate that the effects of telluric currents are expected to be more significant in long buried pipe-like structures having lengths in the order of tenths to hundreds of kilometers (Martin 1993 [DIRS 184437]; Boteler and Seager 1997 [DIRS 184439]). The combined length of EBS structures in a single drift does not add to a length of even one kilometer. A study of pipe-to-soil potentials in a segment of a ~450 km long gas pipeline in Canada (Ontario) shows that a peak value of about +200 mV only occurs within a pipeline segment of ~25 km; the rest of the pipeline experienced much smaller values. It is also expected that rocks in this locality will have larger degrees of saturation and, thus, larger conductivities than the tuffaceous rock in Yucca Mountain drifts. Based on EBS design configuration features (SNL 2007 [DIRS 179354],

Table 4-1, Parameter Number 02-05), it is expected that ground support assemblies including invert steel are sufficiently grounded to preclude any significant effect on potential build-up at the surface of EBS components. Also, the aforementioned metals/alloys used in the EBS components would remain passive under a wide range of applied potentials (SNL 2007 [DIRS 178519], Sections 8.2 and 8.3; SNL 2007 [DIRS 180778], Sections 6.6.1 and 6.6.2). Therefore, it is anticipated that any changes in surface potentials induced directly or indirectly by telluric currents would not significantly affect the corrosion rates of these materials. Moreover, the direct contact of EBS components with rock is to a large extent limited. This rock/metal interaction is mostly restricted to ground support and invert steel components, and the latter is more prone to corrosion degradation than the more noble metal components of the EBS. Any anticipated potentials between ground support and invert steel components, and a largely unsaturated rock in the invert domain, will not be significant enough as to affect corrosion rates on EBS components. Unsaturated tuffaceous gravel from Yucca Mountain, having a volumetric water content in the range 1% to 10%, has low electrical conductivities (Hu et al. 2004 [DIRS 184440]). It is expected that such low conductivity will influence the effective flow of telluric currents in this porous media and any potential interaction with EBS components. Even in the case where telluric currents can indeed affect rock-to-steel (e.g., invert steel) potentials as to enhance corrosion rates, this phenomenon will be largely limited to interface steel structures in contact with rock such as ground support and invert steel assemblies. The corrosion products produced from degradation of ground support and invert steel assemblies would provide a nonconductive interface, thus protecting EBS components from this effect.

In conclusion, chemical effects at EBS component interfaces will have little effect on repository performance.

Based on the previous discussion, omission of FEP 2.1.06.07.0A (Chemical Effects at EBS Component Interfaces) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.06.07.0B

FEP NAME:

Mechanical Effects at EBS Component Interfaces

FEP DESCRIPTION:

Physical effects of steady-state contact (static loading) that occur at the interfaces between materials in the drift may affect the performance of the system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP describes the physical (mechanical) effects of steady-state contact between EBS components (waste package, pallet, drip shield, and invert) and their respective contacting materials on projected long-term performance. Relevant design controls are described that minimize mechanical deformation and the potential for generating stresses sufficient to initiate stress corrosion cracking.

The effects of transient, non-steady-state loading have also been considered and evaluated in other FEPs. For example, the possibility of the drip shield contacting the waste package as a result of non-steady-state mechanical damage caused by rockfall is addressed in excluded FEP 2.1.03.07.0B (Mechanical Impact on Drip Shield). Other FEPs that discuss mechanical effects of non-steady-state seismic, rockfall, and igneous events are included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damages EBS Components), included FEP 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components), and included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components).

The waste package and the drip shield, as designed and emplaced, contact other EBS components. Therefore, administrative, procedural, and design controls are required to maintain the analyzed configuration and basis. The need for such controls and the basis for the controls are identified in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03). The design basis for the configuration interface controls between the as-emplaced waste package and other EBS components is documented in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 02-01 and 02-02).

For example, the waste package is designed to rest on an emplacement pallet (SNL 2007 [DIRS 179354], Table 4-3), which is constructed of Alloy 22 supports and designed to keep the waste package from contacting other dissimilar metals (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). The waste package outer corrosion barrier will only contact the

Alloy 22 emplacement pallet supports (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-05). In the case of the emplacement pallet, stainless steel tubes connect Alloy 22 waste package supports to form the structure (SNL 2007 [DIRS 179354], Table 4-3, Parameter Numbers 08-01 and 08-03). The function of the tubes is to facilitate handling of the emplacement pallet during the preclosure period. The emplacement pallet is also designed to keep the waste package supported in a horizontal position, and away from the invert and ground support under non-seismic scenarios (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). Structural failure or failure due to stress corrosion cracking of the connector tubes under non-seismic (static) conditions will not affect the emplacement pallet performance with respect to supporting the waste package. Thus, the emplacement pallet supports the waste package during handling, emplacement, preclosure, and postclosure periods (nominal position for 300 years, and nominally horizontal for 10,000 years) (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-02). After 300 years, stress due to temperature changes and settlement in the invert from mechanisms such as corrosion of carbon steel can result in changes from the original placement. Thus, the invert and other EBS components are designed to account for these potential in-situ stresses and thermal responses as discussed in excluded FEP 2,1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components), excluded FEP 2.1.06.05.0B (Mechanical Degradation of Invert), excluded FEP 2.1.07.06.0A (Floor Buckling), and excluded FEP 2.1.09.03.0B (Volume Increase of Corrosion Products Impacts Other EBS Components). The effect of uneven invert settlement on drip shield stability as a result of seismic ground motion was analyzed in *Mechanical Assessment of Degraded Waste Packages and Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Section 6.4.6). It was determined that the settlement of the invert is not expected to materially alter the drip shield function as discussed in excluded FEP 2.1.03.07.0B (Mechanical Impact on Drip Shield). Postclosure, the structural integrity of the stainless steel connector tubes is only important in the case of a seismic event of sufficient acceleration to cause the waste package to separate from the emplacement pallet as discussed in included FEP 2.1.06.05.0C (Chemical Degradation of Emplacement Pallet).

For the nominal scenario emplacement configuration, the design is constrained to ensure that the tensile stresses imposed on the Alloy 22 components of both the waste package and the emplacement pallet are less than 257 MPa, the approximate stress corrosion cracking threshold for Alloy 22 (SNL 2007 [DIRS 181953], Tables 8-2 and 8-3; SNL 2007 [DIRS 179354], Table 4-3, Parameter Numbers 08-03 and 08-05). This stress limit precludes deformation and stress corrosion cracking (SNL 2007 [DIRS 179354], Table 4-3, Parameter Numbers 08-03 and 08-05).

The drip shield is emplaced in a controlled manner and in the post-weld stress-relieved condition, which minimizes residual stresses generated from fabrication and welding as discussed in excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields). The drip shield is designed for subsequent postclosure loadings that may occur due to thermal expansion, rockfall, drift collapse, and seismic effects (SNL 2007 [DIRS 179354], Table 4-2, Parameter Numbers 07-03, 07-04, 07-08, 07-14, and 07-15). The drip shield protects the waste package from rockfall as described in excluded FEP 2.1.07.01.0A (Rockfall). In the case of drift collapse, the quasi-static loading of rock rubble will occur as a result of slow, time-dependent strength reduction in the lithophysal rocks. Analyses summarized in excluded FEP 2.1.07.02.0A (Drift Collapse) conclude that drift collapse under nominal (static) loading conditions will not

have a significant effect on long-term performance of the repository. Stress corrosion cracking resulting from rockfall induced static residual stresses is discussed in excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields).

Mechanical loading at the drip shield/invert interface occurs between the Alloy 22 drip shield base plates, which rest on the carbon steel components of the invert (SNL [DIRS 179354], Table 4-2, Parameter Number 07-07). The steel invert structure will provide a framework, consisting of a series of beams bolted to the invert rock mass, that supports the emplacement pallets, waste packages, and drip shields for static and dynamic loads, but excluding fault displacements (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 02-07 and 02-08). Loads can result from thermal expansion of the base plates, drip shield, or invert steel structure; rock movement due to in situ stress release from excavation; and rock deformation of the invert. The design of the carbon steel structure in the invert accounts for these loads as well as loads imposed by construction activities, the gantry crane, waste packages, waste package pallet, drip shield, and seismic and thermal loads, as discussed in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 02-04, 02-07, and 02-08).

Similar to the waste package to pallet contact, the drip shields are designed to contact no other material except the Alloy 22 base (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-07), which is attached to the bottom of the drip shields. The Alloy 22 drip shield base is in resting contact with the invert, which is covered by crushed tuff as ballast. The mechanical loading at the interfaces between the waste package and degraded pallet (i.e., with removal of 2-mm/side corrosion allowance) has also been analyzed using 150°C mechanical properties (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). The maximum contact stresses (257 MPa) between the waste package and (degraded) emplacement pallet are less than 90% of the Alloy 22, 150°C yield strength, the minimum threshold stress for initiation of stress corrosion cracking (SNL 2007 [DIRS 179354], Table 4-3, Parameter Numbers 08-03 and 8-05; SNL 2007 [DIRS 181953], Section 6.2.2, Table 4-1, and Equation 42; FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages)). Further, since this stress is below 90% of the yield strength, plastic deformation is also very limited (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). On this basis, enhanced degradation due to mechanical loading at the waste package-emplacement pallet interfaces is not expected.

The analyses discussed here demonstrate that steady-state loading between EBS components has minimal impact on the long-term performance of these components. Therefore, FEP 2.1.06.07.0B (Mechanical Effects at EBS Component Interfaces) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence. This FEP will not adversely affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment.

FEP: 2.1.07.01.0A

FEP NAME:

Rockfall

FEP DESCRIPTION:

Rockfalls may occur with blocks that are large enough to mechanically tear or rupture drip shields and/or waste packages. Seismic-induced rockfall is addressed in separate FEPs.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses the potential impact of rockfall on the EBS components, including waste packages and drip shields. The term "rockfall" as used in this discussion refers to the dislodging of relatively few, generally large blocks of rock from the sides or crown of an emplacement drift. "Drift collapse," in contrast, refers to the en masse fall of rock fragments into the emplacement drift. Nominal rockfall may result from in situ conditions of gravitational stresses, excavation-induced stresses, and thermally induced stresses, as described in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6). Nominal rockfall does not include dynamic loading caused by seismic events. Seismic induced rockfall and drift degradation and the impacts on the EBS are addressed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components), excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components), and included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). The impacts of rockfall on drift seepage are addressed in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology).

All emplacement drift areas will be circular in cross-section and excavated with a tunnel boring machine (SNL 2007 [DIRS 179466], Table 4-1, Parameter Numbers 01-09 and 01-10). This excavation method produces a nominally circular opening with a predominately smooth surface profile. This is the least destructive technique for excavation since excessive energy (as in blasting) is not used for breakage of the rock and therefore minimizes excavation-induced stresses. The impact of excavation and construction is discussed in more detail in excluded FEP 1.1.02.00.0B (Mechanical Effects of Excavation and Construction in EBS) and included FEP 2.2.01.01.0A (Mechanical Effects of Excavation and Construction in the Near-Field).

Calculations of potential rockfall for the nonlithophysal and lithophysal layers of the repository for nominal and seismic scenarios are described in detail in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4). For both lithophysal and nonlithophysal zones, the potential consequences of rockfall are damage to the drip shields and waste packages. The rock mass surrounding the excavations may undergo over-stressing from thermal heating and/or time-dependent damage associated with static fatigue resulting from stress corrosion mechanisms (BSC 2004 [DIRS 166107], Section 6.3.1.5). Stress corrosion is a term used for time-dependent, sub-critical crack growth that occurs when existing material flaws in the rock

are subjected to stresses that are near the failure state of the material. This process may result in damage and yield of the rock mass at applied stresses that are less than the short-term rock strength (BSC 2004 [DIRS 166107], Section 1.1). Another possible long-term effect includes the increasing amounts of moisture/air induced weathering along the joints close to the tunnels. This damaged and/or weathered material may result in block fallout, particularly in the nonlithophysal units (BSC 2004 [DIRS 166107], Section 6.3.1.5).

Note that there is a 200°C drift wall temperature limit imposed during the repository postclosure period (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-02). The drift wall temperature limit will confine the extent of permanent changes in rock characteristics that could impact drift opening stability. It is noted that drift wall temperatures of 200°C and rock mass temperatures greater than 250°C were achieved in the Drift Scale Test with only minor effects observed (SNL 2008 [DIRS 179962], Section 6.1.1). Furthermore, analyses documented in *Postclosure Analysis of the Range of Design Thermal Loadings* (SNL 2008 [DIRS 179962], Section 7.1) indicate that the anticipated range of thermal loading will result in peak postclosure drift wall temperatures significantly less than 200°C.

The calculations that include the assessement of distinct fracture sets in the lithophysal rock mass (based on field mapping data) show that the formation of small blocks that fall under gravitational forces is expected to be the dominant potential failure mode of drifts in lithophysal rocks (BSC 2004 [DIRS 166107], Section 6.4.3). Small blocks do not have sufficient energy to cause damage, and thus the potential to tear or rupture drip shields or waste packages is precluded. The static load on the drip shield resulting from the en masse fall of small rock blocks is discussed in excluded FEP 2.1.07.02.0A (Drift Collapse) and included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). Thermal effects on rockfall in the lithophysal units are discussed in excluded FEP 2.1.07.02.0A (Drift Collapse). Because rockfall in lithophysal units is predominated by small blocks, calculations regarding the effects of the impact of rockfall on drip shields and waste packages are performed in nonlithophysal rock, which has a greater potential for large block formation. Rockfall analyses in nonlithophysal rock that include thermal loading and exclude seismic loading result in a minor amount of rockfall. Static fatigue failure of asperities along fracture surfaces is possible and would result in gravitationally induced failure of large blocks. Hence, rockfall in nonlithophysal units has the *potential* to cause significant damage to the EBS.

In the calculations relating to rockfall in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6), the potential for drift stability afforded by ground control systems is conservatively not considered. As indicated in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 01-15, 01-16, and 01-17), a substantial ground support system will be installed in the emplacement drifts to facilitate repository operations. The ground support structure will be fabricated of stainless steel for longevity (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). Rockfall results presented in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4) provide input to analyses of possible damage to EBS components (SNL 2007 [DIRS 178851]) in the form of block size and impact energy.

The effects of high-energy blocks have been considered as part of the seismic rockfall analyses in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components), and have been found to be insignificant. These results provide an upper bound to the expected mechanical effects of rockfall during the nominal scenario.

Analyses related to multiple rockfalls were conducted in *Multiple Rock Fall on Drip Shield* (BSC 2004 [DIRS 171756]). Bounding characteristics of the credible multiple rockfalls for postclosure were used in the calculation. The structural response of the drip shield to two identical 2-metric ton rock block impacts onto the same location was analyzed. Along the highly deformed area at the point of impact, the average stress intensity through the drip shield plate thickness (along a line perpendicular to the plate surface) was determined for several locations. It was concluded that at the location of highest average stress intensity, the wall-averaged total stress intensity through the drip shield top plate, and the maximum bending surface principal stress in the longitudinal stiffeners do not exceed the respective true tensile strengths of these titanium drip shield components, as discussed in *Multiple Rock Fall on Drip Shield* (BSC 2004 [DIRS 171756], Section 6.1).

The effects of rockfall on crack initiation in the drip shield are discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 8.1.6), excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield), and excluded FEP 2.1.03.02.0B (Stress Corrosion Cracking (SCC) of Drip Shields). The tightness of stress corrosion cracks in passive alloys such as Titanium Grade 7 (i.e., small crack-opening displacement) and their tortuosity will lead to negligible water flow through these openings (SNL 2007 [DIRS 181953], Section 6.8.5.2). For the case of multiple rockfalls on the same drip shield location, the total damaged area from multiple block impacts during a ground motion is conservatively estimated as the sum of the damaged areas from the individual block impacts (SNL 2007 [DIRS 176828], Section 6.10.2.9). The consequence of stress corrosion cracking on drip shield water diversion performance is discussed in excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids through Cracks in the Drip Shield).

Prior to closure (prior to the installation of the drip shield), waste packages that have come into contact with fallen rock will be inspected to ensure that any damage to the waste package outer corrosion barrier is within acceptable limits (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 03-24). Since the drip shield continues to function through rockfall events as described above, the waste package and cladding will be protected from rockfall during the postclosure period, for as long as the drip shield remains intact, and rockfall will therefore be of low consequence while this is the case.

TSPA considers all fuel cladding (with the exception of naval SNF cladding) to be breached at the time of its arrival at the repository, as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Table 7-2[a]). Furthermore, following waste package failure, clad unzipping is considered to result in the immediate exposure of bare fuel to the waste package environment along the entire length of the fuel rod (included FEP 2.1.02.23.0A (Cladding Unzipping)). Therefore, the impact of rockfall on cladding integrity is of low consequence.

In summary, rockfall, as a result of gravitational-, excavation-, thermal- or corrosion-induced stresses, or weathering, will not affect the dose to the RMEI or release of radionuclides to the environment for as long as the drip shield remains intact. As indicated above, rockfall generated from nominal processes is not sufficient to tear or rupture the drip shield plates. Therefore, the waste packages, cladding, and waste form are protected from rockfall damage. Rockfall can therefore be excluded from the TSPA on the basis of low consequence for 10,000 years.

Based on the previous discussion, omission of FEP 2.1.07.01.0A (Rockfall) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.07.02.0A

FEP NAME:

Drift Collapse

FEP DESCRIPTION:

Partial or complete collapse of the drifts, as opposed to discrete rockfall, could occur as a result of thermal effects, stresses related to excavation, or other mechanisms. Drift collapse could affect the stability of the engineered barriers and waste packages and/or result in static loading from rock overburden. Rockfalls of small blocks may produce rubble throughout part or all of the drifts. Seismic-induced drift collapse is addressed in a separate FEP.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses nominal drift collapse effects. *Drift Degradation Analysis* (BSC 2004 [DIRS 166107]) provides analysis of drift degradation for both nonlithophysal and lithophysal rock. A summary of the analysis and results of the analysis are given in Section 8.1 of that report (BSC 2004 [DIRS 166107]). Section 6.3 of *Drift Degradation Analysis* (BSC 2004 [DIRS 166107]) provides a nonlithophysal rockfall model developed using the three-dimensional discontinuum code 3DEC, while Section 6.4 of that report (BSC 2004 [DIRS 166107]) provides a lithophysal rockfall model developed using the two-dimensional discontinuum code UDEC. The lithophysal rockfall model allows for the formation of stress-induced fractures between blocks (i.e., the formation of internal fracturing), and separation and instability (resulting from gravitational stresses, excavation-induced stresses, thermally induced stresses, and time-dependent strength degradation) of the rock mass around the drift (BSC 2004 [DIRS 166107], Section 6.4.2.1). In both models, appropriate thermal and mechanical properties of rock blocks and joints are used.

Seismic-induced drift collapse damage is addressed in included FEP 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components), and seismic-induced drift collapse effects on thermal-hydrologic processes are addressed in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology). Seismic-induced drift collapse effects on seepage are discussed in excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids through Cracks in the Drip Shield). Although seismic-induced drift collapse may alter in-drift chemistry as discussed in excluded FEP 1.2.03.02.0E (Seismic-Induced Drift Collapse Alters In-Drift Chemistry), this potential alteration is excluded on the basis of low consequence.

Thermally induced stresses at any location depend on the proximity and timing of waste emplacement, the amount of heat generated, the age of the waste, packaging and emplacement configuration, and the thermal-mechanical properties of the rock mass. Thermal stresses are time-dependent and are calculated over the first 10,000 years after repository closure (BSC 2004 [DIRS 166107], Section 6.2). Note that there is a 200°C drift wall temperature limit imposed

during the repository postclosure period (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-02). The drift wall temperature limit will confine the extent of permanent changes in rock characteristics that could impact drift opening stability. It is noted that drift wall temperatures of 200°C and rock mass temperatures greater than 250°C were achieved in the Drift Scale Test with only minor effects observed (SNL 2008 [DIRS 179962], Section 6.1.1). Furthermore, analyses documented in *Postclosure Analysis of the Range of Design Thermal Loadings* (SNL 2008 [DIRS 179962], Section 7.1) indicate that the anticipated range of thermal loading will result in peak postclosure drift wall temperatures significantly less than 200°C.

The rock mass surrounding the emplacement drifts may undergo over-stressing from thermal heating or time-dependent damage associated with static fatigue resulting from stress corrosion mechanisms. This damaged material may result in a slow unraveling (lithophysal rock) or block fallout (nonlithophysal rock). In the nonlithophysal rocks, static fatigue failure of asperities along fracture surfaces is possible and could result in gravitationally induced block failures. Fatigue failure would presumably initiate along asperities on fracture surfaces, reducing the effective friction angle along the fracture surfaces (BSC 2004 [DIRS 166107], Section 6.3.1.5). In the case of the lithophysal rocks, the uniaxial compressive elastic stressalong the immediate rib springline of the emplacement drifts is estimated to be 17.5 MPa (BSC 2004 [DIRS 166107], Section S2.2.5) and will be at or near the unconfined compressive strength of about 20 MPa (BSC 2004 [DIRS 166107], Table 6-41, Category 3), so static fatigue failure is possible. The analyses of the available static-fatigue test data indicate that an approximate 40% reduction in cohesive strength occurs over a 20,000-year period (BSC 2004 [DIRS 166107], Appendix S, Section S3.4.1). To model the lithophysal rock mass, a range of rock mass strength properties were considered, represented as rock mass strength categories 1 through 5 (BSC 2004 [DIRS 166107], Section 6.4.1.2). Depending on the rock mass strength category, varying degrees of drift collapse can be expected in the lithophysal rock resulting from in situ conditions of gravitational stresses, excavation-induced stresses, thermally induced stresses, and time-dependent strength degradation of the rock mass. However, the rock block sizes are predicted to be small (i.e., only a few centimeters to decimeters on a side) due to the ubiquitous fracture fabric found in the lithophysal rock (BSC 2004 [DIRS 166107], Sections 6.1.4.1 and 8.1).

In the calculations relating to rockfall in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6), the potential for drift stability afforded by ground control systems is conservatively not considered. This is a reasonably bounding approach that simplifies the modeling, while increasing the extent of predicted drift degradation. As indicated in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-17), a ground support system will be installed in the emplacement drifts to facilitate repository operations. The ground support structure will be fabricated of stainless steel for longevity (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). The potential effects of ground support material on engineered barrier system components are addressed in excluded FEPs 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) and 2.1.06.02.0A (Mechanical Effects of Rock Reinforcement Materials in EBS).

Analyses presented in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4) show that, for the base case thermal conditions, thermal stresses result in a thin yield zone

around the drifts for all cases of lithophysal and nonlithophysal rock strength, including accouting for time-dependent rock strength degradation. The nominal case for drift degradation (i.e., considering thermal and time-dependent effects, but excluding seismic effects) for both nonlithophysal and lithophysal rock results in only partial collapse of the drift (such that collapsed rock blocks do not cover the drip shield) for the first 10,000-year period of postclosure performance (BSC 2004 [DIRS 166107], Sections 6.3.1.3, 6.4.2.4.2.6, and 8.1).

Drift Degradation Analysis (BSC 2004 [DIRS 166107]) reports analyses of rockfall in the lithophysal and nonlithophysal units that provide time history of "expected" rockfall due to ongoing degradation of the drift. Furthermore, based on other analyses presented in that report (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4), only minor degradation or partial collapse of the drift (including enlargement) will occur for the static (i.e., non-seismic) loading case, such that rubble settles around the sides of the drip shield and does not accumulate on the crown of the drip shield. The structural response calculations for an intact drip shield provide a reasonable representation of the potential for damage to the drip shield plates during the first 10,000 years after repository closure. The mean corrosion rate for Titanium Grade 7 under benign conditions, 5.15 nm/yr (SNL 2007 [DIRS 180778], Table 8-1[a]), is appropriate for the underside of the drip shield plates. The mean corrosion rate for Titanium Grade 7 under aggressive conditions, 46.1 nm/yr (SNL 2007 [DIRS 180778], Table 8-1[a]), is appropriate for the top side of the drip shield plates. The mean thickness reduction from double-sided corrosion during 10,000 years is given by (10,000 years) (5.15×10^{-9} m/yr + 46.1×10^{-9} m/yr) = 5.1×10^{-4} m = 0.51 mm, which is a small fraction of the initial plate thickness of 15 mm (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04). It follows that the results in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Sections 6.8.2 and 6.8.3) for the 15-mm-thick plate, with no thickness reduction, are applicable to the first 10,000 years after closure. The results from drip shield fragility analyses show that for seismic ground motion with a peak ground velocity of 1.05 m/s or less, and considering partial drift collapse with 50% rockfall load, the probability of drip shield failure is zero for the 15 mm thick plate and the intact framework (SNL 2007 [DIRS 176828], Tables 6-36 and 6-40). This seismic ground motion case, which considers nonuniform drip shield loads from a partially filled drift (SNL 2007 [DIRS 176828], Sections 6.8.2 and 6.8.3), provides an upper bound for the static load case. Therefore, it follows that the probability of drip shield failure is also zero for static loads.

Seepage analyses for degraded drifts that consider minor drift damage consistent with the static loading case show that there are no impacts to seepage, and therefore the magnitude of drift seepage for the nominal case (considering thermally induced stresses and time-dependent strength degradation of the rock mass) is determined using non-degraded drifts (SNL 2007 [DIRS 181244], Sections 6.4.2.4.2 and 8.1). To account for uncertainty in seepage simulation results and impacts of minor drift degredation, the intact drift seepage is increased by 20% (SNL 2007 [DIRS 181244], Section 6.2.4[a]). Minor drift damage associated with the static loading case will not significantly impact or alter the existing thermal conditions in the drift.

Thus, drift collapse under nominal (static) loading conditions will not have a significant effect on long-term performance of the repository.

Based on the previous discussion, omission of FEP 2.1.07.02.0A (Drift Collapse) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the

RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.07.04.0A

FEP NAME:

Hydrostatic Pressure on Waste Package

FEP DESCRIPTION:

Waste packages emplaced in the saturated zone will be subjected to hydrostatic pressure in addition to stresses associated with the evolution of the waste and EBS.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Waste packages will be emplaced in the repository (located in the unsaturated zone), under atmospheric pressure, and will lie, on average, approximately 300 m above the present-day water table. The elevation of the repository will range from 1,039 to 1,107 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01), while the measured water table elevation under the repository for present-day conditions varies from approximately 730 m to 850 m (BSC 2004 [DIRS 169855], Figure 6-2). Modeling (SNL 2007 [DIRS 177391], Figure 6-20) shows that water table elevation below the repository is expected to remain lower than 900 m. This is corroborated by Forester et al. (1999 [DIRS 109425], p. 57), who show that the historical water table (over a duration of approximately 500,000 years) has never risen to the level of the repository. Further corroboration is obtained by studies of mineralogic alteration (zeolitization and tridymite distribution) in the unsaturated zone at Yucca Mountain that place an upper limit of past water table rise below 60 m above its present position in the geologic past (Levy 1991 [DIRS 100053], p. 477); and by analysis of $^{87}Sr/^{86}Sr$ ratios in calcite veins of the unsaturated zone and saturated zone at Yucca Mountain indicating an upper limit of past water table rise below 85 m above the present level (Marshall et al. 1993 [DIRS 101142], p. 1,948). These studies, covering a historic time span of over 1 million years, include the effects of glacial climates, and future monsoon and glacial-transition climates are expected to be warmer and dryer than the glacial climate (Sharpe 2003 [DIRS 161591]). Hence, even under the extreme future climate conditions, the water table would not reach the repository horizon.

Water also occurs under fully saturated conditions as perched bodies in the unsaturated zone below the repository horizon. As shown in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.2; DTNs: LB06123DPDUZFF.001 [DIRS 178587], GS031208312232.003 [DIRS 171287], GS031208312232.005 [DIRS 179284], and GS040108312312.001 [DIRS 181234]), even for high infiltration rates corresponding to future wetter climate scenarios of monsoon and glacial transition, the simulated extent and location of perched water is still consistent with observed moisture saturation and water potential. The elevation of the perched water is insensitive to the changes in infiltration rates corresponding to future wetter climates (SNL 2007 [DIRS 184614], Appendix D). Hence, even under the extreme wetter future climate conditions, the perched water bodies would not reach the repository horizon.

In conclusion, FEP 2.1.07.04.0A (Hydrostatic Pressure on Waste Package) can be excluded on the basis of low probability because the repository is designed such that waste will be emplaced within the unsaturated zone well above the water table, and it is very unlikely that the water table will rise to the level of the repository. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 2.1.07.05.0A

FEP NAME:

Creep of Metallic Materials in the Waste Package

FEP DESCRIPTION:

Metals used in the waste package may deform by creep processes in response to deviatoric stress or internal void space.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Creep of metallic materials in the waste package in response to deviatoric stress or internal void space is a function of temperature. A reasonable peak waste package surface temperature is 300°C. This peak temperature bounds all repository-relevant thermal exposure conditions (SNL 2008 [DIRS 184433], Figure 6.3-76[a]) except in the event of a drift collapse within approximately 90 years following closure (SNL 2008 [DIRS 184433], Figure 6.3-82[a]). For the waste package surface to exceed 300°C, a seismic event of sufficient magnitude must occur within approximately 90 years after closure, result in drift collapse and affect a waste package with an unfavorable combination of a high thermal output surrounded by a low conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about one in 10,000 within the first 10,000 years after closure (SNL 2008 [DIRS 179962], Section 6.5.1). Adverse elevated-temperature responses of nickel-based alloys (i.e., creep deformation or creep fracture) are not expected for temperatures below 650°C (Boyer and Gall 1984 [DIRS 155318], Section 32). Although no directly relevant data exist for creep rupture (fracture) of Alloy 22 in this temperature regime, available Alloy 22 1,000-hour creep rupture data at 760°C and above indicate that the creep strength is high and would be expected to increase with decreasing temperature (BSC 2005 [DIRS 173802], Figure 2). Also, the melting point of Alloy 22 is approximately 1,370°C (1,643 K) (Haynes International 1997 [DIRS 100896], p. 13) and the maximum waste package surface temperature (less than 300°C or 573 K) represents a homologous temperature of approximately 0.35. Creep of metallic alloys is generally anticipated only for homologous temperatures of 0.5 or greater (Boyer and Gall 1984 [DIRS 155318]). Therefore, creep of WPOB at low temperatures (e.g., less than 300°C) is not expected, and this process will have no impact on the performance of the waste package. This treatment of creep of metallic materials in the waste package applies to all waste packages.

External stress, induced by rock displacements or ground motion, for example, may lead to plastic deformations and mechanical damage of the waste package. The drip shield is designed to protect the waste package during rockfall and ground motion events. Even if mechanical damage of the waste package were to occur, creep of metallic materials in the waste package will not occur unless an external factor raises the temperature of the waste package surface above 650°C (Boyer and Gall [DIRS 155318], Section 32) and will therefore have no impact on the

performance of the waste package. Based on the previous discussion, omission of, FEP 2.1.07.05.0A (Creep of Metallic Materials in the Waste Package) will not affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.07.05.0B

FEP NAME:

Creep of Metallic Materials in the Drip Shield

FEP DESCRIPTION:

Metals used in the drip shield may deform by creep processes in response to deviatoric stress.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The drip shield can be subjected to plastic deformation and mechanical damage due to stresses resulting from static and dynamic load resulting from rockfall or from vibratory ground motion. Mechanical damage of the drip shield by rockfall is discussed in excluded FEP 2.1.07.01.0A (Rockfall). Mechanical damage of the drip shield during seismic events is discussed in excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damages EBS Components), and included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components). Thus, this FEP only addresses creep of the metallic materials of the drip shield in response to static loads, which is temperature dependent. Due to the long duration of the regulatory period and the possibility of early drift collapse after the waste emplacement, it is important to analyze time-dependent deformation and the stability of the drip shield when non-uniformly loaded by the rock rubble mass.

Plastic deformation and mechanical damage of the drip shield are expected to be enhanced at elevated temperatures due to the combined effect of thermal and mechanical stresses. Without drift collapse, the waste package temperature will be below 300°C (SNL 2008 [DIRS 184433], Figure 6.3-76[a]). Due to greater distance of the drip shield from the heat source (i.e., the waste form) than the waste package, surface temperatures of the drip shields will be lower than those for the waste packages. For the waste package surface to exceed 300°C, a seismic event of sufficient magnitude must occur within approximately 90 years after closure, result in drift collapse, and affect a waste package with an unfavorable combination of a high thermal output surrounded by a low conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about one in 10,000 within the first 10,000 years after closure (SNL 2008 [DIRS 179962], Section 6.5.1). Therefore, a reasonably bounding drip shield exposure temperature in the repository is 300°C and is used in the analysis of creep of metallic materials in the drip shield.

A review of scientific literature (Dutton 1995 [DIRS 173919], p. 8; Dutton 1996 [DIRS 174750], Section 2) reveals that Titanium Grades 7 and 29 can undergo creep deformation at temperatures as low as room temperature when subject to tensile stresses exceeding approximately 50% of the yield strength. Therefore, one of the important impediments to drip shield performance during the period of 10,000 years after closure is potential creep deformation under long-term applied loads. With the exception of the stresses imposed on the drip shield due to its own weight

(which represent a small fraction of the stress which the drip shield is designed to endure), the only long-term load on the drip shield could be due to pressure (weight) of the rock rubble mass that would cover the drip shield following collapse (degradation) of the emplacement drift. This can occur in cases of strong ground motions (e.g., ground motions with a peak ground velocity greater than about 2 m/s in lithophysal rock mass – an event with a mean annual exceedance frequency of ~8.8×10^{-7} per year (SNL 2007 [DIRS 176828], Table 6-3)) or as a result of time-dependent rock mass strength degradation (BSC 2004 [DIRS 166107], Section 6.4.2). Analyses presented in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Attachment S, Section S3.4.2, Figures S-42 to S-44) suggest that total collapse of the emplacement drifts due to time-dependent strength degradation alone is not expected in the first 10,000 years. The load of the rock rubble resting on the drip shield structure is a consequence of the interaction between the structure and the surrounding rock rubble. The initial loads on the drip shield are calculated accounting for that interaction, and analysis of the drip shield stability for short-term loading conditions shows that the drip shield will be stable with a relatively large margin of safety (BSC 2004 [DIRS 169753], Section 5.4.3.2). Because of the long duration of the regulatory period and the possibility of early drift collapse after the waste emplacement, it is important to analyze time-dependent deformation and the stability of the drip shield non-uniformly loaded by the rock rubble mass. Such an analysis has been performed using creep equations that bound available literature and YMP-generated low-temperature creep results for both Titanium Grade 7 and the higher strength Titanium Grade 24 (or their analogues, Titanium Grades 2 and 5, respectively) over the range of temperatures and stresses of most interest (in BSC 2005 [DIRS 174715]). Titanium Grade 24 is similar to Titanium Grade 29 in that they are both platinum group metal-containing versions of Titanium Grade 5.

The initial loading of the rubble on the drip shield was derived from a series of realizations of discontinuum numerical analyses of complete drift collapse (BSC 2004 [DIRS 166107], Section 6.4). It should be noted that the rockfall estimates presented in the aforementioned document overestimate the actual extent of rockfall as the effect of ground support (which will serve to prevent rockfall), is not included in that analysis. These analyses showed the rubble loading to be highly non-uniform in nature. The non-uniform loads around the drip shield derived from these analyses were used as direct input to the creep analysis. Creep strain as a function of time in titanium and other metals follows three distinct stages—an initial, transient stage of primary creep; secondary or steady-state creep, which occurs at a relatively uniform rate; and tertiary creep, in which the creep strain rate rapidly accelerates until rupture occurs. In the creep analyses of the drip shield, the primary and secondary creep were simulated using a creep power law expression derived from a literature review of laboratory tensile creep tests on various grades of titanium (BSC 2005 [DIRS 174715], Section 5.6). Tertiary creep was not explicitly simulated because this is the point of rapid creep acceleration. When the magnitude of the creep strain at any point within the structure was equivalent to the onset of tertiary creep, it is assumed that the drip shield has failed. Based upon the literature, tertiary creep of Titanium Grades 7 and 24 (or analogous alloys such as Titanium Grade 29) could occur at creep strains of approximately 15% (Dutton 1996 [DIRS 174750], Section 5.1).

The drip shield creep analysis (BSC 2005 [DIRS 174715], Section 5.6) considered six rock rubble-loading scenarios derived from *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.4). These analyses applied the nonuniform rock rubble loading states, and assumed that the loads were constant with time (i.e., dead loads). Results of these analyses indicate that

the maximum resultant total creep strains remain below 5% during the 10,000-year period analyzed (BSC 2005 [DIRS 174715], Section 5.6). The maximum creep strains occur in the plates; the maximum creep strain in the support beams and the bulkheads are significantly less than that observed for the plate. These relatively low long-term strain levels, which are much less than the creep strains expected for the onset of tertiary creep, indicate that while some creep deformation may occur, it does not impact the drip shield seepage diversion function or the ability of the drip shield to protect the waste package from load (static or dynamic) by the rock overburden mass.

Based on the relatively low, structurally acceptable creep strains calculated for loading conditions more severe than those anticipated within Yucca Mountain both pre- and postclosure (BSC 2005 [DIRS 174715]), and the lack of potential resultant effects on dose, the effect of creep on the drip shield is negligible.

Based on the previous discussion, omission of FEP 2.1.07.05.0B (Creep of Metallic Materials in the Drip Shield) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.07.06.0A

FEP NAME:

Floor Buckling

FEP DESCRIPTION:

Buckling, or heave, of the drift floor may occur in response to changing stress. Floor buckling may affect the performance of EBS components such as the drip shield, the invert, and the pallet. Effects may include movement of EBS components and changes in the topography of the surface of the drift floor and invert that may affect water flow.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Consideration of floor buckling (or heave) is centered on thermal stressing and excavation stress unloading. Ground motion associated with seismic activity and fault displacement and the impacts on EBS components are addressed in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.02.03.0A (Fault Displacement Damages EBS Components).

Drift response during the first 10,000 years after repository closure has been analyzed considering in situ stresses, excavation-induced stresses, thermally induced stresses, and time-dependent rock strength degradation (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4). Stresses sufficient to cause floor buckling did not occur in the drift degradation models, which included appropriate stress changes and rock properties for the repository horizon. Calculations have demonstrated that prior to repository closure, the vertical displacement of the floor due to in situ stress and thermal response will be less than 1 mm per 6 m of drift (BSC 2004 [DIRS 168889], Table 6.4-3).

According to the U.S. Army Corps of Engineers manual for the planning, design, and construction of tunnels and shafts in rock for civil works, floor buckling is most common under the following conditions (Department of Army 1997 [DIRS 183771], pp. 6-18 to 6-19):

- Weak, laminated, clay-grade rock conducive to swelling
- Tunnels with a flat floor
- High in situ horizontal stresses.

In contrast to these conditions, the repository site at Yucca Mountain is located within a densely welded tuff unit with the following conditions:

- The rock is divided into two broad categories: nonlithophysal and lithophysal welded tuffs. The nonlithophysal rocks are hard, strong, fine-grained and fractured volcanic rocks. The lithophysal rocks are composed of the same strong, hard matrix material, but

have porosity in the form of lithophysal cavities (BSC 2004 [DIRS 166107], Section 1.1). Clay is not a common mineral in the crystallized rocks of the repository host horizon, nor are clay minerals a volumetrically significant fracture-coating material (BSC 2004 [DIRS 166107], Section 6.3.1.5).

- The excavated opening of all emplacement drifts will be circular in cross-section (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-10).

- While in situ horizontal stresses are initially approximately half of the vertical stresses at the repository site (BSC 2004 [DIRS 166107], Section 6.3.1.1), temperature increases anticipated in the repository result in thermally induced stresses such that horizontal stresses will exceed vertical stresses within the first 1,000 years after repository closure (BSC 2004 [DIRS 166107], Section 6.2). However, the stress states around the emplacement drift are generally well below the yield strength of the rock mass (BSC 2004 [DIRS 166107], Section 6.4.2.3).

Because of the limited vertical displacement of the floor expected as a result of in situ and thermal stresses, drip shield displacement, pallet displacement, and damage to invert will be minor. The limited vertical displacement of the floor will result in an insignificant impact to water flow. Seismic-induced impacts to water flow are addressed in excluded FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity) and included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology).

Based on the previous discussion, omission of FEP 2.1.07.06.0A (Floor Buckling) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (10 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.08.01.0A

FEP NAME:

Water Influx at the Repository

FEP DESCRIPTION:

An increase in the unsaturated water flux at the repository may affect thermal, hydrologic, chemical, and mechanical behavior of the system. Increases in flux could result from climate change, but the cause of the increase is not an essential part of the FEP.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Long-term changes in ambient unsaturated zone flow in response to climate changes are incorporated in the infiltration maps developed in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5.7[a]), and in flow fields developed for use in the TSPA by *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.6.2). These flow fields incorporate different climate stages, and capture uncertainty in local percolation flux rates through use of infiltration maps representing the 10th, 30th, 50th, and 90th percentiles of infiltration. They are used in calculations of seepage flux into the drift in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.3.6) and *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244]), and in calculations that track radionuclide transport from the repository to the water table in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748]). Radionuclide transport in the unsaturated zone is strongly a function of the percolation flux at the repository level (SNL 2008 [DIRS 184748], Addendum Section 6.5.15).

Climate changes, and their impact on infiltration and percolation, are also considered in models simulating the thermal-hydrogical, chemical, and mechanical response of the repository rocks to the waste heat. This is done by setting infiltration or percolation rates at the top model boundaries that reflect the different climate stages and scenarios. Also, during the thermal period, waste heat causes water to boil and move as vapor to cooler regions, where it condenses and becomes available to locally increase the percolation flux. Flux increases related to climate change and/or thermal perturbation are directly accounted for in coupled process model simulations used for TSPA calculations or to evaluate FEPs for screening purposes, such as the multiscale thermohydrologic model (SNL 2008 [DIRS 184433]), the thermal-hydrological seepage model (BSC 2005 [DIRS 172232]), the thermal-hydrological-chemical seepage model (SNL 2007 [DIRS 177404]), the near-field chemistry model (SNL 2007 [DIRS 177412], Section 6.3.2), the in-drift condensation model (SNL 2007 [DIRS 181648]), and the drift-scale thermal-hydrological-mechanical model (BSC 2004 [DIRS 169864]). Most of these process models do not use the UZ flow fields directly, but parametrically evaluate the effects of changes in percolation flux in the abstractions provided to TSPA. The TSPA selects from the

abstractions using sampled infiltration conditions and the resulting percolation fluxes determined from the UZ flow fields.

FEP: 2.1.08.01.0B

FEP NAME:

Effects of Rapid Influx into the Repository

FEP DESCRIPTION:

Extremely rapid influx could reduce temperatures below the boiling point during part or all of the thermal period. Increases in flux could result from climate change, but the cause of the increase is not an essential part of the FEP.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP evaluates the potential concern that influx of liquid water could cause rapid, localized temperature reduction during the thermal period, which could thermally perturb a waste package or drip shield leading to failure from the effects of thermal stresses. The thermal period is defined in this context as the time period during which the in-drift and near-field temperatures are elevated and thermally driven flow processes are induced in the host rock. The FEP allows that liquid water is the cause of the perturbation, and significant quantities of liquid water will be present in the repository only for temperatures up to approximately 100°C, thus limiting the temperature range for consideration.

A sudden or strong reduction of temperature can only result from very large influx of water to the repository. The percolation flux at the repository horizon is limited and transients are dampened by the overlying PTn unit (see excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). Also, percolation flux has a limited effect on repository temperature, as shown by the multiscale model, for which variation of percolation between the 10th and 90th percentile conditions produced ranges of less than 10°C for peak temperature, among the coolest and hottest drip shields and waste packages (SNL 2008 [DIRS 184433], Table 6.3-49[a], uncertainty cases P10 and P90). Substantially higher flux rates than those considered in the multiscale model (which uses flux estimates from the unsaturated zone flow model) would be necessary to cause rapid, localized reduction in temperature. Such conditions could occur only for high magnitude, strongly episodic seepage flow, which is not expected for the reasons given below.

Episodic seepage requires episodic flow in the host rock. Episodic natural percolation is not significant and has been excluded from the performance assessment (see excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). Simulations conducted in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Sections 6.1.2 and 6.9[a]) show that the PTn unit dampens and homogenizes downward flowing transient pulses arising from episodic surface infiltration events.

Episodic flow in the host rock due to repository heating has also been evaluated, and was also found to be insignificant (BSC 2005 [DIRS 172232]). During the thermal period (while the drift wall temperature is above the boiling point of water) condensate in the host rock above the drift does not seep into the drift opening because of capillary diversion and vaporization effects. After the drift wall cools to below the boiling point, boiling no longer occurs anywhere in the host rock, and the amounts of evaporation and condensation are greatly decreased. These processes are addressed in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.2) and in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.3.2). These reports show that seepage during cooldown (after the drift wall has cooled below the boiling point) is bounded by the ambient seepage abstraction. The ambient seepage abstraction is then used for this condition (defined for this purpose as drift wall temperature less than 100°C) in TSPA. Factors potentially affecting flow and temperature conditions near drifts, such as climate change (included FEP 1.3.01.00.0A (Climate Change)) and flow focusing (included FEP 2.2.07.04.0A (Focusing of Unsaturated Flow (Fingers, Weeps))) are accounted for in the thermal seepage model (BSC 2005 [DIRS 172232]) and are included in TSPA drift seepage calculation (SNL 2007 [DIRS 181244]).

If seepage does enter the drift during cooldown (after the host rock cools below the boiling point of water), the drip shield will prevent direct contact with the waste package and pallet, thus protecting the waste package from transient thermal effects.

For the reasons discussed above, the potential for a large quantity of liquid water to contact a hot waste package during the thermal period is insignificant.

In the unexpected event that a significant quantity of liquid water would contact a waste package directly during cooldown, for example due to breach of the drip shield by seismically induced rockfall (included FEP 1.2.03.02.0C (Seismic Induced Drift Collapse Damages EBS Components)), the following two cases can be considered:

(1) Waste package surface temperature is slightly greater than the boiling point:

When seepage is possible (drift wall below 100°C), the waste package surface temperature is limited to only a few degrees above the boiling point of water. Water contacting the waste package for such conditions would initially boil, cooling the waste package surface to just below the boiling temperature. This would produce temperature variations of a only a few degrees Celsius on the waste package surface, because the water temperature would be close to that of the waste package. Temperature variations of similar magnitude are predicted for nominal performance of the waste package during the thermal period (for example, the thermal envelope calculated for naval SNF packages; BSC 2005 [DIRS 175761], Attachment I) and are inconsequential. Further discussion of thermal expansion effects is provided for excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components).

(2) Waste package temperature is below the boiling point:

Here, the same justification described in (1) is valid, with the exception that boiling will not occur on the WPOB surface.

These cases also apply to the drip shield, which is directly exposed to seepage but will not undergo significant degradation as a consequence.

In summary, rapid water influx into the repository with the possibility of contacting waste packages during the thermal period is not expected because of dampening of natural percolation in the unsaturated zone, capillary diversion and vaporization processes in the host rock, and the presence of the drip shield. Even if such contact occurred, its effects would be inconsequential.

Based on the above discussion, omission of FEP 2.1.08.01.0B (Effects of Rapid Influx into the Repository) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.08.02.0A

FEP NAME:

Enhanced Influx at the Repository

FEP DESCRIPTION:

An opening in unsaturated rock may alter the hydraulic potential, affecting local saturation around the opening and redirecting flow. Some of the flow may be directed to the opening where it is available to seep into the opening.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The impact of an underground opening on the unsaturated flow field (including a capillary barrier effect and flow diversion around the drifts) and its relevance for seepage is represented in the data acquired in *In Situ Field Testing of Processes* (BSC 2004 [DIRS 170004], Section 6.2). These data were used in *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.1.2, 6.3.3, and 6.6.3) for calibrating unsaturated flow parameters of the formation around the underground opening. The flow parameters derived in the seepage calibration model are used to evaluate the impact of an underground opening on the unsaturated flow field and seepage into the drift in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.3), and in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Sections 6.1.1 and 6.2.1.4), for ambient and elevated temperatures, respectively. Results of these process models are abstracted for TSPA calculations in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.4.1, 6.4.2, and 6.4.3). Seepage model uncertainty is incorporated by sampling probability distributions for the rock hydrologic properties and using percolation fluxes based on multiple infiltration scenarios (SNL 2007 [DIRS 181244], Section 6.6).

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.08.03.0A

FEP NAME:

Repository Dry-Out Due to Waste Heat

FEP DESCRIPTION:

Repository heat evaporates water from the UZ rocks near the drifts, as the temperature exceeds the vaporization temperature. This zone of reduced water content (reduced saturation) could migrate outward during the heating phase and then migrate back to the waste package as heat diffuses throughout the mountain and the radioactive heat sources decay. This FEP addresses the effects of dry-out within the repository drifts.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The postclosure in-drift thermal and hydrologic conditions are calculated in accordance with the methodology presented in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]). This includes a calculation of the postclosure thermohydrologic conditions including dryout during the heating phase and rewetting during the cooling phase. Using the modeling methodology described in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2[a]), the repository dryout is implemented in the TSPA by MSTHM output variables of temperature, relative humidity, and invert saturation at waste package locations throughout the repository. These output variables are used in the TSPA model.

Additional considerations of evaporation/condensation are discussed as part of included FEPs 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-scale Cold Traps)) and 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-scale Cold Traps)).

Ventilation Model and Analysis Report (BSC 2004 [DIRS 169862], Section 8.1) calculates the preclosure thermal conditions in the host rock and characterizes the preclosure host rock response in terms of ventilation efficiency. The ventilation efficiency is the fraction of total decay heat removed from the repository by the vent air. The ventilation efficiency is determined through simulation of temporally and spatially dependent heat transfer processes (thermal radiation, convection, and conduction), which occur simultaneously in the drift and the surrounding rock mass during the ventilating or preclosure period. The ventilation efficiency is a direct input to *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]), which in turn provides postclosure thermal, humidity, and saturation conditions to the TSPA.

Drift-Scale Coupled Processes (DST and TH Seepage) Models (BSC 2005 [DIRS 172232], Section 6.2) discusses the thermal-hydrologic seepage model and associated alternate conceptual models. The dual-permeability, integrated finite-difference code TOUGH2 V1.6 (Pruess 1991 [DIRS 100413]) specifically models thermal seepage including dryout and rewetting. Numerous saturation and temperature results are presented as functions of varied boundary and initial

conditions. Vertical liquid fluxes are presented along with various sensitivity analyses. The thermal-hydrologic seepage model results (DTN: LB0301DSCPTHSM.002 [DIRS 163689]) include these effects. *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244]) utilizes these modeling results to develop an appropriate seepage abstraction methodology for use in the TSPA.

FEP: 2.1.08.04.0A

FEP NAME:

Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)

FEP DESCRIPTION:

Emplacement of waste in drifts creates thermal gradients within the repository. Such thermal gradients can lead to drift-scale cold traps characterized by latent heat transfer from warmer to cooler locations. This mechanism can result in condensation forming on the roof or other parts of the drifts, leading to enhanced dripping on the drip shields, waste packages, or exposed waste material.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Cold-trap effects within the emplacement drift are represented in TSPA as documented in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Sections 6.3 and 6.1.2[a]). As discussed in that report (SNL 2007 [DIRS 181648], Section 6.3.3), three stages are identified during condensation within the emplacement drifts. Stage 1 designates the period when all locations are above the saturation temperature at the drift wall (and thus also all drip shields and waste packages) and condensation cannot occur. Stage 2 is a transitional stage where some locations are above the saturation temperature while others are below. Stage 3 condensation occurs when all waste packages and drip shields (and thus the drift wall) are below the saturation temperature. Abstractions are developed independently for stages 2 and 3 condensation for use in TSPA.

A bounding approach for predicting in-drift condensation rates during stage 2 has been developed in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.2[a]). The approach for stage 2 condensation requires that every waste package simulated in TSPA have two associated parameters: the onset time (in years) of stage 2, and the transition time from stages 2 to 3. For a given waste package location, the onset time of stage 2 is the time when the local drift wall temperature cools to 96°C (i.e., condensation is possible). The onset times for Stage 2 and for transition from Stages 2 to 3 are provided by *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.18[a]). These times are used in TSPA for each waste package to limit the period of time when stage 2 condensation can occur. Stage 2 condensation rates are developed for codisposal (codisposal, HLW-long, and HLW-short) packages and commercial SNF (commercial SNF, PWR, and BWR) packages in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.2.2[a]). Condensation rates represent a reasonable upper bound for drift wall condensation and are scaled to represent only condensation that forms over the drip shield (potential for enhanced dripping on the drip shields, waste packages, or exposed waste material).

The condensation model developed in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.3) applies to stage 3 condensation. This condensation model is a one-dimensional network model that produces estimates for the frequency and magnitude of condensation at waste package locations. Condensation on the drift walls is included in TSPA and is represented in the same manner as drift seepage, although with a different spatial distribution and flux rate. Drift wall seepage affects the transport of radionuclides through the drift invert and the partitioning of radionuclides onto the fractures and the matrix of the host rock.

Seven drifts in the repository are analyzed for condensation location and quantity as shown in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Figure 6-2 [a]). These drifts are chosen to reflect the range of conditions expected in the repository. Choices #1, #2, and #3 are collinear (having axes lying end to end in a straight line) and cut across the northern end of the repository. Choice #3 is shorter than most emplacement drifts and is at the edge of the repository. Choices #4, #5, and #6 are collinear and cut across the middle of the repository. Choice #7 is in the southern section of the repository. For each drift, the heated portion of the drift was identified using the nominal waste package end-point coordinates from *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02) and unheated drift length at each end of the emplacement drifts from *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-18).

The stage 3 condensation model calculations consist of evaluating drift wall and drip shield condensation, for the seven drift choices, at six different times (1,000, 3,000, 10,000, 30,000, 100,000, and 300,000 years), and at three different percolation flux conditions (a range of average-flux values for each drift, representing uncertainty on percolation flux). The drift nearest the edge of the repository was also assessed at 300 years, as it reached stage 3 (all waste packages below 96°C) more rapidly that the other, hotter drifts. Additional parametric variations were used to quantify and bound model uncertainty, including:

- Two dispersion limits
- Two limits on the degree of mixing in the gas separated by the drip shield
- Two limits on invert transport.

The dispersion limits refer to the degree that water vapor is transported along the drift according to the one-dimensional axial dispersion coefficients calculated by the in-drift convection model (SNL 2007 [DIRS 181648], Section 6.3.5.1). Limits on the degree of mixing between gas volumes inside and outside the drip shield (i.e., perfect mixing and no-mixing) are used to capture the model uncertainty on the extent of such mixing. High and low invert transport cases use two different methods for determining the local vapor pressure at the invert surface. High-invert transport cases assume that the local vapor pressure is controlled by the temperature calculated at the top-center of the invert. Low-invert transport cases assume the local vapor pressure is controlled by the temperature of the drift wall. Calculations implemented in TSPA are for the "low invert transport" cases as discussed in the condensation analysis (SNL 2007 [DIRS 181648], Section 6.1.2[a]). Uncertainty in the occurrence and amount of condensation is

propagated to TSPA through the use of model outputs from all four "low invert transport" cases (low/high dispersion, ventilated/unventilated drip shield).

Condensate dripping from drift walls affects TSPA model calculations by adding additional water flow onto the drip shield. This flow is diverted to the invert, or it may flow through breaches in the drip shield where it interacts with the underyling waste package. The TSPA model calculates a probability of condensate on the drift walls at any location and, if condensation occurs, rate of condensation. The probability of condensation occurrence and condensation rate are abstracted as functions of the percolation flux, as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 8.3).

The model developed in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 8.1) is used to quantify the release of radionuclides from the EBS to the unsaturated zone. Dripping flux comprises a major source of liquid flow into the EBS. Condensation represents one source of dripping flux into the radionuclide transport model (SNL 2008 [DIRS 177407], Section 8.1). The EBS flow model is implemented directly in TSPA (SNL 2008 [DIRS 177407], Section 8.1).

Related included FEP 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-scale Cold Traps)) considers larger-scale variability in condensation behavior.

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.08.04.0B

FEP NAME:

Condensation Forms at Repository Edges (Repository-Scale Cold Traps)

FEP DESCRIPTION:

Emplacement of waste in drifts creates thermal gradients within the repository. Such thermal gradients can lead to repository-scale cold traps characterized by latent heat transfer from warmer to cooler locations. This mechanism can result in condensation forming at repository edges or elsewhere in the EBS, leading to enhanced dripping on the drip shields, waste packages, or exposed waste material.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Cold-trap effects within the repository are represented in TSPA as documented in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]). As discussed in that report (SNL 2007 [DIRS 181648], Section 6.3.3), three stages are identified for the occurrence of condensation within the emplacement drifts. Stage 1 designates the period when all locations are above the saturation temperature at the drift wall (and thus, also all drip shields and waste packages) and condensation cannot occur. Stage 2 is a transitional stage in which some locations are above the saturation temperature while others are below the saturation temperature. Stage 3 condensation occurs when all waste packages and drip shields (and thus, the drift wall) are below the saturation temperature. Abstractions are developed independently for stages 2 and 3 condensation for use in TSPA.

A bounding approach for predicting in-drift condensation rates during the Stage 2 period has been developed in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.2[a]). The approach for stage 2 condensation requires that every waste package realized in TSPA have two parameters established, namely the time (in years) for onset of stage 2, and the time for transition from stage 2 to stage 3. For a given waste package location, the time for onset of stage 2 can be approximated by the time when the local drift wall temperature cools to 96°C and condensation becomes possible. The times for the onset of stage 2 and for transition from stage 2 to stage 3 are provided by *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]). These times are used in TSPA as cutoffs for stage 2 condensation. Stage 2 condensation rates are developed for codisposal (codisposal, HLW-long, and HLW-short) packages and commercial SNF (commercial SNF, PWR, and BWR) packages in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.2.2[a]). Condensation rates represent a reasonable upper bound for drift wall condensation, and are scaled to represent only that condensation that forms over the drip shield, which may lead to enhanced dripping on the drip shields, waste packages, or exposed waste material.

The condensation model developed in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.3) applies to stage 3 condensation. This condensation model is a one-dimensional network model that produces estimates for the frequency and magnitude of condensation at waste package locations. Condensation on the drift walls is included in the TSPA and is represented in the same manner as drift seepage, although with a different spatial distribution and flux rate. As such, it affects the transport of radionuclides through the drift invert and the partitioning of that transport into the fractures and the matrix of the host rock.

Seven drifts in the repository are analyzed for condensation location and quantity as shown in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Figure 6-2 [a]). These drifts are chosen to reflect the range of conditions expected in the repository. Choices #1, #2, and #3 are collinear (having axes lying end to end in a straight line) and cut across the northern end of the repository. Choice #3 is shorter than most emplacement drifts and is at the edge of the repository. Choices #4, #5, and #6 are collinear and cut across the middle of the repository. Choice #7 is in the southern section of the repository. For each drift, the heated portion of the drift was identified using the nominal waste package end-point coordinates from *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02) and unheated drift length at each end of the emplacement drifts from *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-18).

The stage 3 condensation model calculations consist of evaluating drift wall and drip shield condensation for the seven drift choices at six different times (1,000, 3,000, 10,000, 30,000, 100,000, and 300,000 yr) and at three different percolation flux conditions (a range of average-flux values for each drift, representing uncertainty in percolation flux). The drift nearest the edge of the repository was also assessed at 300 years, because it reached stage 3 (all waste packages below 96°C) more rapidly than the other, hotter drifts. Additional parametric variations were used to quantify and bound model uncertainty, including:

- Two dispersion limits
- Two limits on the degree of mixing in the gas separated by the drip shield
- Two limits on invert transport.

The dispersion limits refer to the degree that water vapor is transported along the drift by one-dimensional axial dispersion coefficients calculated by the in-drift convection model (SNL 2007 [DIRS 181648], Section 6.3.5.1). Limits on the degree of mixing in the gases separated by the drip shield are used to capture epistemic uncertainty associated with that aspect of the model. High- and low-invert transport cases use two different methods for determining the local vapor pressure at the invert surface. High-invert transport cases assume that the local vapor pressure is controlled by the temperature calculated at the top-center of the invert. Low-invert transport cases assume that the local vapor pressure is controlled by the temperature of the drift wall. Calculations implemented in TSPA are for the low-invert transport cases as discussed in the condensation analysis (SNL 2007 [DIRS 181648], Section 6.1.2[a]). Uncertainty in the occurrence and amount of condensation is propagated to TSPA through the

use of model outputs from all four "low-invert transport" cases (low/high dispersion, ventilated/unventilated drip shield).

The stage 3 condensation model described above is based on simulations of water vapor transport and condensation in single drifts, and is used to evaluate not only the location of condensation within the drift cross-section, but also the longitudinal location of condensation along a drift with an axial temperature gradient (see related included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps))). The effects of repository-scale cold traps are captured within the model, as the repository temperature field used in the simulations is calculated using the principle of superposition—the heat contribution from all 108 drifts, plus the natural geothermal gradient, is summed in calculating the thermal conditions along the drift of interest (SNL 2007 [DIRS 181648], Section 6.3.5.1.1). Thus, the temperature effects resulting from proximity to the repository edge are captured in the model, as described in the condensation model report (SNL 2007 [DIRS 181648], Section 6.3.5.1.1). Drifts at the north end of the repository reflect the cooler portion of the repository, and drifts in the middle reflect the hotter portions of the repository (SNL 2007 [DIRS 181648], Section 6.3.5.1.1 and Figure 6.3.5-2). The effects of moisture being driven from hot areas in the repository and becoming available for condensation in cooler regions are captured in the bounding percolation rates. The bounding percolation rates are incorporated for each of the times and each of the emplacement drifts. The percolation rates vary with both location and time (SNL 2007 [DIRS 181648], Section 6.1.1[a]). The stage 2 analysis does not model different locations within the repository because that analysis is based on a model of a single drift (SNL 2007 [DIRS 181648], Section 6.2.1[a]), but the edge effects within a single drift are modeled. Due to the bounding nature of the Stage 2 analysis, repository scale effects may be considered to be bounded within the results.

Condensate dripping from drift walls affects TSPA model calculations by adding additional water flow onto the drip shield. This flow is diverted to the invert, or it may flow through breaches in the drip shield where it interacts with the underlying waste package. The model implemented in the TSPA calculates a probability of condensate on the drift walls at any location and, if condensation occurs, rate of condensation. The probability of condensation occurrence and condensation rate are abstracted as functions of the percolation flux, as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 8.3).

The model developed in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 8.1) is used to quantify the release of radionuclides from the EBS to the unsaturated zone. Dripping flux comprises a major source of liquid flow into the EBS. Condensation represents one source of dripping flux into the radionuclide transport model (SNL 2008 [DIRS 177407], Section 8.1). The EBS flow model is implemented directly in TSPA, as discussed in Section 8.1 of *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407]).

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.08.05.0A

FEP NAME:

Flow Through Invert

FEP DESCRIPTION:

The invert, a porous material consisting of crushed tuff, separates the waste package from the bottom of the drift. Flow and transport through and around the invert can influence radionuclide release to the UZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Flow within the EBS is addressed within several included FEPs as follows: FEP 2.1.08.05.0A (Flow Through the Invert) (this FEP), FEP 2.1.08.06.0A (Capillary Effects (Wicking) in EBS), and FEP 2.1.08.07.0A (Unsaturated Flow in the EBS). FEP 2.1.08.09.0A (Saturated Flow in the EBS) is excluded.

Hydraulic properties of EBS components and flow pathways within the EBS are discussed in detail in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3). The EBS radionuclide transport abstraction model is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the EBS radionuclide transport abstraction model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, and water chemistry), and the degradation state of the EBS components (SNL 2008 [DIRS 177407], Section 6.1). Outputs consist of the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility and ingrowth/decay, retardation, and the degree of liquid saturation of the waste form and invert materials. The EBS radionuclide transport abstraction model is implemented directly into the TSPA GoldSim model to compute the radionuclide release rates from the EBS (SNL 2008 [DIRS 177407], Section 8).

The conceptual model for EBS flow used in the performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standard (10 CFR 63.331 [DIRS 180319]) is described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3.1). The source of inflow to the EBS is the seepage flux that drips from the crown (roof) of the drift, drift wall condensation, and imbibition flux from the unsaturated zone into the invert. This inflow can flow through the EBS along eight pathways: (1) drift seepage and drift wall condensation flux, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package into the invert, (7) imbibition flux from the unsaturated

zone matrix to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2008 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). These pathways are time- and location-dependent, because drip shield penetrations and waste package penetrations will vary with time and local conditions in the repository.

The conceptual model for radionuclide transport through the EBS consists of transport through three separate domains: the waste form (e.g., fuel rods or defense high-level radioactive waste (defense HLW) glass), waste package corrosion products, and the invert (SNL 2008 [DIRS 177407], Section 6.3.4). Because the pallet is not considered to contribute to the EBS barrier capability in regards to the transport of radionuclides through the EBS, water and radionuclides pass directly from the waste package to the invert.

The EBS flow abstraction, which is a component of the EBS radionuclide transport abstraction model (SNL 2008 [DIRS 177407], Section 6.3.1), includes invert flows in the net flow of water from the EBS and the advective transport of radionuclides. Flow through the invert consists of the flux diverted by the drip shield and waste package and the flux through the waste package, and is reduced by any evaporation from the invert. Each of these terms is accounted for in the EBS flow abstraction, which is used directly in TSPA.

Advection and diffusion transport radionuclides into the invert from the corrosion products domain and from this domain to the unsaturated zone. Groundwater colloids are also available in this domain if there is any water flow. Reversible sorption of radionuclides is modeled on these colloids. Because the chemical environment of the invert may be different from the corrosion products domain, colloid stability may be affected and dissolution or precipitation of radionuclides may take place. The submodel for transport through the invert is summarized in transport pathway 3 of the transport abstraction summary in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Table 8.1-2).

Water saturation in the invert is an input to the EBS radionuclide transport abstraction model and is provided by the MSTHM. The MSTHM determines the imbibition flux from the host rock matrix into the invert, as well as the water saturation in the invert (SNL 2008 [DIRS 177407], Section 6.3.3.4). Water saturation is used in calculating the diffusion coefficient both in the waste package and in the invert, and so it impacts radionuclide transport in the EBS. The amount of water that flows into the EBS by capillary effects and the resulting water saturation are documented in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.3).

Multiscale Thermohydrologic Model (SNL 2008 [DIRS 184433], Appendix XV) also calculates the matrix saturation of the invert based on the inputs described in Table 4.1-1 of that report. These inputs include the hydrologic properties of the invert, which are consistent with *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). Unlike the EBS radionuclide transport abstraction model, the MSTHM simulates the invert as a dual-permeability medium consisting of “matrix” and “fracture” flow. This calculation develops the retention and unsaturated flow properties of the invert using a non-dimensionalized van Genuchten retention relation. The treatment of the invert as a single continuum for flow and transport is justified in *EBS Radionuclide Transport Abstraction*

(SNL 2008 [DIRS 177407], Section 6.5.2.3). Invert matrix saturations are then used in that report (SNL 2008 [DIRS 177407], Section 6.5.2.5) for the calculation of radionuclide transport.

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). For the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), an intrusion borehole is assumed to be drilled from the ground surface, through a drip shield and a single waste package to the water table. Radionuclide mass is released from the intruded waste package to the EBS Transport submodel (SNL 2008 [DIRS 183478], Section 6.3.8). Therefore, this FEP is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.08.06.0A

FEP NAME:

Capillary Effects (Wicking) in EBS

FEP DESCRIPTION:

Capillary rise, or wicking, is a potential mechanism for water to move through the waste and EBS.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Flow within the EBS is addressed in several included FEPs as follows: Capillary Effects (Wicking) in EBS (this FEP), FEP 2.1.08.05.0A (Flow through Invert), and FEP 2.1.08.07.0A (Unsaturated Flow in the EBS). Related FEP 2.1.08.09.0A (Saturated Flow in the EBS) is excluded.

The effect of capillary flux of water from the host rock to the invert is captured by the analysis described in the MSTHM (SNL 2008 [DIRS 184433], Section 6.3.3). Chemistry of the water in the invert is represented by the P&CE model (SNL 2007 [DIRS 177412], Section 6.15.2). The invert matrix saturations calculated by the MSTHM and the invert water chemistry calculated by the P&CE model are used (along with other parameters such as the seepage flux rate) to calculate flow and transport in and around the invert (SNL 2008 [DIRS 177407], Section 6.5.2.3). Hydraulic properties of EBS components and flow pathways within the EBS are discussed in detail in that report.

Wicking is not modeled as a flow mechanism in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407]). However, the abstraction does account for the mass of water brought into the invert because of wicking through the invert water saturation term (SNL 2008 [DIRS 177407], Section 6.5.2.3). The effects of water saturation on radionuclide transport are incorporated in the model in that water saturation is used to calculate the radionuclide diffusion coefficient both in the waste package and in the invert (SNL 2008 [DIRS 177407], Section 6.3.4).

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.1.08.07.0A

FEP NAME:

Unsaturated Flow in the EBS

FEP DESCRIPTION:

Unsaturated flow may occur along preferential pathways in the waste and EBS. Physical and chemical properties of the EBS and waste form, in both intact and degraded states, should be considered in evaluating pathways.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The emplacement drift will contain waste packages. A freestanding drip shield sits over the waste packages on the invert. The waste package sits on an emplacement pallet that raises the bottom of the waste package above the invert (SNL 2007 [DIRS 179354], Section 4.1). Flow within the EBS is addressed within several included FEPs as follows: FEP 2.1.08.06.0A (Capillary Effects (Wicking) in EBS), FEP 2.1.08.05.0A (Flow through Invert), FEP 2.1.06.06.0A (Effects of Drip Shield on Flow), and this FEP. Saturated flow is discussed in excluded FEP 2.1.08.09.0A (Saturated Flow in the EBS).

The conceptual model flow in the EBS is described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Sections 6.3 and 6.5). Hydraulic properties of EBS components and flow pathways within the EBS are discussed in detail in that report. The conceptual model for EBS flow is also described (SNL 2008 [DIRS 177407], Section 6.3). Sources of significant inflow of liquid water to the EBS are the seepage flux, plus any condensation that may occur on the walls of the drift and drip onto the drip shield, plus the small capillary imbibition flux that can flow from the host rock into the invert. This water can flow through the EBS along eight pathways: (1) seepage flux plus condensation, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package into the invert, (7) imbibition flux from the UZ matrix to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2008 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). These pathways are time- and location-dependent, in the sense that drip shield gaps, drip shield breaches, and waste package breaches will vary with time and local conditions in the repository.

The conceptual model for flow and transport of radionuclides through the EBS includes three domains: the waste form (e.g., fuel rods or defense HLW glass), waste package corrosion products, and the invert. The presence of the emplacement pallet is not considered; water and radionuclides pass directly from the waste package to the invert. Initially, water inside a breached waste package will encounter intact metallic supports and cladding, unoxidized fuel, and uncorroded defense HLW glass. Water is expected to move over these surfaces as a thin film. Ultimately the waste form will degrade to a high surface area, small particle size mixture

of iron oxides, clays (in defense HLW glass-containing packages), and oxidized fuel remnants. Water will move through this aggregate as it would a porous medium, such as a soil.

Because the repository is located above the water table, water movement in the EBS is conceptualized as flow under varying degrees of partial saturation. Pathways for liquid water inflow are modeled as described above (SNL 2008 [DIRS 177407], Section 6.3.1 and Table 6.3-1). When seepage occurs, advective transport pathways that include the waste package and drip shield are modeled as quasi-steady state (i.e., non-episodic) flow (SNL 2008 [DIRS 177407], Sections 6.3.3.2 and 6.3.2.4, respectively); within the waste package, the waste form and corrosion product domains are treated as being fully saturated (SNL 2008 [DIRS 177407], Section 6.3.3.2).

For conditions or locations for which seepage and drift wall condensation do not occur, unsaturated conditions control the mobility of radionuclides by diffusion (SNL 2008 [DIRS 177407], Section 6.3.3.2). For these no-seep conditions, the degree of water saturation in the waste package is calculated in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.5.2.2) and used to modify the effective diffusion coefficient (SNL 2008 [DIRS 177407], Sections 6.3.4.1, 6.3.4.3, and 6.3.4.6). The effective diffusion coefficient is enhanced by greater liquid saturation, and is at maximum for fully saturated conditions.

For no-seep conditions, flow in the invert is described by *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.3), which represents the invert liquid saturation and the imbibition flux from the host rock, for use in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3.3.4). The in-drift temperature and humidity conditions provided by the multiscale model control the liquid saturation of degradation products within the waste package. Liquid saturation in the invert, and in the waste package, is used in calculating the effective diffusion coefficients for radionuclide transport. The multiscale model also provides the flux of water that wicks into the invert from the host rock (SNL 2008 [DIRS 184433], Section 6.3.3), and this small advective flux is incorporated in the EBS transport model (SNL 2008 [DIRS 177407], Section 6.5).

The composition of water in the EBS, whether present due to seepage, condensation, or capillary wicking, is represented in TSPA as discussed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.15). In-drift water composition is equilibrated to local conditions of temperature, relative humidity, and in-drift partial pressure of carbon dioxide. Seepage water and gas phase (carbon dioxide) compositions are abstracted from time-dependent outputs of the near-field chemistry model (SNL 2007 [DIRS 177412], Sections 6.7 and 6.9) corresponding to locations at or adjacent to the drift wall. In-drift evolution of seepage, condensation, and capillary waters is described by the seepage evaporation abstraction and the invert pore-water abstraction (SNL 2007 [DIRS 177412], Sections 6.9, 6.13, and 6.15).

Transport predictions are particularly sensitive to the porosity and pore volume, water saturation, interfacial diffusive areas, diffusive path lengths, and diffusion coefficients. Uncertainty in the output of the EBS flow and transport model is accounted for by using a range of these values as inputs (SNL 2008 [DIRS 177407], Sections 6.3.4 and 6.5.2.2).

For the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), an intrusion borehole is assumed to be drilled from the ground surface, through a drip shield and a single waste package to the water table. Radionuclide mass is released from the intruded waste package to the EBS Transport submodel (SNL 2008 [DIRS 183478], Section 6.3.8). The percolation flux is used to calculate a volumetric flux through the intrusion borehole. The volumetric flux is assumed to flow directly into the penetrated waste package; no diversion of the water by the drip shield or waste package is considered. Thus, the volumetric flux represents the flow through the waste package for the advective component of the EBS transport calculation. For the diffusive component of the EBS transport calculation, the diffusive area is set equal to the cross-sectional area of the borehole and, by giving the invert a very large water volume, the downstream concentration boundary condition is set to a zero concentration to maximize diffusion out of the waste package (SNL 2008 [DIRS 183478], Section 6.7.3.1). The radionuclide mass (dissolved and colloidal) released from the waste package is assumed to be transported down the intrusion borehole to the water table.

FEP: 2.1.08.09.0A

FEP NAME:

Saturated Flow in the EBS

FEP DESCRIPTION:

Saturated flow and radionuclide transport may occur along preferential pathways in the waste and EBS. Physical and chemical properties of the EBS and waste form, in both intact and degraded states, should be considered in evaluating pathways.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses the potential for localized conditions of full saturation and the significance for TSPA. Flow within the EBS is additionally addressed in part by included FEP 2.1.08.06.0A (Capillary Effects (Wicking) in EBS), included FEP 2.1.08.05.0A (Flow Through Invert), and included FEP 2.1.08.07.0A (Unsaturated Flow in the EBS). The potential for ponding in the invert is addressed by excluded FEP 2.1.08.12.0A (Induced Hydrologic Changes in Invert).

The model for flow in the EBS is described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Sections 6.3 and 6.5). Hydraulic properties of EBS components and flow pathways within the EBS are discussed in detail in that report. The source of groundwater inflow to the EBS is the seepage flux that drips from the crown (roof) of the drift and imbibition flux from the unsaturated zone into the invert. In addition, there is a condensation flux. The inflow can flow through the EBS along eight pathways: (1) seepage flux, plus any condensation that may occur on the walls of the drift above the drip shield, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package into the invert, (7) imbibition flux from the unsaturated zone matrix to the invert, and (8) flux from the invert to the unsaturated zone fractures (SNL 2008 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1).

The repository drifts will be located, on the average, approximately 300 m above the current water table. The elevation of the repository will range from 1,039 to 1107 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01), while the measured water table elevation under the repository for present-day conditions varies from approximately 730 m to 850 m (BSC 2004 [DIRS 169855], Figure 6-2). *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.8) estimates from evidence of past changes in the water table that the water table will rise no more than 120 m in response to climate change in the future. Because the repository is located above the water table, water movement in the EBS as described above is conceptualized as flow under varying degrees of partial saturation (see included FEP 2.1.08.07.0A (Unsaturated Flow in the EBS)). For the invert, which is the lowest point in the EBS and one of the first places where saturation buildup could occur, the EBS radionuclide transport abstraction model explicitly represents the effects from advective liquid

inflow on radionuclide transport (SNL 2008 [DIRS 177407], Section 6.5). Under seep conditions, the waste form is assumed to be fully saturated; under no-seep conditions, the saturation is calculated from the temperature, relative humidity, and material properties. The effects of ponding within waste packages (bathtub condition) are also addressed as an alternative conceptual model in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.6.1). Specifically, calculated releases from a fully saturated "bathtub waste package" are found to be less than or equal to those predicted by the model. Hence, the latter bounds releases, and the bathtub model was not carried forward into TSPA calculations.

While transient liquid saturation may approach 100% locally, large persistent saturated flow pathways in the EBS are not expected to occur. As shown by results from *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.3), without seepage or drift wall condensation the liquid saturation in the invert is less than 100% at all times. With seepage or local drift wall condensation, more water is available to potentially saturate EBS materials. The repository emplacement drift is designed to promote drainage and preclude wetting or ponding along the invert–rock interface (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02; also see excluded FEP 2.1.08.12.0A (Induced Hydrologic Changes in Invert)). It is conceivable that granular debris from tunnel boring machine cuttings created during excavation could accumulate in fractures in the floor and inhibit drainage locally. Similarly, crushed tuff in the invert might be ground finer by waste emplacement and find its way into fractures. Saturation buildup in the invert, if it occurs, will form at the bottom and spread up the curved surface, accessing additional fractures for drainage and unsaturated rock. Spreading of saturation axially down the drift will also access additional fractures and unsaturated rock. In this manner, localized seepage or condensation can readily drain downward into the host rock. Spreading of the flow will therefore ultimately decrease the maximum flux per unit area and thereby reduce the overall potential for local rock saturation, thus decreasing the potential for saturated transport of released radionuclides.

Based on the above discussion, omission of FEP 2.1.08.09.0A (Saturated Flow in the EBS) will not result in a significant adverse change to the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.08.11.0A

FEP NAME:

Repository Resaturation Due to Waste Cooling

FEP DESCRIPTION:

Following the peak thermal period, water in the condensation cap may flow downward, resaturating the geosphere dry-out zone and flowing into the drifts. This may lead to an increase in water content and/or resaturation in the repository.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The thermal-hydrologic seepage model (BSC 2005 [DIRS 172232]) as abstracted for TSPA (SNL 2007 [DIRS 181244], Section 6.5.2) provides a detailed description of dryout, condensation, reflux, resaturation, and the potential impacts from these processes on seepage. This abstraction is incorporated into the TSPA along with thermal and hydrologic conditions provided by *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]) to account for thermal effects on seepage (SNL 2007 [DIRS 181244], Section 6.5.2.1).

The MSTHM represents postclosure in-drift thermal-hydrologic conditions including the effects from host-rock dryout and resaturation, characterized by the output variables of temperature and liquid saturation at the drift wall (SNL 2008 [DIRS 184433], Section 6.2[a]). The effects of resaturation are represented at locations within the drift using MSTHM output, based on an assumption of uniform gas-phase composition at all points enclosed by the drift wall and above the invert (SNL 2008 [DIRS 184433], Section 5.5). Uncertainty in MSTHM results is propagated to TSPA calculations through the use of different rock thermal conductivities and a suite of percolation flux values (SNL 2008 [DIRS 184433], Section 6.3.16[a]). Other sources of uncertainty that could affect drift wall resaturation, and hence, in-drift thermal-hydrologic conditions, were evaluated using sensitivity analyses and found to be insignificant. These include uncertainties in rock hydrologic properties (SNL 2008 [DIRS 184433], Section 6.3.16[a]), in ventilation heat removal efficiency (SNL 2008 [DIRS 184433], Section 6.3.12), and in the effects of axial vapor transport (SNL 2008 [DIRS 184433], Section 6.3.18[a]).

Dryout conditions are explicitly represented by the maximum lateral extent of the boiling zone (dryout zone) in the pillars between drifts. The lateral extent of boiling is much smaller than the half-spacing between emplacement drifts (SNL 2008 [DIRS 184433], Figure 6.3-79[a]; SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-13), enabling condensate and percolation flux to continuously drain between emplacement drifts. Storage of condensate in the rock will not be sufficient to augment seepage, nor will refluxing activity that converges on the drift opening as the dryout zone collapses (BSC 2005 [DIRS 172232], Section 6.2.4). These are significant factors in the thermal seepage model, in which seepage cannot occur until the drift

wall cools to below 100°C and resaturates. Uncertainty associated with the effect of the dryout zone on seepage was evaluated using sensitivity analyses varying the percolation flux, different fracture flow conceptual models, other thermal loads, and transient versus steady-state flow conditions (BSC 2005 [DIRS 172232], Section 6.2.4.2). The results of these calculations support the conclusion that seepage will not occur until the dryout zone resaturates to the drift wall.

The effect of resaturation on the composition of potential seepage is addressed in *Drift-Scale THC Seepage Model* (SNL 2007 [DIRS 177404], Section 6.5.5) and in the near-field chemistry model, described in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.2). Sensitivity calculations have shown that seepage is dilute when it occurs after the drift wall cools to 100°C (SNL 2007 [DIRS 177413], Section 6.6.3). After cooldown, the composition of potential seepage waters converges to the composition of nearby pore waters in the host rock (SNL 2007 [DIRS 177413], Section 6.6.3). This behavior is represented in the near-field chemistry model (SNL 2007 [DIRS 177412], Section 6.3.2) by evaluating the evolution of in situ pore waters as they percolate downwards to the repository level, interacting with host-rock minerals. The predicted water compositions are used in performance assessment calculations to represent potential seepage after resaturation of the near field when seepage becomes possible.

FEP: 2.1.08.12.0A

FEP NAME:

Induced Hydrologic Changes in Invert

FEP DESCRIPTION:

Drainage in the drifts may be altered by plugging of fractures or floor buckling. Possible effects include wetting or ponding in the invert until the water level reaches the fractures in the wall or until there is sufficient hydraulic head to clear the fractures. Wetting or ponding could provide a continuing source of water vapor for interaction with the drip shields, waste packages, and their supports.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The repository horizon lies above the water table, as documented in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-04). The emplacement drifts will be configured as a series of tunnels in the mountain. As described in *Geologic Framework Model (GFM2000)* (BSC 2004 [DIRS 170029], Table 6-2), the repository lies within four host-rock units (Tptpul, Tptpmn, Tptpll, and Tptpln). For the range of hydrologic properties of the four host-rock units (see SNL 2007 [DIRS 179545], Table 6-6), fracture permeability is sufficiently large and fractures are sufficiently well-connected to allow gravity-driven drainage of percolation to occur in an unrestricted fashion, thus preventing wetting and ponding in the invert. Included FEP 2.1.08.05.0A (Flow Through the Invert) discusses flow through the invert and saturation properties. If water build-up in the invert occurs, the relatively large permeability in this region will cause the flow to spread along the curved surface towards adjacent fractures. Moreover, as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 6.3.3.2.9), condensate on the drift wall will tend to be imbibed into the host rock, away from the drift opening. Moreover, this report indicates that elevated saturation at the invert surface is not expected at representative in-drift conditions, and that axial transport will play an important role mobilizing water vapor into other regions of the drift (see excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield)).

It is conceivable that granular debris from tunnel-boring machine cuttings created during excavation could accumulate in fractures in the floor and inhibit drainage or affect infiltration in localized areas. However, the effect of dust filling fractures may be temporary since infiltration studies in Alcove 8 show stabilization of infiltration/seepage rates between 400 to 700 days as described in *Analysis of Alcove 8/Niche 3 Flow and Transport Tests* (BSC 2006 [DIRS 178275], Sections 6.2.1, 6.2.4, and 6.4.2). According to that report (BSC 2006 [DIRS 178275]), infiltrating water in these tests mobilized particles away from percolation paths leading to eventual stabilization of seepage rates. Excavation activities tend to increase fracture permeability by about an order of magnitude as described in *In Situ Field Testing of Processes*

(BSC 2004 [DIRS 170004], Section 6.1.2.2.1). This increase in fracture permeability upon excavation could counteract the effect of fracture plugging as a result of accumulating rock debris by excavation activities. Therefore, the effect of fracture plugging on fracture permeability should be considered transitory and minimal within the time scale of the repository performance.

To preclude "wetting or ponding" as described in this FEP, the repository is designed with horizontal emplacement drifts. *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Numbers 01-11 and 01-12) specifies the emplacement drift design:

> The grade of the emplacement drift shall be nominally horizontal so that overall water drainage travels directly into the rock to prevent water accumulation…. The repository nonemplacement opening shall provide a repository grade so overall water drainage and accumulation travels away from emplacement areas.

Excluded FEP 2.1.07.06.0A (Floor Buckling) corroborates this justification as drift floor buckling is determined to be negligible with respect to creating conditions that would support ponding.

Thus, the repository emplacement drift is designed to preclude full wetting or ponding in the invert domain. Saturation buildup in the invert, if it occurs, will form at the bottom and spread up the curved surface, accessing additional fractures for drainage. Spreading of saturation axially down the drift will also access additional fractures. In this manner, localized seepage or condensation can readily drain downward into the host rock. Spreading of the flow and water vapor migration through axial transport in the drift will limit the maximum attainable flux and thereby reduce the potential for rapid transport of released radionuclides.

Consistent with the above discussion, omission of FEP 2.1.08.12.0A (Induced Hydrologic Changes in Invert) will not result in a significant adverse change to the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.08.14.0A

FEP NAME:

Condensation on Underside of Drip Shield

FEP DESCRIPTION:

Condensation of water on the underside of the drip shield may affect the waste package hydrologic and chemical environment.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

In-Drift Natural Convection and Condensation (SNL 2007 [DIRS 181648], Section 8[a]) predicts condensation rates and probabilities within the EBS. Condensation rates and probabilities are predicted using bounding cases that address vapor transport, mixing of gas under the drip shield, and the availability of moisture to evaporate in the invert. These bounding analyses (SNL 2007 [DIRS 181648], Sections 6.3.7.2 and 6.1[a]) evaluate the occurrence of condensation under the drip shield for several different conditions, including "unventilated" cases in which the regions under the drip shield and outside the drip shield are isolated, and "ventilated" cases with a single well-mixed region. Simulations under both conditions provide inputs to TSPA, to ensure that the uncertainty in the efficiency of gas-phase mixing is fully captured (SNL 2007 [DIRS 181648], Section 6.1.2[a]). The location and amount of condensation was also evaluated using upper and lower bounding water vapor pressures, corresponding to the saturated vapor pressures for temperatures at the top and at the base of the invert—the "high-invert transport" and "low-invert transport" conditions, respectively. As discussed in the following sections, condensation under the drip shield occurs only in the "high-invert transport" case, which is not anticipated to occur (SNL 2007 [DIRS 181648], Section 6.1.2[a]).

Analysis of the potential for condensation on the underside of the drip shield and its possible effects leads to a conclusion that condensation under drip shields will not occur. Even if it does occur, the overall effect on dose will be insignificant. This screening justification addresses the following issues:

- Conditions needed for condensation to occur under drip shields
- Conditions that limit condensation under drip shields
- Effect of condensate on corrosion of the drip shield/waste package
- Effects from condensate dripping onto waste packages
- Effect of condensation on transport of radionuclides outside the waste package.

Conditions Needed for Condensation to Occur Under Drip Shields – Condensation under the drip shield (particularly where condensate could contact the waste package) requires the invert temperature where evaporation occurs to be greater than the temperature of the upper half of the drip shield. Other conditions also apply as discussed below. Using this invert temperature criterion actually overstates the likelihood of condensation because the partial pressure of water vapor in the invert is decreased, relative to the saturation vapor pressure at the invert temperature, due to capillary vapor pressure lowering—the vapor pressure is equal to the saturation vapor pressure at the invert temperature minus the capillary pressure exerted by the invert porosity. Temperatures of the drip shield crown and the top of the invert beneath the drip shield are always within a few degrees of each other (higher or lower) as calculated in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Table 6.3-45). This result is corroborated by experimental data from a 44%-scale natural convection test of the in-drift configuration, reported in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Tables 7.4.1-23 and 7.4.1-24). Because the temperature difference is minor, the difference in relative humidity at the two locations is small, and condensation under the drip shield requires that the top of the invert be very moist. This condition is evident from the bounding cases in the condensation model (SNL 2007 [DIRS 181648], Table 6.2[a]), which predict drip shield condensation only for cases with "high-invert transport" and none for "low-invert transport." In the "low-invert transport" cases, the vapor pressure in the drift is controlled by the lower-temperature bottom of the invert, resulting in drier conditions (lower relative humidity) at the hotter top of the invert.

In the "high-invert transport" cases, the occurrence of condensation under drip shields in the first 10,000 years is restricted to conditions of limited gas-phase exchange with the air outside of the drip shield. The drift wall outside the drip shield is cooler than the invert, because the invert is closer to the waste package. If water vapor can readily migrate to the air space outside of the drip shield—either through the drip shield interfaces or through the invert—then condensation will occur at the drift wall rather than under the drip shield. This condition is evident from the condensation model, which predicts drip shield condensation within the first 10,000 years only for "high-invert transport" cases with an "unventilated" drip shield (SNL 2007 [DIRS 181648], Tables 6.2[a] and 6.3[a]).

Finally, condensation within the emplacement region is more likely under conditions of limited axial transport, as efficient axial transport results in water vapor migration to the unheated portions of the drift and condensation in that region (SNL 2007 [DIRS 181648], Section 6.1.2[a]).

In summary, condensation on the underside of the drip shields requires very moist conditions in the invert, restricted vapor movement from the volume enclosed by the drip shield to the gas phase within the drift, and limited axial transport of water vapor to the cool regions at the ends of the drifts. However, as detailed below, these conditions are not anticipated in the emplacement drifts, and the process has limited consequence to system performance.

Conditions that Limit Condensation Under Drip Shields – In analyses in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Sections 6.3.7.2 and 6.1[a]), condensation under the drip shield occurs only in the "high-invert transport" case, which is not considered representative of in-drift conditions. Thermal-hydrologic simulations (SNL 2007

[DIRS 181648], Sections 6.3.3.2.1, 6.1.2[a], and 8[a]) show that condensation under any drip shield does not occur when the local water vapor partial pressure is controlled by the temperature at the bottom of the invert (the "low-invert transport" case), which is always cooler than the top of the invert and than the crown of the drip shield (SNL 2008 [DIRS 184433], Section 6.3.11 and Table 6.3-45). This is the expected condition in the emplacement drifts. The dewpoint is controlled by the lower invert, unless vapor transport through the invert is limited or the invert is flooded. Both of these conditions are not anticipated, because the porous, coarse-grained invert is permeable to gases and has little capability for water retention. At even the highest seepage rates, water does not pool in the invert. Also, water shed from the drip shield travels downward through the invert instead of laterally underneath it. Thus, the top of the invert cannot be maintained in a moist state by lateral flow from edges of the drip shield. In addition, the "high invert transport" cases use predicted temperatures directly under the waste package, which are higher than the average value for the entire invert surface under the drip shield. For these reasons, the "high-invert transport" cases are not implemented by TSPA, and condensation on the underside of the drip shield is not anticipated to occur (SNL 2007 [DIRS 181648], Section 6.1.2[a]).

In the bounding "high-invert transport" cases, condensation on the underside of a drip shield may occur if water vapor evaporates from the invert at one waste package location, then migrates under the connected drip shield segments and condenses on the underside of a cooler drip shield at another location (SNL 2007 [DIRS 181648], Section 6.3.7.2). However, calculations in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.11 and Table 6.3-45) show that for any given cross-section, the coolest and most humid location is always at the bottom of the invert. Thus, water vapor that is transported axially along the drift will have a greater tendency to condense near the bottom of the invert, where it is coolest, rather than at the top of the invert or the underside of the drip shield. Thus, condensation on the underside of the drip shield will be limited by the efficiency of axial water vapor migration as compared with radial mixing.

The radial thermal gradient is much greater than the axial thermal gradient (SNL 2007 [DIRS 181648], Figures 6.3.5-13 and J-1). Such thermal gradients drive mixing, promoting condensation on cooler surfaces such as the drift wall, the bottom of the invert, or possibly the sides of the drip shield. Experimental results reported in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Table 7.4.1-24) show that the drip shield sides are cooler than the top, because of proximity to the waste package surface and because of natural convection. Therefore, any condensation occurs preferentially on the sides, where it cannot contact the waste package. This effect is not represented in the condensation model, which represents the underside of each drip shield as a single node in a lumped-parameter network, and does not distinguish the top and sides (SNL 2007 [DIRS 181648], Section 6.3.5.1.3).

A test was conducted to corroborate predictions of condensation under the drip shield as discussed in *Engineered Barrier System – Pilot Scale Test #3, Heated Drip Shield Test Results* (Howard et al. 2001 [DIRS 153282], Section 4.3). The test was a 1/4-scale heated experiment intended to evaluate a seeping environment within a simulated emplacement drift that included a simulated waste package, drip shield, invert, and supporting components similar to the EBS design. Water was introduced through the top of the test cell and fell onto the drip shield, from which it drained to the invert. The test showed that the invert under the drip shield remained

consistently dryer than outside the drip shield. These observations support the assertion that boundary conditions for the condensation model are bounding with respect to the physical reality of the test. The coolest temperatures on the drip shield were hotter than the coolest temperatures of the invert, and no condensation was observed under the drip shield (Howard et al. 2001 [DIRS 153282], Section 5). The important findings of this test include: (1) the "high invert" condition evaluated in the condensation model is an extreme bound that is not anticipated to occur even with seepage; and (2) if water vapor can readily migrate from inside to outside the drip shield (i.e., the drift wall, which is cooler than the drip shield, controls the dewpoint), then condensation on the underside of the drip shield will not occur.

The thermal-hydrologic modeling in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Sections 6.3.7.2 and 6.1[a]) is not applicable under conditions of drift collapse. In this case, moisture transport is limited, and the processes of evaporation and condensation are localized, and tend to cancel each other out (SNL 2007 [DIRS 181648], Section 6.2.2[a]). Should the drip shield remain intact, effective radiative coupling between the waste package and drip shield will ensure that drip shield temperatures are elevated relative to the bottom of the invert. Hence, condensation on the underside of the drip shield is not expected to occur in the drift collapse case.

Effects of Condensate on Corrosion of the Drip Shield/Waste Package – Although condensation on the underside of the drip shield is not anticipated, should it occur, the impact with respect to drip shield or waste package corrosion is negligible. The potential existence of condensate on the underside of the drip shield is limited to drip shield temperatures below the boiling point of water at the repository level, 96°C. Condensate on the underside of the drip shield will have a composition similar to rain water (i.e., a very dilute solution of carbonic acid with a pH of approximately 5.6) (Stumm and Morgan 1996 [DIRS 125332], p. 161), varying somewhat with the temperature and the partial pressure of carbon dioxide in the drift. Such an environment is a significant deviation from the nominal environments expected to form on the WPOB by evaporative concentration of seepage, as the dissolved ionic content will be extremely low in the case of condensation, and the chloride load will be negligible.

Cyclic polarization testing of Titanium Grade 7 has been carried out over a range of pH, temperature, cation and anion types, and concentrations (SNL 2007 [DIRS 180778], Tables 19 to 21), representing much more potentially corrosive conditions than dilute condensation, and localized corrosion was not observed. By extension, no localized corrosion is expected in condensation. Localized corrosion of the drip shield is never anticipated to occur within the repository environment (excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields)).

The model used to predict the localized corrosion initiation on the Alloy 22 WPOB was developed using data primarily from mixed salt solutions with significant concentrations of chloride, nitrate, and other cations and anions (SNL 2007 [DIRS 178519], Section 6.4.4.6.6). The regression fit to the model is therefore weighted towards representing medium to high concentration brines rather than extremely dilute solutions. This modeling approach is appropriate because the model will best represent behavior in electrolytes that are more likely to support the electrochemical and chemical reactions associated with localized corrosion. Applying the model to extremely dilute solutions results in predicting high open circuit values and can lead to an overestimation of the probability of localized corrosion initiation.

However, experimental data do not support the occurrence of localized corrosion of either Titanium Grade 7 or Alloy 22 in dilute solutions representing condensation. Long-term exposure testing of creviced Titanium Grade 7 and Alloy 22 was performed in the LTCTF, with samples located both in the aqueous phase and suspended above the aqueous phase in the vapor-phase environment. The experimental configuration was such that the temperature of the lid of the chamber was less than that of the heated aqueous solution, and evaporated electrolyte continuously condensed and dripped back down into the test chamber. Samples hung in the vapor phase experienced this dripping condensate environment (SNL 2007 [DIRS 178519], Section 6.4.3) and, therefore, reasonably estimate the response of the materials to the condensing environments that could potentially develop under repository conditions. Optical examination of the creviced samples in the vapor phase revealed no indication of crevice initiation on either of the materials for exposure periods of up to five years (SNL 2007 [DIRS 178519], Section 6.4.3; SNL 2007 [DIRS 180778], Section 6.5.3). This result is confirmation that condensing environments, even those that form above concentrated, repository-relevant electrolytes, will not initiate crevice corrosion of either Alloy 22 or Titanium Grade 7.

Further support for the conclusion that Alloy 22 will not undergo crevice corrosion when exposed to the potential condensate environments is provided by the results of long-term exposure of Alloy C (UNS N06455), a less corrosion resistant material than Alloy 22, to a marine environment. Alloy C specimens exposed for 44 years to a marine environment at North Carolina's Kure Beach (i.e., with salt, air, and alternate wetting and drying, as well as the presence of surface deposits) (Baker 1988 [DIRS 154510], p. 134 and Table 6) indicated that passivity of this alloy was maintained over this long exposure period, as evidenced by the observation of a mirror-like surface finish after surface deposits were removed. Examination of specimens from this alloy after more than 50 years of exposure indicated that the samples continued to maintain a mirror-like finish indicative of passive behavior (McCright 1998 [DIRS 114637], Figure ES-1).

Brines formed by deliquescence of salts in dust on the waste package or drip shield may mix with condensate to yield somewhat more concentrated solutions than condensate alone. However, the resulting solutions are no more aggressive than the deliquescent brines without condensate. Brines formed by dust deliquescence are addressed by excluded FEPs 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence) and 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces Due to Deliquescence).

Effects from Condensate Dripping Onto Waste Packages – Condensation on the underside of the drip shield could mobilize radionuclides out of the waste package if the water were to drip onto and penetrate the waste package wall, particularly the WPOB. Seismic ground motion and the resulting dynamic interaction of waste packages, pallets, and the drip shield can produce waste package damage from end-to-end impacts and package-pallet impacts (SNL 2007 [DIRS 176828], Section 6.5). Seismic damage occurs as stress corrosion cracks, and advective flow of liquid water through such cracks is addressed by excluded FEP 2.1.03.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package). General corrosion of the Alloy 22 WPOB will be very slow, and the lifetime will be well in excess of 10,000 years (SNL 2007 [DIRS 178519], Section 8.1); thus, the types of breaches that occur under intact drip shields (no seepage contact) are limited to stress corrosion cracks. In summary, condensate will not increase corrosion, and the gravity-influenced flow of any condensate under the drip shield will not

penetrate the waste package wall, thus limiting advective transport of radionuclides from the waste package. It is recognized that condensation can run down to the underside of the waste package, but this water would need to move against gravitational force, at that point, to enter the waste package. Consequently, condensation under the drip shield will not increase the net quantity of radionuclides exiting a waste package damaged by a seismic event, even were it to drip or condense on the WPOB.

Dripping of condensate is only possible if water droplets form near the top of the drip shield; otherwise they will flow down the underside of the drip shield. If drops contact the waste package, they will tend to evaporate because the waste package is warmer than the drip shield and the relative humidity at the waste package surface is lower, thus reducing the volume of condensate available for advective transport of radionuclides. As noted above, the most probable breaches are stress corrosion cracks. These cracks do not allow advective flow. By the time the waste package has degraded to allow general corrosion breaches, there are no drip shields present. In addition, in other cases (fault displacement and igneous intrusion) there is no drip shield that could be the location of condensation.

Effect of Condensation on Transport Outside the Waste Package – In *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 8.1), the gap between the waste package and the invert, which could inhibit diffusive transport of radionuclides, is ignored for transport purposes, and the waste package is assumed to contact the invert. Hence, the occurrence of condensate would have no effect on transport pathways from the waste package. Condensation under the drip shield could result in increased invert flux or saturation, potentially resulting in greater radionuclide transport through the invert. However, the effects of drift wall condensation on invert transport are accounted for in TSPA, and mass balance requirements ensure that any increased flux due to condensation under the drip shield is balanced by a corresponding decrease in drift wall condensation.

Based on the above discussion, omission of FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded form the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.08.15.0A

FEP NAME:

Consolidation of EBS Components

FEP DESCRIPTION:

Physical and chemical degradation of the drip shield, invert, waste form, and waste package may cause collapse and settlement within the repository. This consolidation may affect the development of the chemical environment and, therefore, the radionuclide transport out of the EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses the nonseismic-induced consolidation of EBS components due to physical and chemical degradation processes. Seismic-induced collapse and subsequent settling are considered in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components). Collapse and settlement of engineered barrier components as they weaken from continuous degradation processes such as corrosion have the potential to impact long-term repository performance. If the components are reduced to essentially granular form, the remnants of the engineered barrier could more readily interact with water in the drift and thereby alter the potential for chemical transport of radionuclides. Granular materials might better filter colloids and/or sorb dissolved radionuclides. Complete degradation of EBS components might also produce colloidal material. Chemical degradation of EBS components, however, tends to produce insoluble metal oxides and, other than to locally consume oxygen, to have minor impact on the chemistries of the fluids that contact them. The fact that degradation rates are low means that degradation impacts on fluid chemistry will be low as well. The net effect is that neglecting these secondary impacts of degradation of the EBS components (as opposed to degradation that opens up fluid pathways to and from the waste) will not affect dose.

Mechanical damage to the drip shield or waste package due to nonseismic rockfall or drift collapse has been excluded from the TSPA (see excluded FEPs 2.1.07.01.0A (Rockfall) and 2.1.07.02.0A (Drift Collapse)). Thus, EBS consolidation due to waste package or drip shield mechanical failure, or both, is excluded. The same conclusion holds for the invert. Degradation and consolidation of the invert are excluded from the TSPA, as documented in excluded FEPs 2.1.06.05.0B (Mechanical Degradation of Invert) and 2.1.06.05.0D (Chemical Degradation of Invert). Thus, EBS consolidation due to invert, waste package and/or drip shield failure is excluded from the TSPA.

The corrosion rates associated with the drip shield and waste package are very slow compared to the time-scale of interest, and these features will not collapse for at least 10,000 years. Analyses for the Alloy 22 WPOB demonstrate that general corrosion would lead to a loss of only

145 nm/yr of the wall thickness, or about 1.45 mm in 10,000 years (SNL 2007 [DIRS 178519], Section 8.1). Because the thickness of the WPOB is 25.4 mm (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-03), the corrosion lifetime of the WPOB will greatly exceed 10,000 years, and the corrosion impacts on ambient fluid chemistry will be minimal.

Analyses for the drip shield show that general corrosion would lead to loss of approximately 46 nm/yr of the wall thickness for the aggressive environment, or about 0.46 mm in 10,000 years (SNL 2007 [DIRS 180778], Table 6.5[a]). The nominal minimum thickness of the drip shield is 15 mm (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04). Thus, the corrosion lifetime of the drip shield is expected to exceed 100,000 years and the corrosion impacts on ambient fluid chemistry will be minimal.

Localized corrosion of the drip shield is not expected to occur under repository conditions as discussed in excluded FEPs 2.1.03.03.0B (Localized Corrosion of Drip Shields) and 2.1.09.28.0B (Localized corrosion on Drip Shield Surfaces due to Deliquescence), both of which are excluded on the basis of low consequence. Localized corrosion of the waste package is discussed in included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages). As discussed in that analysis, localized corrosion of the waste package requires the presence of an aqueous phase on the waste package surface. Possible sources of such liquid are dust deliquescence and seepage. Localized corrosion from dust deliquescence on the waste package surface is excluded from TSPA as discussed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence). Seepage water can contact the waste package only if the overlying drip shield has failed (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)). An analysis of the type of drip shield failure required to allow seepage to contact the waste package is presented in included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components), which addresses the effects of fault displacements on the EBS components.

Following waste package breach, in-package radionuclide transport is described in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3.4). Once the waste package is breached, the waste form inside will degrade, and consolidation of materials inside the waste package will eventually occur. This will ultimately result in some mixing of waste form and steel components and settling as the structural integrity of the package interior erodes. Consolidation of waste package internals is expected to lower net porosity and decrease the movement of water and radionuclides through the degraded waste form. Moreover, occlusion of reactive surface areas of the waste form by steel corrosion products would tend to lower releases of radionuclides by decreasing waste form degradation rates. For these reasons, excluding the consolidation of waste package internals will not overestimate predicted transport from the package.

Because collapse and extensive degradation of EBS components does not occur (except as seismically induced degradation processes described by other FEPs), any consolidation of these items will be minor.

Based on the previous discussion, omission of FEP 2.1.08.15.0A (Consolidation of EBS Components) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate

compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.01.0A

FEP NAME:

Chemical Characteristics of Water in Drifts

FEP DESCRIPTION:

When flow in the drifts is re-established following the peak thermal period, water may have chemical characteristics influenced by the near-field host rock and EBS. Specifically, the water chemistry (pH and dissolved species in the groundwater) may be affected by interactions with cementitious materials or steel used in the disposal region. These point source contaminated waters may coalesce to form a larger volume of contaminated water. This altered groundwater is referred to as the carrier plume because dissolution and transport will occur in this altered chemical environment as contaminants move through the EBS, and down into the unsaturated zone. (Note: there is no defining limit as to what volume of contaminated water constitutes a plume.)

SCREENING DECISION:

Included

TSPA DISPOSITION:

The composition of seepage water entering the drift is used in the suite of models developed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Sections 6.3 and 6.9), referred to as the P&CE report hereafter. The potential seepage water composition inputs for in-drift chemistry modeling were selected from the available pore-water analyses for the TSw and utilized in the near-field chemistry (NFC) model. The NFC model is developed in and provides feeds to the P&CE report (SNL 2007 [DIRS 177412], Section 6.3.2). The pore-water selection process is also documented in the P&CE report, as is an analysis of the interaction between seepage waters and the steels of the ground support and the invert (SNL 2007 [DIRS 177412], Sections 6.6 and 6.8). This analysis concluded that there is no significant effect of corroding steel on incoming groundwater owing to the precipitation of various Fe-Ni-Cr-bearing solid phases. Ground support interactions with water chemistry are also discussed in FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS), which is excluded on the basis of low consequence. In the event that additional materials are introduced in the subsurface, their impact on water chemistry will be evaluated (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 02-03).

The starting point for evaluating potential water compositions in the near field is the composition of ambient pore waters in the TSw. The available pore-water data from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and grouped into four compositional groups. This analysis is documented in the P&CE report (SNL 2007 [DIRS 177412], Section 6.6). Representative waters for the four groups were selected statistically, by choosing the sample closest to the centroid of the group. The representative waters and their compositions are listed in the P&CE report (SNL 2007 [DIRS 177412], Tables 4.1-2 and 4.1-3) and discussed in included FEP 2.2.08.12.0A (Chemistry of Water Flowing Into the Drift). Once the potential

seepage waters were selected, the NFC model evaluated the ambient feldspar dissolution rate, the dissolution rate temperature dependence, the model for the thermal field, and the plug flow model for transport through the TSw, and combined these to evaluate the amount of feldspar that dissolves as the water percolates downward through the unit to the repository. The result is WRIP that is the quantity of alkali feldspar to be added to the starting waters (SNL 2007 [DIRS 177412], Table 6.3-5). The WRIP value was calculated by taking as inputs the location-specific thermal field, and the percolation flux values (SNL 2007 [DIRS 177412], Section 6.3.2.4.3 and Table 6.3-1). Because the TSw is represented as a single unit with averaged rock properties and the feldspar dissolution rate is calculated from average alteration mineral abundances, the results of the WRIP calculation represent water–rock interaction over an average flow path through the unit.

To determine the range of potential seepage water compositions, the calculated amount of feldspar (WRIP) was titrated into the starting waters and brought to the drift wall temperature (SNL 2007 [DIRS 177412], Sections 6.3.2.4.2 and 6.3.2.7). To model the evaporative evolution of these seepage waters, the IDPS process model was applied (SNL 2007 [DIRS 177411]). To cover the expected range of environmental conditions, each seepage water was equilibrated with three temperatures (30°C, 70°C, and 100°C) and three pCO_2 values (10^{-2}, 10^{-3}, and 10^{-4} bar) and then evaporated to the eutectic mineral assemblage (SNL 2007 [DIRS 177412], Section 6.9). In addition, each starting seepage composition was diluted by a factor of 100 in order to account for dilution by condensation. It was determined that 11 discrete WRIP values were required to adequately represent the expected range of water–rock interactions. This resulted in the generation of 396 lookup tables (4 starting waters × 11 WRIP × 3 T × 3 pCO_2) that present the water chemistry data from combined dilution and evaporation simulations as a function of relative humidity (SNL 2007 [DIRS 177412], Section 6.9).

These lookup tables are used to account for uncertainty in incoming water compositions for performance assessment by randomly choosing one of the four starting waters and implementing the P&CE dilution/evaporation abstraction model according to the instructions provided by the P&CE report (SNL 2007 [DIRS 177412], Section 6.15) The predicted temperature and partial pressure of CO_2 in the drift is then used to determine the appropriate lookup table for that starting water, and the water composition is determined as a function of predicted relative humidity in the drift (SNL 2007 [DIRS 177412], Section 6.15).

Parameters extracted from the water chemistries archived in the lookup tables and used by the TSPA are pH, ionic strength, and Cl^- and NO_3^- concentrations as a function of in-drift relative humidity. The Cl^- and NO_3^- concentrations are taken as total [Cl] and total [N].

The potential effects of cementitious materials on water chemistry and repository hydrology are described in excluded FEPs 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) and 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near-Field). As discussed in these FEPs, leaching of cementitious materials used in the turnouts in the main access and exhaust drifts could modify the composition of seepage water from the surrounding rock immediately below the main turnoff intersection footprints. This will occur sufficiently far from emplacement drifts that repository performance will not be affected.

Chemical interactions with corrosion products in the drift are discussed in included FEP 2.1.09.02.0A (Chemical Interaction with Corrosion Products).

FEP: 2.1.09.01.0B

FEP NAME:

Chemical Characteristics of Water in Waste Package

FEP DESCRIPTION:

Chemical characteristics of the water in the waste packages (pH and dissolved species) may be affected by interactions with steel and other materials used in the waste packages or waste forms, as well as by the inflowing water from the drifts and near-field host rock. The in-package chemistry, in turn may influence dissolution and transport as contaminants move through the waste, EBS, and down into the unsaturated zone.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The chemical characteristics of water in the waste package are included in *In-Package Chemistry Abstraction* (IPC) (SNL 2007 [DIRS 180506]). *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]) develops a fully coupled reaction-path chemical model that includes the effects of waste form dissolution, metal alloy corrosion or dissolution, precipitation of metal oxide corrosion products, precipitation of complex mineral phases, reaction kinetics, interior waste package void space, oxidation–reduction reactions, heterogeneous chemical reactions, and seepage composition on the resulting fluid chemistry. The abstraction primarily provides the distributions of pH and ionic strength predicted to prevail in the inner portions (i.e., the waste form) of breached waste packages exposed to either incoming seepage or condensed fluids (SNL 2007 [DIRS 180506]). The chemistry of fluids outside of the waste form, in contact primarily with steel and corrosion products, is provided in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.5.2.4.6).

The variability in the initial chemistry of incoming water is included by using five different types of groundwaters at Yucca Mountain and three different groundwaters from basalt aquifers in sensitivity analyses (SNL 2007 [DIRS 180506], Section 6.6.2[a]). Sensitivity studies considered include these compositions, variations in seepage flux, and the corrosion rates of the steels that make up the waste package internals (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-07; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07). Uncertainty bands over pH and ionic strength were modified, as necessary, to incorporate results of sensitivity simulations that varied the incoming water composition and the degradation rates of the various materials in the waste form cells (SNL 2007 [DIRS 180506], Section 6.6[a]).

In-Package Chemistry Abstraction (SNL 2007 [DIRS 180506], Section 6.10[a]) produces abstractions (including uncertainty) of solution pH, ionic strength, fluoride ion concentration, and total carbonate concentration that set the ranges over which the dissolved concentrations model (SNL 2007 [DIRS 177418]) is used to evaluate radionuclide solubilities. Separate abstractions are developed for commercial SNF waste packages and codisposal waste packages.

EBS Radionuclide Transport Abstraction (SNL 2008 [DIRS 177407], Section 6.5.2.4.6) estimates pH in the outer portions of the waste form (the corrosion products domain). This calculation is done by numerically equilibrating a range of waste form effluents with corrosion products to parameterize pH as a function of ambient carbon dioxide levels and to estimate the distribution of radionuclides between colloids, stationary corrosion products, and the solution.

Chemical Interaction with Corrosion Products

FEP DESCRIPTION:

Corrosion products produced during degradation of the waste form, metallic portions of the waste package, and metals in the drift (i.e., rock bolts, steel in the invert, gantry rails) may affect the mobilization and transport of radionuclides. Corrosion products may facilitate sorption/desorption and co-precipitation/dissolution processes. Corrosion products may form a "rind" around the fuel that could (1) restrict the availability of water for dissolution of radionuclides or (2) inhibit advective or diffusive transport of water and radionuclides from the waste form to the EBS. Corrosion products also have the potential to retard the transport of radionuclides to the EBS. Finally, corrosion products may alter the local chemistry, possibly enhancing dissolution rates for specific waste forms, or altering radionuclide solubility.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consideration is first given to chemical interaction with corrosion products in the waste form and waste package, followed by a discussion of the chemical interaction with corrosion products in the drift.

The in-package chemistry model developed in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]) and the EBS radionuclide transport abstraction in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.5.2.4.6) address in-package corrosion products (including gases) and their effect on in-package chemistry. The corrosion products of the steel and aluminum alloys in the waste package and their control on the concentration of aqueous species are of primary importance in determining the pH and ionic strength of the solution. In this way, the presence of steel corrosion products constitutes an indirect control over radionuclide solubilities.

As described in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423]), fixed and suspended colloidal corrosion products are modeled in the waste package. Suspended colloidal corrosion products are modeled in the drift. Corrosion colloids are assumed to form and are subject to concentration and stability constraints controlled by the aqueous chemistry. The potential development of rinds on fuel and glass waste surfaces has been included in the development of waste form degradation models by incorporating laboratory data derived from fuel and glass waste corrosion experiments. Clogging of stress corrosion cracks by corrosion products is considered in excluded FEP 2.1.03.10.0A (Advection of Liquids and Solids through Cracks in the Waste Package).

Model implementation of the following phenomena related to colloids and steel corrosion in the waste package is described in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423]):

- Formation of iron oxyhydroxide colloids and fixed corrosion products in the waste package (Section 6.3.1)
- Estimation of stability and mass concentration of iron oxyhydroxide colloids from experimental results and calculated ionic strength and pH of in-package and in-drift fluids (Section 6.3.2.1)
- Irreversible sorption of plutonium and americium onto iron oxyhydroxide colloids and fixed corrosion products (Section 6.3.12.2)
- Reversible sorption of dissolved plutonium, americium, protactinium, thorium, and cesium onto iron oxyhydroxide colloids using developed K_d values and the estimated colloid mass concentrations (Section 6.3.12.1).

The effects of dissolved iron on the glass dissolution rates are addressed by using the results of tests in which iron products were added to the test solution (BSC 2004 [DIRS 169988], Appendix A) when determining model parameter values for pH dependence in acidic and alkaline solutions (BSC 2004 [DIRS 169988], Sections 6.5.2.4 and 6.5.2.5). The effects of glass alteration phases on the glass dissolution rate (k_E) are addressed by including the results of tests in which alteration phases and/or alteration product rinds form when determining model parameter values for k_E (BSC 2004 [DIRS 169988], Section 6.5.3.3).

The effects of corrosion product formation on in-drift water chemistry and gas composition are evaluated in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Sections 6.6 and 6.7, respectively). The report examines the effects of corrosion products and includes in-drift water chemistry and gas composition as part of the modeled chemical processes. In addition, the report accounts for corrosion in its oxygen mass balance analysis, where in-drift gas composition calculations are used to evaluate oxygen consumption due to corrosion of ground support materials and other committed materials (SNL 2007 [DIRS 177412], Section 6.7). In the physical and chemical environment model, water compositions abstracted from the thermal-hydrological-chemical seepage model are reacted with the Stainless Steel Type 316L ground support at the drift wall (SNL 2007 [DIRS 177412], Section 6.8). The general picture that emerges is that only under a limited range of early times can steel corrosion consume more oxygen than naturally advects into the drift. For this reason, it is reasonable to model the drift atmosphere as oxidizing.

The effect of corrosion products on the transport of radionuclides internal to the waste package is included in the TSPA model. However, no radionuclide sorption is modeled to occur on corrosion products in the invert. As discussed in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Sections 6.3.4.2, 6.5.1.2, and 6.5.2), retardation of radionuclides in the waste package corrosion products is modeled by application of sorption coefficients on corrosion products. Sorption of dissolved radionuclides on corrosion products is discussed in included FEP 2.1.09.05.0A (Sorption of Dissolved Radionuclides in EBS), and

implementation in the TSPA is explained in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3.4.2).

Corrosion products can form pseudocolloids as discussed in included FEP 2.1.09.17.0A (Formation of Pseudo-colloids (Corrosion Product) in EBS).

The primary uncertainties associated with corrosion product behavior are the degradation rates of the absolute masses of the steels and the surface areas of the corrosion products (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-07; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 04-07; SNL 2007 [DIRS 179466], Section 4.1.1). Uncertainties are quantified by considering a broad range of laboratory-measured degradation rates and surface areas and are propagated in the model by sampling over this range. The effects of corrosion products and their uncertainties on EBS chemistry, glass dissolution, and the transport of radionuclides internal to the waste package are included in the TSPA model through the previously discussed processes.

FEP: 2.1.09.03.0A

FEP NAME:

Volume Increase of Corrosion Products Impacts Cladding

FEP DESCRIPTION:

Corrosion products have a higher molar volume than the intact, uncorroded material. Increases in volume during waste form and cladding corrosion could change the stress state in the material being corroded and lead to cladding unzipping.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], it is considered that all commercial SNF cladding (stainless steel and Zircaloy) is breached on emplacement in the repository as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal) and in *Cladding Degradation Summary for LA* (SNL 2007 [DIRS 180616], Sections 6.2.1.2[a] and 7.2[a]). Furthermore, the zirconium-based (Zircaloy) and stainless steel SNF cladding is assumed to split instantly along the length of the fuel rods at the time of waste package failure. Cladding unzipping is assumed to result in immediate exposure of the commercial SNF fuel matrix to the failed waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). A waste package is considered to be failed at the time of the first penetration of the waste package by any process, including cracking, that allows ingress of oxygen and water vapor into the package.

Degradation of DOE SNF cladding (other than naval SNF cladding) is discussed in excluded FEP 2.1.02.25.0A (DSNF Cladding). As described in that FEP, the TSPA model considers that the DOE SNF cladding (with the exception of naval SNF cladding) will be breached upon emplacement in the repository and will neither inhibit groundwater contacting the DOE SNF matrix nor the release of radionuclides from the DOE SNF after groundwater contact.

Using this approach, commercial SNF and DOE SNF (other than naval SNF) cladding does not prevent the release or substantially reduce the release rate of radionuclides from the waste. Therefore, even if the volume increase associated with formation of corrosion products were to degrade the cladding, the additional impact of this FEP on cladding performance is of low consequence and will not affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment. FEP 2.1.09.03.0A (Volume Increase of Corrosion Products Impacts Cladding) can be excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319].

Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

FEP NAME:

Volume Increase of Corrosion Products Impacts Waste Package

FEP DESCRIPTION:

Corrosion products have a higher molar volume than the intact, uncorroded material. Increases in volume during waste form, cladding, and waste package corrosion could change the stress state in the material being corroded and lead to waste package damage.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

In general, corrosion products have greater volume than the parent metal as they are (typically) oxides (i.e., oxygen atoms are present in the corrosion products as well as parent metal atoms). When the corrosion products form in a tightly confined space, their increase in volume may generate swelling pressures that could lead to mechanical damage of the surrounding material. This FEP discusses the potential impact of corrosion products formed prior to and after breach of the waste package outer corrosion barrier. The discussion evaluates the possible mechanisms by which the waste package outer corrosion barrier could be breached. Cracks formed in the waste package outer corrosion barrier closure weld region and those due to seismic events are considered. Crack propagation rates are used to estimate the time required for cracks to penetrate the waste package outer corrosion barrier and aspects of crack morphology are discussed. Estimates of the time required to form significant amounts of corrosion products are determined and the characteristics of these corrosion products are summarized. Finally, the insignificant consequences of stresses resulting from corrosion product volume increase are discussed.

The waste package outer corrosion barrier will be fabricated from Alloy 22 (UNS N06022) with additional elemental and chemical composition restrictions (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-19, and Table 4-3). The inner vessel of the waste package is fabricated from Stainless Steel Type 316 (UNS S31600) (SNL 2007 [DIRS 179394], Table 4-3). For commercial SNF waste package types, a TAD canister will be placed inside the double-walled waste package. The TAD canister shall be constructed of 300-series stainless steel (such as UNS S31603, which may also be designated as Stainless Steel Type 316L) (SNL 2007 [DIRS 179394], Section 4.1.1.4). The codisposal waste packages containing HLW and DOE SNF will consist of an internal structure that cannot act as a viable structural component exerting stresses on the inner vessel.

Volume changes due to corrosion of components internal to the inner vessel or TAD canister (e.g., the internal structures within the commercial SNF packages or the canisters within the codisposal packages that contain HLW and DOE SNF) are of little concern as there is ample void space within the waste package to accommodate the expected change in volume due to

corrosion of these materials. The impacts of volume changes due to corrosion on cladding are addressed in excluded FEP 2.1.09.03.0A (Volume Increase of Corrosion Products Impacts Cladding). This FEP, therefore, considers the possible impacts of corrosion of the stainless steel inner vessel and the TAD canister. The current waste package design precludes the use of shrink fitting for the outer and inner cylinder components of the waste packages and requires the radial gap between the inner vessel and the outer corrosion barrier for the as-fabricated waste packages to be at least 1 mm and could be a maximum of 5 mm (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-04). The minimum radial gap between the TAD canister and the waste package inner vessel is 0.60 in. (15 mm) (SNL 2007 [DIRS 179394], Section 4.1.2.5). The waste package barrier longitudinal gap will be at least 30 mm (between the stainless steel inner vessel lid and the Alloy 22 waste package outer corrosion barrier lid) (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-05; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-05). The inner vessel for the TAD waste package configuration has an exterior length of 5,499.10 mm and has 50.8-mm-thick top and bottom lids (SNL 2007 [DIRS 179394], Table 4-3). Therefore, the interior length of the inner vessel for the TAD canister waste package configuration is 5,397.5 mm (5,499.10 mm – 2 × 50.8 mm). The exterior length of the TAD canister is 5,385.00 mm (SNL 2007 [DIRS 179394], Table 4-3). Therefore, the longitudinal gap between the TAD canister and waste package inner vessel for the TAD canister waste package configuration is 6.25 mm. As the radial gap between the waste package outer corrosion barrier and the waste package inner vessel is smaller than the axial gaps and the radial gap between the waste package inner vessel and TAD canister, the analyses in this FEP focus on the radial gap between the waste package outer corrosion barrier and the waste package inner vessel.

Prior to breach of the waste package outer corrosion barrier, only dry oxidation is possible. As discussed in excluded FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach), residual moisture in the waste packages could result in formation of a thin (on the order of 0.13 μm) corrosion product layer prior to breach of the waste package outer corrosion barrier. The impact of this thin corrosion product layer is not expected to lead to significant thermal expansion stresses in the waste package, as discussed in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components). Therefore, mechanical damage to the Alloy 22 waste package outer corrosion barrier or the waste package inner vessel (Stainless Steel Type 316) due to the pressure exerted by corrosion products (e.g., Cr_2O_3, NiO, and iron oxides) will not occur prior to breach of the waste package outer corrosion barrier.

In order for significant corrosion of the waste package outer corrosion barrier inner surface and the stainless steel inner vessel to occur, the waste package outer corrosion barrier must first be breached. In those cases where the breach is modeled as complete failure (e.g., by early failure processes, igneous intrusion, or localized corrosion), volume increase of corrosion products does not need to be accounted for. General corrosion, even under extreme exposure conditions (e.g., a constant exposure temperature of 150°C for 10,000 years), will not cause breach of the waste package outer corrosion barrier in the first 10,000 years after repository closure (SNL 2007 [DIRS 178519], Section 8.1). Consequently, stress generation from volume increase of corrosion products could only occur within the first 10,000 years after repository closure if the waste package outer corrosion barrier is penetrated by stress corrosion cracking resulting either from a seismic event or residual stresses in the waste package closure lid region as discussed in included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages).

The waste package outer lid closure weld region will be stress mitigated by plasticity burnishing, which will limit residual tensile stresses to below 90% of yield stress (the lower bound of the threshold stress for initiation of SCC) for a minimum depth of about 5 mm (SNL 2007 [DIRS 181953], Section 8.1.3 and Figure 6-48). In the absence of weld flaws or seismic activity, this mitigated layer must be removed by general corrosion before SCC can initiate on the waste package outer corrosion barrier. Using the median Alloy 22 general corrosion rate value (determined using the median temperature dependence) at 150°C of about 145 nm/yr (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*, worksheet: "MedU_MedC_Chart"), 5 mm of Alloy 22 would be removed in about 34,000 years. Using the median Alloy 22 general corrosion rate value (determined using the median temperature dependence) at 100°C of about 31 nm/yr (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*, worksheet: "MedU_MedC_Chart"), 5 mm of Alloy 22 would be removed in about 160,000 years. However, Alloy 22 general corrosion and SCC crack growth rates are uncertain, and may be fast enough to cause crack penetration within 10,000 years. The minimum and maximum SCC crack growth rates for Alloy 22 measured in aggressive brines relevant to the repository are 4.94×10^{-12} and 4.23×10^{-9} mm/s, respectively (SNL 2007 [DIRS 181953], Table 7-4). At these crack growth rates, it takes between approximately 150 and 130,000 years to penetrate the remaining 20 mm of the 25-mm-thick WPOB, assuming a constant crack growth rate as the cracks propagate. For seismic-induced residual stresses, the crack growth rate slows down (and may arrest) as the tensile stress and the stress intensity factor at the crack tip redistributes (decreases) during the crack propagation (SNL 2007 [DIRS 181953], Sections 6.7.1.2 and 7.5.1.2). The model-predicted mean crack propagation rate at a stress intensity factor of 40 MPa$\sqrt{m}$ is 1.00×10^{-9} mm/s (DTN: MO0705CREEPSCC.000 [DIRS 183681], file: *SDFRvData.xls*, worksheet: "Graphs1", cell F32), requiring approximately 630 years to penetrate the remaining 20 mm of the 25 mm thick WPOB. The model-predicted mean crack propagation rate at a stress intensity factor of 20 MPa$\sqrt{m}$ is about 4×10^{-11} mm/s (DTN: MO0705CREEPSCC.000 [DIRS 183681], file: *SDFRvData.xls*, worksheet: "Graphs1", cell F12), requiring approximately 16,000 years to penetrate the remaining 20 mm of the 25-mm-thick WPOB. In summary, in the absence of weld flaws or seismic activity, cracks are not expected to penetrate the waste package outer corrosion barrier within 10,000 years of closure.

Cracks originating from weld flaws that extend beyond the stress mitigated layer can propagate without any general corrosion of the mitigated layer. However, analyses estimate that about 16% of waste packages may have one or more weld flaws after ultrasonic inspection and repair (SNL 2007 [DIRS 178765], Table 6-6). These remaining weld flaws will be generally small (SNL 2007 [DIRS 178765], p. A-11, Figure "Marginal Pre to Post Repair Flaw Size"), with less than a one percent being longer than 5 mm (SNL 2007 [DIRS 178765], top of p. A-12). Also, as discussed previously, in the absence of seismic activity, for cracks to penetrate the waste package outer corrosion barrier within 10,000 years of closure, the waste package must have an unfavorable combination of several parameters (e.g., a stress and stress intensity factor profile and crack growth rate).

Cracks due to seismic activity are considered in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.5), which analyzes several degraded waste package states, the most intact of which has a waste package outer corrosion barrier thinned to 23 mm from its initial thickness of about 25 mm. A seismic event with a mean annual exceedance value of 4.3×10^{-4}/yr

or greater is needed to possibly cause damage to a waste package resulting in SCC. For earlier times, prior to the waste package thinning to 23 mm; therefore, a seismic event of greater magnitude would be required to cause damage to a waste package. Damage from a 4.3×10^{-4}/yr mean annual exceedance value seismic event has only a small probability of occurrence on a codisposal waste package (0.029 using the lower bound 90% of yield strength stress threshold) (SNL 2007 [DIRS 176828], Table 6-16) and zero probability for a TAD canister-containing waste package (SNL 2007 [DIRS 176828], Table 6-4). The probability of damage occurring on a codisposal waste package from a 4.3×10^{-4}/yr mean annual exceedance value seismic event using a stress threshold of 100% of the yield strength is zero (SNL 2007 [DIRS 176828], Table 6-16). Thus, for a codisposal waste package, a bounding overall probability of damage per year is about 1.2×10^{-5}/yr ($0.029 \times 4.3 \times 10^{-4}$/yr). In order for seismic activity to result in crack penetrations on the waste package outer corrosion barrier within 10,000 years of closure, a seismic event with a mean annual exceedance probability of 4.3×10^{-4}/yr or lower (particularly for a TAD canister-containing waste package) would have to occur.

The seismic damage model determines an area damaged by seismic activity and considers this damaged area to have a network of crack penetrations. In the seismic damage model: (1) cracks are considered to be arranged in a tight hexagonal array, (2) cracks instantly propagate through the waste package outer corrosion barrier, independent of local stress gradients, (3) the area of the crack opening is maximized, based on a stress difference given by the yield stress, (4) the crack opening is constant throughout the waste package outer corrosion barrier thickness, and (5) there is no stress relief when a crack forms, even though there is no internal pressure to drive the cracks through the waste package outer corrosion barrier (SNL 2007 [DIRS 176828], Section 6.1.4). These conservatisms are discussed further in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.7). In regard to point (1), it has been determined that the minimum distance between through-wall cracks is the thickness of the component. This value is used in determining the density of the network of crack penetrations due to seismic activity. The same minimum crack distance is used to characterize the density of cracks resulting from residual stresses in the waste package outer corrosion barrier closure weld region (i.e., cracks not resulting from seismic activity). The crack density will be lower than is represented by the seismic damage model or the stress corrosion cracking models used to evaluate repository performance. In regard to point (2), as discussed above in relation to crack growth in the waste package outer corrosion barrier closure weld region, there may be a significant period of time before crack penetration occurs. In regard to points (3), (4), and (5), as discussed above, crack growth and penetration will decrease the residual stress state. Because the crack opening area is determined by the magnitude of the residual stress and the yield stress is conservatively used for this value, the crack opening area determined is conservative.

As discussed in excluded FEP 2.1.03.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package), stress corrosion cracks in passive alloys such as Alloy 22 tend to be tight (i.e., small crack-opening displacement) and tortuous, often with many branches. SCC is a corrosion process that requires the presence of water to support crack propagation. The SCC process will result in accumulation of corrosion products and mineral precipitates in the limited crack volume. The tight and tortuous SCC cracks in the WPOB are expected to be continuously filled with tightly compact cemented agglomerates of solid corrosion products and mineral

precipitates as the cracks grow through the wall thickness. These agglomerates will limit water transport through these cracks. However, analyses documented in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.6.2) indicate that there is sufficient water vapor transport through stress corrosion cracks so as not to limit corrosion reactions on the stainless steel waste package inner vessel. For waste packages exposed to seepage, it was estimated that crack plugging could require anywhere from hundreds to thousands of years. In the absence of seepage, crack plugging could take longer times.

When SCC occurs, no corrosion performance credit is taken for the waste package inner vessel and TAD canisters. Once the waste package outer corrosion barrier is breached by SCC, these components are treated as degraded material with minimal strength and cohesion. This is a reasonable treatment because the waste package inner vessel and TAD canisters are not stress relief annealed rendering them susceptible to stress corrosion cracking, and the corrosion rates of these stainless steel components are expected to be greater than the Alloy 22 waste package outer corrosion barrier. Thus, it is expected that the stainless steel waste package inner vessel and TAD canister will not function as effective mechanical components after breach of the waste package outer corrosion barrier. This is consistent with the treatment in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.1.3.2).

Once the waste package outer corrosion barrier is breached by SCC, a significant amount of time is required before the radial gap between the waste package outer corrosion barrier and inner vessel can become filled with corrosion products. As the Alloy 22 waste package outer corrosion barrier and Stainless Steel Type 316 inner vessel corrode, the radial gap between the remaining uncorroded metal, $gap(t)$, is increased by the removal of metal by the corrosion process. However, the overall radial gap is decreased by the formation of corrosion products. The radial gap between the remaining uncorroded metal as a function of time is:

$$gap(t) = igap + \left(CRA22 + CR316\right) t \qquad \text{(Eq. 2.1.09.03.0B-1)}$$

where t is exposure time in years, $igap$ is the initial radial gap (1 mm to 5 mm, as discussed above), $CRA22$ is the Alloy 22 corrosion rate and $CR316$ is the Stainless Steel Type 316 corrosion rate. The decrease in the radial gap from the formation of corrosion products is given by:

$$c(t) = \left(CRA22 + CR316\right) \sqrt[n]{PB}\, t \qquad \text{(Eq. 2.1.09.03.0B-2)}$$

where PB refers to the Pilling-Bedworth volume ratio (i.e., the volume ratio of the metal to its corrosion product) (ASM International 1987 [DIRS 133378], p. 65). The Pilling-Bedworth ratio for Cr_2O_3 is 2.02, that for NiO is 1.70, and that for Fe_3O_4 is 2.10 (ASM International 1987 [DIRS 133378], p. 64, Table 2). Thus, given that the aforementioned oxides are possible corrosion products of Alloy 22 and Stainless Steel Type 316, a reasonable choice for PB would be 2.10. The factor n is included in Equation 2.1.09.03.0B-2 to account for the degree of constraint on the corrosion products formed. If the corrosion product is constrained in all directions except for the radial direction, then all of the corrosion product volume expansion would result in a decrease in the radial gap and $n = 1$. If the corrosion product is unconstrained then $n = 3$. A realistic choice might be $n = 2$. Setting the right-hand sides of Equations 2.1.09.03.0B-1 and 2.1.09.03.0B-2 equal to each other and solving for time, yields the time

required to fill the radial gap between the Alloy 22 waste package outer corrosion barrier and Stainless Steel Type 316 inner vessel, t_{fill}.

$$t_{fill} = \frac{igap}{CRA22\left(\sqrt[n]{PB}-1\right)+CR316\left(\sqrt[n]{PB}-1\right)} \qquad \text{(Eq. 2.1.09.03.0B-3)}$$

The median Alloy 22 general corrosion rate value (determined using the median temperature dependence) at 150°C is about 145 nm/yr (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*) and decreases to 31 nm/yr at an exposure temperature of 100°C (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*). According to *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Section 6.3.4.3.4.3) the corrosion rate of Stainless Steel Type 316 is given by a truncated normal distribution (between 0.01 and 0.51 μm/yr) with a true mean of 0.267 μm/yr (DTN: SN0703PAEBSRTA.001 [DIRS 183217], file: *Bayesian Updating Short Term Fresh Water Corrosion Rate - 3-6-2007.xls*, worksheet: "A316 SS Short Term Fresh Water"). Using the parameter values discussed earlier, values of t_{fill} can be evaluated for various choices of input values as shown in Table 2.1.09.03.03.0B-1.

Table 2.1.09.03.0B-1. Parameter Values Used to Calculate t_{fill}

			igap = 1 mm	igap = 3 mm	igap = 5 mm
CRA22 nm/yr	CR316 nm/yr	n	t_{fill} yr	t_{fill} yr	t_{fill} yr
145	510	1	1,388	4,164	6,940
31	510	1	1,680	5,041	8,402
145	510	2	3,399	10,198	16,996
31	510	2	4,116	12,347	20,578
145	267	1	2,207	6,620	11,033
31	267	1	3,051	9,152	15,253
145	267	2	5,404	16,212	27,020
31	267	2	7,471	22,414	37,357

As can be seen from Table 2.1.09.03.03.0B-1, exposure times between about 1,400 and 37,000 years are required to fill the radial gap between the Alloy 22 waste package outer corrosion barrier and Stainless Steel Type 316 inner vessel with corrosion products depending on the values of *CRA22, CR316, n,* and *igap*. These fill times would be required in addition to the crack penetration times discussed previously before the volume increase of corrosion products could have any mechanical impact on the waste package outer corrosion barrier.

It would be expected that corrosion products under compressive stress would have a lower effective porosity than corrosion products that are not under compressive stress, and would be expected to limit water ingress and radionuclide egress from the waste package. The adherent stainless steel and Alloy 22 corrosion products are responsible for their passive behavior. Corrosion products of less corrosion resistant materials such as carbon steel have been found to be protective for periods of thousands of years. As discussed by Miller et al. (1994 [DIRS 126089], pp. 114 to 119), a hoard of over one million nails were buried in a five meter deep pit and then covered with compacted earth around 87 A.D. Nails in the outer regions of the

hoard, unearthed in the 1950s, were found to have undergone extensive corrosion presumably forming a low permeability solid crust of corrosion products resulting in minimal corrosion attack of nails in the hoard interior. Similar processes could significantly decrease the corrosion rates of the materials internal to the waste package outer corrosion barrier as well as decreasing the rate of diffusive radionuclide transport out of breached waste packages. Taking no credit for this process in performance assessment may be conservative.

Even if the gap between the waste package outer corrosion barrier and waste package inner vessel were to become filled with corrosion products, significant impacts to degradation of the waste package outer corrosion barrier and the rate of radionuclide release are not expected. As mentioned previously, once the waste package corrosion outer barrier is breached, the waste package inner vessel and TAD canisters are degraded materials with reduced strength. If the corrosion products formed could apply stress on the waste package outer corrosion barrier, stress would then also be applied to the degraded waste package inner vessel. It is expected that these stresses would result in enhanced degradation of the already degraded waste package inner vessel (e.g., more stress corrosion cracking than would occur in the absence of the corrosion products). This would lead to the already degraded waste package inner vessel failing to act as an effective mechanical substrate from which the corrosion products could exert stresses on the waste package outer corrosion barrier. Significant degradation of the waste package inner vessel would then allow the corrosion products to expand into the internal void volume of the waste package instead of exerting significant stress on the waste package outer corrosion barrier.

Even if the corrosion products exert pressure on the waste package outer corrosion barrier, the modeled releases from stress corrosion cracking would not be increased, because as mentioned previously, the stress corrosion crack opening area used to evaluate repository performance is maximized in that the highest crack density is used and the cracks are considered to be held open by a residual stress equal to the yield stress. Thus, if some amount of actual crack widening occurred on the Alloy 22 waste package outer corrosion barrier surface resulting from stresses induced by corrosion product formation, it has been sufficiently accounted for in performance evaluations through the use of a maximized stress corrosion crack opening area (SNL 2007 [DIRS 176828], Section 6.1.4; SNL 2007 [DIRS 181953], Section 6.7) and by taking no credit for the decreased rate of radionuclide transport through compressed corrosion products in the cracks.

Related excluded FEP 2.1.09.03.0A (Volume Increase of Corrosion Products Impacts Cladding) discusses volume increase of corrosion products that could impact cladding.

Based on the previous discussion, omission of FEP 2.1.09.03.0B (Volume Increase of Corrosion Products Impacts Waste Package) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.03.0C

FEP NAME:

Volume Increase of Corrosion Products Impacts other EBS Components

FEP DESCRIPTION:

Corrosion products have a higher molar volume than the intact, uncorroded material. This FEP addresses volume increase in all EBS components other than waste package, waste form, and cladding. Increases in volume during corrosion of steel in the invert may change the stress state or structural integrity of the invert.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The effects of volume increase caused by corrosion of steel in the invert is excluded on the basis of low consequence, in accordance with proposed 10 CFR 63.342 (70 FR 53313 [DIRS 178394]). This FEP represents one mechanism by which corrosion might cause mechanical failure of the invert. Mechanical degradation of the invert is addressed under FEP 2.1.06.05.0B (Mechanical Degradation of Invert), which is excluded on the basis of low consequence. Corrosion product impacts on cladding, waste form, and waste packages are discussed in excluded FEPs 2.1.09.03.0A (Volume Increase of Corrosion Products Impacts Cladding) and 2.1.09.03.0B (Volume Increase of Corrosion Products Impacts Waste Package).

The bulk of EBS materials degrade slowly and with only minor volume changes. Carbon steel is the notable exception. As discussed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.5.2, Figure 6.5-3), the carbon steel components in the invert are predicted to corrode relatively rapidly (i.e., within a few hundred years) as compared to other in-drift committed materials. Moreover, it corrodes to iron oxide and hydroxides whose molar volume is larger than the original steel.

The ability of carbon steel mechanical supports, which comprise the invert substructure, to induce mechanical loads by volume expansion will not be large. As the steel invert structural components degrade, their total volume, including the corrosion products, will increase; however, as the volume of these materials increases, it can expand vertically without resistance into the drift, and thus, will create no increase in stresses in the support system. Any volume expansion in the invert of the drip shield due to corrosion will impose no added stress because the drip shield is not rigidly mounted to the invert and would move as a rigid body into the drift (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-01). Configuration of the invert steel structure is shown in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 02-08 and 02-10).

Corrosion of steel rock bolts, plates, and Bernold sheets would result in the formation of corrosion products in the ground support system and possibly local buckling in the latter. This would not affect performance as no credit is taken for postclosure performance of the ground support system.

Based on the previous discussion, omission of FEP 2.1.09.03.0C (Volume Increase of Corrosion Products Impacts Other EBS Components) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.04.0A

FEP NAME:

Radionuclide Solubility, Solubility Limits, and Speciation in the Waste Form and EBS

FEP DESCRIPTION:

Degradation of the waste form will mobilize radionuclides in the aqueous phase. Factors to be considered in this FEP include the initial radionuclide inventory, justification of the limited inventory included in evaluations of aqueous concentrations, and the solubility limits for those radionuclides.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Dissolved Concentration Limits of Elements with Radioactive Isotopes (SNL 2007 [DIRS 177418]) develops thermodynamic models for quantifying speciation, and estimating dissolved concentration limits of radionuclides, in the package and invert. TSPA uses these models to estimate maximal levels of sparingly soluble actinides over time. An initial assessment of radionuclide inventories is made to identify those radioelements that will be present in the repository and are expected to contribute to dose (SNL 2007 [DIRS 177424]). The speciation of, and solubility limits for, plutonium, neptunium, uranium, thorium, americium, protactinium, and tin are then calculated and tabulated as functions of pH and $\log f\mathrm{CO}_2$.

The primary uncertainties in calculated solubilities are temperature, fluoride levels, and the identity of the solubility-controlling phase(s). There are also uncertainties inherent in the thermodynamic functions describing the solubility of a given phase. Temperature and oxygen fugacity were conservatively bounded by using 25°C and 20% O_2 levels. Similarly, higher solubility phases were used to bound dissolved concentrations. A range of fluoride levels was used in the calculations. Lastly, uncertainties in thermodynamic data were accounted for by using a range of values.

For very soluble elements, solubility limits are not determined. Instead, their releases are considered to be controlled by the dissolution rate of waste forms and the waste inventory. Elements in this category are technetium, carbon, iodine, cesium, strontium, selenium, and chlorine. In part, because of the relatively short half-lives of ^{227}Ac and ^{210}Pb, solubility limits of actinium and lead were not investigated in the dissolved concentrations report. Instead their levels are conservatively set in TSPA to be in secular equilibrium with their parent isotopes.

FEP: 2.1.09.05.0A

FEP NAME:

Sorption of Dissolved Radionuclides in EBS

FEP DESCRIPTION:

Sorption of dissolved radionuclides within the waste package may affect the aqueous concentrations of radionuclides released to the EBS.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Sorption of dissolved radionuclides in the EBS is an important component of the radionuclide transport abstraction model. Sorption parameters (sorption coefficients and distribution coefficients) appropriate for sorption onto corrosion products inside the waste package, onto colloids, and onto crushed tuff in the invert are developed or summarized in *EBS Radionuclide Transport Abstraction* (SNL 2008 [DIRS 177407], Sections 6.3.4.2 and 6.5.2.4). The sorption coefficients are uncertain parameters that are sampled in the TSPA. The radionuclide transport abstraction model, including sorption of dissolved radionuclides, is implemented directly in the TSPA, and thus has a direct impact on estimated releases of radionuclides from the EBS.

The radionuclide transport abstraction model is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface.

EBS Radionuclide Transport Abstraction (SNL 2008 [DIRS 177407], Sections 6.3.4.2 and 6.5.2.4) describes the model for sorption of radionuclides on the stationary corrosion products and iron oxyhydroxide colloids:

1. Both equilibrium and kinetic sorption-desorption processes are modeled.

2. Competition for a finite number of sorption sites among various species whose concentration varies as a function of pH and pCO_2 is considered. The elements considered for competitive sorption calculations are uranium, neptunium, plutonium, americium, thorium, and nickel. The competitive sorption calculations are done using single-site surface complexation reactions in PHREEQC V. 2.11 (STN: 10068-2.11-00 [DIRS 175698]).

3. Desorption reactions are implemented to account for desorption from stationary corrosion products.

4. For modeling radionuclide transport through the EBS, equilibrium sorption is modeled for uranium, neptunium, and thorium, while the kinetic sorption-desorption is applied to

plutonium and americium, because they also get transported while irreversibly sorbed onto iron oxyhydroxide colloids.

The conceptual model for flow through the EBS includes three domains: the waste form (e.g., fuel rods or defense HLW glass; this domain includes a small amount of corrosion products from steel components closely associated with the waste form, such as fuel basket tubes and glass pour canisters), waste package steel corrosion products, and the invert (SNL 2008 [DIRS 177407], Section 6.3.1.1). Because the presence of the emplacement pallet is not credited with any barrier capability, water and radionuclides pass directly from the waste package to the invert.

The sorption processes are implemented only in the corrosion products domain of the EBS transport model (SNL 2008 [DIRS 177407], Sections 6.3.4.2 and 6.5.2.4), where the majority of the corrosion products from degradation of steel components inside the waste package are expected to be present. The corrosion products from the degradation of steel are expected to be a mixture of goethite, ferrihydrite (referred to as hydrous ferric oxide), chromium oxide, and nickel oxide, among others. Radionuclide sorption is modeled only on the fraction of corrosion products that are represented by the goethite and ferrihydrite mineralogy. This approach is justified because the surface complexation constants on iron oxyhydroxide surfaces are known with a great degree of confidence and are bounding with respect to the other corrosion products.

The basic inputs to the radionuclide transport abstraction model consist of the drift seepage influx, the environmental conditions in the drift (temperature, relative humidity, and water chemistry) (SNL 2008 [DIRS 177407], Section 6.1), and the degradation state of the EBS components. Outputs consist of the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The radionuclide transport abstraction model is implemented directly into the TSPA to compute the radionuclide release rates from the EBS.

FEP: 2.1.09.06.0A

FEP NAME:

Reduction-Oxidation Potential in Waste Package

FEP DESCRIPTION:

The redox potential in the waste package influences the oxidation of waste-form materials and the in-package solubility of radionuclide species. Local variations in the in-package redox potential can occur.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Oxidation of the metal waste package components is the primary process by which the waste packages corrode and the redox state of in-package water is potentially altered. The oxidation–reduction processes inside of the waste package are explicitly modeled in the in-package chemistry model and, thus, included in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]). Waters entering the package and conditions inside the package are modeled to be uniformly oxidizing.

Also, the dissolved concentration model developed in *Dissolved Concentration Limits of Elements with Radioactive Isotopes* (SNL 2007 [DIRS 177418], Appendix V) examines redox potential as it pertains to repository conditions, and develops an adjusted-Eh model based on experimental data and natural analog information. This adjusted-Eh model is used only for the plutonium solubility calculation and accounts for the fact that solutions containing this actinide, in contact with air, are not expected to attain full equilibrium with atmospheric oxygen.

An oxidizing redox potential inside the waste package and its effect on in-package chemistry is included in the abstractions passed to the TSPA as part of *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]). Adjusted solubility lookup tables, which account for redox potential, are provided by *Dissolved Concentration Limits of Elements with Radioactive Isotopes* (SNL 2007 [DIRS 177418]) to the TSPA.

FEP NAME:

Reduction-Oxidation Potential in Drifts

FEP DESCRIPTION:

The redox potential in the EBS influences the oxidation of the in-drift materials and the in-drift solubility of radionuclide species. Local variations in the in-drift redox potential can occur.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Engineered Barrier System: Physical and Chemical Environment (SNL 2007 [DIRS 177412], Section 6.7) evaluates the reduction-oxidation (redox) potential in the EBS drifts as part of the modeled chemical processes. The report accounts for redox potential in its oxygen mass balance analysis (SNL 2007 [DIRS 177412], Section 6.7). Specifically, in-drift gas composition calculations evaluated oxygen composition due to corrosion of ground support materials and other committed materials. The estimate of oxygen flux begins with calculating the gas flux across the drift wall and into the drift (SNL 2007 [DIRS 177412], Section 6.7.1). Oxygen fugacities may drop to as low as 10^{-9} bar for a brief period of time, but they recover rapidly exceeding 10^{-2} bars after approximately 3,000 years and approach ambient values before 10,000 years (SNL 2007 [DIRS 177412], Figure 6.7-5). When the analysis considered the retardation of oxygen consumption by the formation of a corrosion layer, the fO_2 values do not fall below approximately 10^{-6} bar and return to ambient before 1,000 years (SNL 2007 [DIRS 177412], Figure 6.7-6 and Section 6.7.1.7). The analysis concludes that oxidizing conditions, relative to important redox couples such as goethite/magnetite and nitrate/nitrite (SNL 2007 [DIRS 177412], Section 6.7.1.6) will persist in the in-drift environment. Thus, the effects of redox reactions are included in the inputs provided to the TSPA.

The lower fO_2 conditions produced by the corrosion of materials in the EBS would be confined to a limited time during the thermal pulse (i.e., for a few thousand years) as shown in the P&CE report (SNL 2007 [DIRS 177412], Section 6.7.1.5 and Figures 6.7-5 and 6.7-6), which presents the fO_2 time histories. The potential for reducing conditions to occur in the drift is also examined and dismissed in *In-Drift Precipitates/Salts Model* (IDPS) (SNL 2007 [DIRS 177411], Section 4.1.2). The IDPS model is only validated for oxidizing conditions and all evaporation simulations are set for atmospheric conditions (SNL 2007 [DIRS 177411], Section 6.6.2). Oxidizing conditions prevail, with respect to the examined redox couples, for equilibrium fugacity of oxygen of 10^{-9} bars (SNL 2007 [DIRS 177411], Section 4.1.2). The IDPS model lookup table output includes boundary values, abstraction output, and supplemental calculations (SNL 2007 [DIRS 177411], Section 6.6.3.5). Boundary values include temperature, the fugacities of carbon dioxide and oxygen, and the reaction progress.

FEP NAME:

Reaction Kinetics in Waste Package

FEP DESCRIPTION:

Chemical reactions, such as radionuclide dissolution/ precipitation reactions and reactions controlling the reduction-oxidation state, may not be at equilibrium within the waste package.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Dissolution kinetics is included in the TSPA in-package chemistry model abstraction. The in-package chemistry model uses kinetic expressions—linear or transition state theory rate laws—to describe SNF degradation, defense HLW glass degradation, and steel degradation (SNL 2007 [DIRS 180506], Section 4.1.3[a]).

Kinetics are also taken into account in both the in-package chemistry model (SNL 2007 [DIRS 180506]) and the dissolved concentrations model (SNL 2007 [DIRS 177418]) when secondary phases that are kinetically inhibited from forming under repository conditions are suppressed in the calculations. The in-package chemistry model generally allows precipitation and/or corrosion reactions of non-kinetically inhibited reactions to reach thermodynamic equilibrium. The adjusted Eh model takes account of kinetic controls over plutonium speciation (SNL 2007 [DIRS 177418], Section 6.5.3). With these two exceptions, all other reactions are assumed to maintain equilibrium in an oxidized environment (SNL 2007 [DIRS 180506]).

FEP NAME:

Reaction Kinetics in Drifts

FEP DESCRIPTION:

Chemical reactions, such as radionuclide dissolution/precipitation reactions and reactions controlling the reduction-oxidation state, may not be at equilibrium in the drifts.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The effects of reaction kinetics are included in each geochemical submodel developed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Sections 6.2.3, 6.2.4, and 6.2.5), which takes its mineral suppressions from *In-Drift Precipitates/Salts Model* (IDPS) (SNL 2007 [DIRS 177411]). In particular, the IDPS model, which uses an EQ3/6 reaction path model to simulate evaporation of potential seepage waters, takes account of reaction kinetics when it suppresses individual mineral phases (SNL 2007 [DIRS 177412], Section 6.2.4.1 and Table 6.2-2).

Individual mineral phases were suppressed if those phases are kinetically inhibited from forming under repository conditions. A list of minerals inhibited during the modeling, including justification for the decision to suppress each mineral, is presented in Section 6.2.4.1 and Table 6.2-2 of the P&CE report (SNL 2007 [DIRS 177412]). The choice of mineral suppressions directly affects the modeled evolution of the in-drift waters, and hence the water compositions that are used by TSPA.

In addition, the kinetics of corrosion of steel in the drift was examined with respect to its effect on in-drift water and atmosphere compositions. Seepage water interactions with Stainless Steel Type 316L ground support components and low alloy invert steels were found to be of low consequence (SNL 2007 [DIRS 177412], Sections 6.7 and 6.8). A sensitivity analysis shows that increasing corrosion rates parametrically has no significant effect on in-drift water and atmospheric compositions (SNL 2007 [DIRS 177412], Sections 6.7 and 6.8). Oxygen consumption due to corrosion of ground support materials and other committed materials is evaluated using in-drift gas composition calculations that consider two different drift spacings (SNL 2007 [DIRS 177412], Section 6.7). A sensitivity study of in-drift oxygen fugacity showed that corrosion of invert steel will decrease oxygen fugacity, but as a transient phenomenon, and with insufficient magnitude to qualitatively change any important chemical reactions in the EBS (SNL 2007 [DIRS 177412], Section 6.7.1). Long-term conditions are expected to be oxidizing. Because of this, IDPS model calculations are done assuming atmospheric levels of oxygen and reduced phases (e.g., sulfides) are suppressed accordingly.

As stated above, the effects of reaction kinetics are implicitly included in the geochemical submodels developed in the P&CE report (SNL 2007 [DIRS 177412], Sections 6.2.3, 6.2.4, and 6.2.5) through the selection of mineral species allowed to form. Thus, the effects are propagated to the chemical composition data tables used by the TSPA. Reduction-oxidation potential in the drift is discussed in included FEP 2.1.09.06.0B (Reduction-oxidation Potential in the Drifts).

Radionuclide precipitation/dissolution kinetics are expected to happen rapidly and maintain equilibrium with in-drift fluids. The kinetics of sorption/desorption of americium and plutonium on colloids and corrosion products are included in the TSPA (SNL 2008 [DIRS 177407], Section 6.5.2.7). Uncertainty in sorption is considered by using a range of model input fluid chemistries and substrate abundance and area.

FEP NAME:

Diffusion of Dissolved Radionuclides in EBS

FEP DESCRIPTION:

Radionuclide transport of dissolved radionuclides by diffusion, in response to chemical gradients, may occur within the EBS. Physical and chemical properties of the EBS and waste form, in both intact and degraded states, should be considered in evaluating diffusive transport.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The model developed in *EBS Radionuclide Transport Abstraction* (RTA) (SNL 2007 [DIRS 177407], Section 6.3.4) is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, and water chemistry), and the degradation state of the EBS components (SNL 2007 [DIRS 177407], Section 6.1). Outputs from the RTA model are used in the TSPA to calculate the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The RTA model is implemented directly into the TSPA GoldSim model to compute the radionuclide release rates from the EBS. This FEP addresses diffusion of dissolved species in the EBS. Included FEP 2.1.09.24.0A (Diffusion of Colloids in EBS) addresses diffusion of colloids in the EBS. Advective transport of dissolved radionuclides is addressed in included FEP 2.1.09.08.0B (Advection of Dissolved Radionuclides in EBS).

The conceptual model for flow through the EBS includes three domains: the waste form (e.g., fuel rods or defense HLW glass; included in this domain is a small amount of corrosion products from steel components closely associated with the waste form, such as fuel basket tubes and glass pour canisters), waste package steel corrosion products, and the invert. The EBS domains are defined in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.1.1). Because the presence of the emplacement pallet is not represented in TSPA for the purposes of estimating radionuclide transport path length, radionuclides pass directly from the waste package to the invert.

The source of inflow into the EBS is the seepage flux that drips from the crown (roof) of the drift, drift wall condensation, and imbibition flux from the unsaturated zone into the invert. This inflow can flow through the EBS along eight pathways: (1) seepage flux plus any drift wall condensation that may occur, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from

the waste package and drip shield into the invert, (7) imbibition flux from the drift host rock to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2007 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). These pathways are time dependent, because drip shield and waste package penetrations will vary with time and local conditions in the repository.

Diffusive transport of dissolved radionuclides in the EBS is a major component of the RTA model. The effects of saturation, temperature, porosity, and chemical potential gradient in the invert are discussed in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.4.1). The effects of waste form properties and degradation state on diffusion in the waste package are modeled; diffusion from the waste form is dependent on the volume, effective surface area, and thickness of the "rind" of degraded waste form (SNL 2007 [DIRS 177407], Section 6.3.4.6), and the amount of corrosion products in the waste package determines both their saturation (and consequently, the diffusivity) (SNL 2007 [DIRS 177407], Section 6.3.4.3) and their sorptive capacity (SNL 2007 [DIRS 177407], Section 6.3.4.2.3). Note that the model of the commercial SNF waste form used in the abstraction model does not account for the cladding, consistent with the approach in the TSPA in which no credit is taken for the cladding.

The free water diffusion coefficient for each radionuclide species in water is used for all concentrations of radionuclides at a given temperature (DTN: LB0702PAUZMTDF.001 [DIRS 180776]). The diffusion coefficients for the corrosion products and waste form domains are modified for temperature, as is the invert diffusion coefficient (SNL 2007 [DIRS 177407], Section 6.3.4.1.2). Modification for the effect of concentrated aqueous solutions is not addressed in the TSPA (SNL 2007 [DIRS 177407], Section 6.3.4.1.3).

Uncertainty in diffusive transport is addressed by developing probability distribution functions that describe uncertainty, and then sampling from these probability distribution functions in implementing the RTA model in the performance assessment calculations. The following parameters are treated this way: invert diffusion coefficient uncertainty (SNL 2007 [DIRS 177407], Section 6.3.4.1.1), stainless steel and carbon steel corrosion rates (SNL 2007 [DIRS 177407], Section 6.3.4.3.4.3), water vapor adsorption isotherms for corrosion products (SNL 2007 [DIRS 177407], Sections 6.3.4.3.2), waste form rind (SNL 2007 [DIRS 177407], Section 6.3.4.6.1), density and porosity of commercial SNF rind materials (SNL 2007 [DIRS 177407], Section 6.3.4.6.1), and the specific surface area of corrosion products (SNL 2007 [DIRS 177407], Section 6.3.4.3.3).

TSPA DISPOSITION:

The model developed in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.4) is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, and water chemistry), and the degradation state of the EBS components (SNL 2007 [DIRS 177407], Section 6.1). Outputs from the RTA are used in the TSPA to calculate the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The RTA model is implemented directly into the TSPA GoldSim model to compute the radionuclide release rates from the EBS. This FEP addresses advection of dissolved species in the EBS. Included FEP 2.1.09.19.0B (Advection of Colloids in EBS) addresses advection of colloids in the EBS.

The source of inflow to the EBS is the seepage flux that drips from the crown (roof) of the drift, drift wall condensation, and imbibition flux from the unsaturated zone into the invert. This inflow can flow through the EBS along eight pathways: (1) seepage flux plus any condensation that may occur on the walls of the drift above the drip shield, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package and drip shield into the invert, (7) imbibition flux from the drift host rock to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2007 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). These pathways are time dependent, in the sense that drip shield and waste package penetrations will vary with time and local conditions in the repository.

Radionuclide transport is modeled with three domains (SNL 2007 [DIRS 177407], Section 6.3.1.1). These are: (1) The waste form (e.g., fuel rods or defense HLW glass; included in this domain is a small amount of corrosion products from steel components closely associated with the waste form, such as fuel basket tubes and glass pour canisters); (2) waste package steel corrosion products; and (3) the invert. Radionuclides dissolved from the waste form are

transported from the waste form to the corrosion products and then to the invert via advection and diffusion; for simplicity, longitudinal and transverse dispersion are neglected in TSPA. Radionuclides interact with the crushed tuff in the invert by adsorption processes.

Radionuclide solubilities are specified in *Dissolved Concentration Limits of Radioactive Elements* (SNL 2007 [DIRS 177418], Sections 6.5 to 6.18) to provide radionuclide concentrations in each of the flow pathways in the RTA model, specifically in the waste form and waste package corrosion products. The seepage and drift wall condensation flux into a drift is also an input to the RTA model. The flux-splitting model determines the fraction of the seepage flux that flows through a failed drip shield and waste package. Fluxes that flow through a failed drip shield are split between those that flow around the waste package and those that flow into the waste package. Fluxes that are diverted around the waste package and the drip shield flow into the invert. These fluxes will not contain radionuclides. Water that flows into a waste package will contain radionuclides as it exits the waste package, as described in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.4). The RTA model does not require or address details about the flow mechanisms or type of flow (such as film flow) that is occurring in the waste form. Uncertainty in advective transport through the waste form is addressed, in part, by sampling over a range of dissolved concentrations and sorption parameters (e.g., surface areas, corrosion product masses).

The invert cell is in intimate contact with the waste package and is 0.934 m in thickness (SNL 2007 [DIRS 177407], Section 6.5.2.3). This is the average thickness of the invert directly beneath the waste package. This value is appropriate because flow out of the waste package is primarily downward, centered over the thickest part of the invert. The presence of an emplacement pallet is not represented in TSPA for the purposes of estimating radionuclide transport path length. Consequently, radionuclides pass directly from the waste package to the invert.

The total mass flux of the radionuclides entering the unsaturated zone from the invert is the sum of radionuclides transported by advection and diffusion (SNL 2007 [DIRS 177407], Section 6.5.2). Flow through the invert is discussed in included FEP 2.1.08.05.0A (Flow through Invert).

FEP: 2.1.09.09.0A

FEP NAME:

Electrochemical Effects in EBS

FEP DESCRIPTION:

Electrochemical effects may establish an electric potential within the drift or between materials in the drift and more distant metallic materials. Migration of ions within such an electric field could affect corrosion of metals in the EBS and waste, and could also have a direct effect on the transport of radionuclides as charged ions.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Electrochemical effects include electrophoresis and galvanic coupling. Electrophoresis is the movement of an electrically charged element or molecule (e.g., a radionuclide ion) under the influence of an electric field. Galvanic coupling refers to flow of electricity due to the potential differences that arise when two dissimilar metals or alloys are in electrical contact. In a galvanic couple consisting of two metals or alloys with significantly different corrosion potentials in the environment of concern, the metal or alloy that acts as the anode will corrode preferentially. The nobler of the two metals or alloys in the galvanic couple will act as the cathode.

A variety of materials are in the repository emplacement drifts. These materials are summarized in *Total System Performance Assessment Data Input Package for Requirements Analysis for EBS In-Drift Configuration* (SNL 2007 [DIRS 179354]).

The emplacement drifts include a ground support composed of Stainless Steel Type 316L (UNS S31603) drift liners and rock bolts (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). The waste package design is a double-walled waste package (inner vessel with outer corrosion barrier, SNL 2007 [DIRS 179394], Table 4-3) placed underneath a protective drip shield (SNL 2007 [DIRS 179354], Section 4.1.1). The WPOB will be constructed of Alloy 22 (UNS N06022) with additional elemental and chemical composition restrictions (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-19). The inner vessel of the waste package is constructed of Stainless Steel Type 316 (UNS S31600) (SNL 2007 [DIRS 179394], Table 4-3). The waste package rests on an emplacement pallet, which in turn rests on the invert structure, which is covered by crushed tuff as ballast. The waste package emplacement pallet is fabricated from Stainless Steel Type 316 and Alloy 22 (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-01). Stainless Steel Type 316 tubes connect to the Alloy 22 waste package supports to form the emplacement pallet (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-01). The drip shield plate material is Titanium Grade 7 (UNS R52400) and the drip shield structural support material is Titanium Grade 29 (UNS R56404) (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-04). The drip shields are designed to contact no other material except the Alloy 22 base (SNL 2007 [DIRS 179354], Table 4-2, Parameter

Number 07-07), which is attached to the bottom of the drip shields. The Alloy 22 drip shield base is in contact with the invert.

A commercial SNF TAD canister will be placed inside the double-walled waste package. The design characteristics used in modeling the TAD canister-bearing waste packages are documented in *Total System Performance Assessment (TSPA) Data Input Package for Requirements Analysis for TAD Canister and Related Waste Package Overpack Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179394]). The TAD canister vessel and structural internals (i.e., basket) shall be constructed of 300-series stainless steel (such as UNS S31603, which may also be designated as Stainless Steel Type 316L).

The main codisposal waste package (N Reactor) components use the following materials: Alloy 22 for the outer corrosion barrier, Stainless Steel Type 316 for the inner vessel, Carbon Steel Type A516 for the divider plate fuel support plate assemblies, Stainless Steel Type 304L for the MCO and glass pour canisters , and Aluminum Alloy Type 1100 for the MCO spacer (SNL 2007 [DIRS 180506], Sections 4.1.4 and 4.1.4[a]).

In the 10,000 years following repository closure, the waste package emplacement pallet prevents direct contact of the waste package with the invert (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-02). The Alloy 22 waste package supports are the main load-bearing members because the geometry of the pallet and waste package supports prevents direct contact between the waste package and the emplacement pallet tubes (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). The emplacement pallet keeps the waste package from contacting other dissimilar metals in the absence of seismic activity (SNL 2007 [DIRS 179354], Table 4-3, Parameter Number 08-03). The affects of seismic activity on mechanical degradation of EBS components is addressed in included FEPs 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components) and 1.2.03.02.0C (Seismic-induced Drift Collapse Damages EBS Components), and excluded FEP 1.2.03.02.0B (Seismic-induced Rockfall Damages EBS Components).

The carbon steel invert structure will provide a framework, consisting of a series of beams bolted to the invert rock mass, that supports the emplacement pallets, waste packages, and drip shields (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-08). The base plates of the drip shield are fabricated from Alloy 22 to prevent direct contact between the titanium and steel members in the invert, thus minimizing electrochemical effects at this interface (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-07). The corrosion resistance of the Alloy 22 WPOB, emplacement pallet components, and base plates of the drip shield, as well as the titanium drip shield components, is much greater than the carbon steel and, to a lesser extent, the stainless steel invert components. If any electrical contact were to be established between these Alloy 22 or titanium components and the invert materials, the invert materials would corrode preferentially. The potential for corrosion-generated hydrogen to embrittle the waste package or drip shield is discussed in excluded FEPs 2.1.03.04.0A (Hydride Cracking of Waste Packages) and 2.1.03.04.0B (Hydride Cracking of Drip Shields), respectively. If the invert components completely degrade before such electrical contacts were possible, no galvanic effects would occur.

Overall, the emplacement drift design is such that EBS materials shall be inert relative to each other so that physical contact between EBS materials minimizes dissimilar material interaction mechanisms (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 02-05). There are, however, a number of possible EBS component contacts between Alloy 22 and Stainless Steel Type 316 (e.g., between the Alloy 22 WPOB and the Stainless Steel Type 316 inner vessel or between the Alloy 22 emplacement pallet-bearing surfaces and the Stainless Steel Type 316 connector tubes). The corrosion potentials of Alloy 22 and Stainless Steel Type 316 are very close to each other under similar exposure conditions (e.g., Davison et al. 1987 [DIRS 162971], Figure 10; where Hastelloy C is comparable to Alloy 22), with Alloy 22 slightly more noble than Stainless Steel Type 316. After breach of the Alloy 22 WPOB, electrochemical coupling of the Alloy 22 WPOB with the Stainless Steel Type 316 waste package inner vessel could occur. Due to the similarity in corrosion potential of Alloy 22 and Stainless Steel Type 316 (e.g., Davison et al. 1987 [DIRS 162971], Figure 10), any enhanced degradation of either material due to galvanic interaction is expected to be negligible, although Alloy 22 would be expected to be the cathode relative to Stainless Steel Type 316 (SNL 2007 [DIRS 178519], Section 6.3.3).

A number of crevice corrosion studies of galvanically coupled specimens have been conducted in repository-relevant exposure conditions. Ikeda and Quinn (2003 [DIRS 162662]) studied the crevice corrosion of galvanically coupled Alloy 22 and Stainless Steel Type 316 in a simulated concentrated groundwater at about 90°C. The study found a limited amount of acidification in the creviced regions between Alloy 22 and Stainless Steel Type 316 and evidence of localized corrosion initiation on the Stainless Steel Type 316 surface. No enhanced degradation of the Alloy 22 was observed. This finding is consistent with the Alloy 22 functioning as the cathode and the Stainless Steel Type 316 as the anode in the galvanic couple. Stainless Steel Type 316 would also be expected to undergo localized corrosion even in the absence of electrical connection to Alloy 22 in the concentrated groundwater solution at 90°C. The results of Ikeda and Quinn (2003 [DIRS 162662]) are consistent with those of He et al. (2007 [DIRS 182722]), who also studied crevice corrosion of galvanically coupled Alloy 22 and Stainless Steel Type 316 and compared it to the behavior of uncoupled specimens. Their tests were conducted in 4 M NaCl solution at 95°C. They concluded that Stainless Steel Type 316 was susceptible to crevice corrosion in the test solution and did not significantly depend on the crevicing material (e.g., whether the crevicing material was Alloy 22 or a polytetrafluoroethylene washer). Given that no corrosion performance credit is taken for the Stainless Steel Type 316 inner vessel in evaluating waste package corrosion performance (SNL 2007 [DIRS 178519], Section 6.3.3), electrochemical coupling of the Alloy 22 WPOB and the Stainless Steel Type 316 waste package inner vessel is of low consequence with respect to potential degradation of the waste package. The same low consequence justification would apply to any galvanic coupling of Alloy 22 and any Stainless Steel Type 300 component within the waste package (e.g., the TAD and stainless steel pour canisters). Chemical degradation of the emplacement pallet connector tubes is discussed in included FEP 2.1.06.05.0C (Chemical Degradation of Emplacement Pallet), where it is concluded that the connector tubes retain their structural integrity during the first 10,000 years after closure. Also, as discussed in included FEP 2.1.06.05.0C (Chemical Degradation of Emplacement Pallet), the function of the emplacement pallet becomes less important to mechanical performance at later times when the drip shield is collapsed and rubble accumulates adjacent to waste packages.

The possibility of the drip shield contacting the waste package as a result of mechanical damage caused by rockfall was considered. This possibility is addressed in excluded FEP 2.1.03.07.0B (Mechanical Impact on Drip Shield). As emplaced, the only contact between Titanium Grade 7 and Alloy 22 occurs at the bottom of the drip shields where Alloy 22 feet are attached to prevent contact between titanium and the invert (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-07). The choice of Alloy 22 for the feet was based on similarity of the two materials in the electrochemical series (ASM International 1987 [DIRS 103753], p. 557, Figure 10), which indicates that any enhanced degradation of either material due to galvanic interaction would be negligible. After seismic drift collapse or mechanical failure of the drip shield, contact between the Alloy 22 WPOB and the Titanium Grade 7 drip shield plate material is possible. Ikeda and Quinn (2003 [DIRS 162662]) studied the crevice corrosion of galvanically coupled Alloy 22 and Titanium Grade 7 in a simulated concentrated groundwater at about 90°C. Although a limited amount of acidification was observed in the creviced region, no evidence of localized corrosion initiation was observed on either alloy. He et al. (2007 [DIRS 182722]) also studied crevice corrosion of galvanically coupled Alloy 22 and Titanium Grade 7 and compared it to the behavior of uncoupled specimens. Their tests were conducted primarily in 4 M NaCl solution at 95°C and a limited amount of testing was carried out in 0.5 M NaCl and 4 M $MgCl_2$ solutions. They concluded that metal-to-metal crevices were less susceptible to crevice corrosion than the corresponding metal-to-polytetrafluoroethylene crevices and that crevice repassivation models based on data from uncoupled specimens should bound crevice corrosion susceptibility determinations. Therefore, electrochemical coupling of the Alloy 22 WPOB and the Titanium Grade 7 drip shield is of low consequence with respect to potential degradation of the EBS and the waste package.

Another possible galvanic contact in the repository is between the Titanium Grade 7 drip shield plates and the Stainless Steel Type 316L (a low-carbon version of Stainless Steel Type 316) drift liners and rock bolts, which may fall on the drip shield surface after they degrade. Ikeda and Quinn (2003 [DIRS 162662]) studied the crevice corrosion of galvanically coupled Stainless Steel Type 316 and Titanium Grade 16 (an alloy similar to Titanium Grade 7 with a lower palladium content) in a simulated concentrated groundwater at about 90°C. Although a limited amount of acidification was observed in the creviced region, no evidence of localized corrosion initiation was observed on either alloy. Based on these results, deleterious effects of galvanic coupling between Titanium Grade 7 and Stainless Steel Type 316 are not expected under repository exposure conditions. Similar results would be expected for galvanic coupling between the Titanium Grade 29 drip shield supports and Stainless Steel Type 316, although galvanic contact between these materials in the repository will be limited due to the location of the drip shield supports in the drip shield configuration (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-01). The possibility of hydrogen-induced cracking of the drip shield due to galvanic contact with iron-based materials such as the Stainless Steel Type 316L drift liners and rock bolts is discussed in excluded FEP 2.1.03.04.0B (Hydride Cracking of Drip Shields).

Telluric currents (i.e., currents that move through the ground) can, under some conditions, affect corrosion rate in carbon steels, copper alloys, and other less corrosion-resistant alloy systems. This is especially true for cathodically protected buried carbon steel pipeline systems. In the case of the repository, the ground supports and invert are sufficiently grounded to prevent any significant build-up of telluric currents. The drip shields are grounded to the invert through the Alloy 22 feet. Also, in the case of the highly passive Alloy 22 WPOB material and the Titanium

Grade 7 drip shield material, telluric current effects would not be expected to affect corrosion response since these materials remain highly passive over a very broad range of applied potentials. Thus, small varying changes in local surface potentials that could potentially result from telluric currents or other stray current sources would not measurably affect the very low corrosion rates of these materials. The effect of telluric currents is also discussed in excluded FEP 2.1.06.07.0A (Chemical Effects at EBS Component Interfaces).

Commercial SNF and DOE SNF (other than naval SNF) cladding is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the fuel matrix nor the release of radionuclides from the fuel after groundwater contact (included FEPs 2.1.02.12.0A (Degradation of Cladding Prior to Disposal), 2.1.02.23.0A (Cladding Unzipping), and 2.1.02.25.0A (DSNF Cladding)).Zirconium is a highly corrosion-resistant material because it forms a protective and adherent oxide film when exposed to oxygen-containing environments (Yau and Webster 1987 [DIRS 165063], p. 707). This oxide film forms spontaneously in air or water at ambient temperatures, is self-healing, and protects the base metal from chemical and mechanical attack (Yau and Webster 1987 [DIRS 165063], p. 707). Zirconium-based cladding, with its thick oxide layer produced in reactor operation, is kinetically noble (Yau and Webster 1987 [DIRS 165063], Table 15, p. 717). Due to the self-healing properties of the oxide layer formed on zirconium-based cladding (Yau and Webster 1987 [DIRS 165063], pp. 707 and 718), any mechanical disruption of the oxide layer is not expected to have a significant impact on the corrosion behavior of this material. For instance, Hansson (1984 [DIRS 101676], p. 6) observed that zirconium-based cladding that had its oxide film scratched off reformed a passive oxide layer within seconds in a synthetic cement pore solution of pH values 12.0 to 13.8. Therefore, although the zirconium cladding is considered to be unzipped after a waste package breach, the cladding is still present in proximity to the waste forms and other waste package materials, which could influence radionuclide transport as discussed below.

Cragnolino (1999 [DIRS 152354], p. 4-13) surveyed various corrosion mechanisms for zirconium cladding under repository conditions and concluded:

> Zr is not susceptible to galvanic corrosion because the protective ZrO_2 passive film leads to E_{corr} values in the galvanic series in flowing seawater close to those of noble metals and graphite but slightly lower than that of Ag. However, local corrosion promoted by galvanic coupling to a more noble metal may occur if the film is mechanically disrupted. Nevertheless, the repassivation rate of Zr and its alloys is sufficiently fast in many aqueous solutions that unless fretting is continuously occurring no substantial corrosion can be expected.

If the oxidized zirconium cladding were to be electrically coupled to a less corrosion resistant material (e.g., the stainless steel fuel boxes), the corrosion rate of that material is expected to be accelerated (Yau and Webster 1987 [DIRS 165063], p. 717). Brossia et al. (2002 [DIRS 161988], Figure 4) showed that the resistance of the oxide film formed on zirconium increases by about three orders of magnitude (from 10^4 to 10^7 ohms) as the film thickness increases from about zero to 3.4 μm. Thus, it is reasonable to expect that the oxide film on zirconium cladding will serve to electrically isolate the cladding from other materials, limiting the possibility of galvanic coupling effects.

The lack of an observable galvanic effect is demonstrated within the radionuclide release rate model of *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987], Section 8.1). A validation comparison of that model to cladded fuel rod segments (with potential for galvanic effect), and to fuel fragments (no possible galvanic effects) show radionuclide release rates do not indicate any obvious increase in these rates due to the presence of clad; in fact the fuel fragments are seen to have a greater release rate (BSC 2004 [DIRS 169987], Table 7-9). The effects of galvanic coupling on the corrosion and associated radionuclide release rate from DOE SNF are of no consequence to radionuclide release rates because the model for DOE SNF corrosion uses a bounding instantaneous radionuclide release rate (BSC 2004 [DIRS 172453], Section 8.1). As for electrochemical effects on defense HLW, these are negligible because the principal dissolution reactions involved are glass hydrolysis reactions that are not influenced by electrochemical effects.

Electrochemical effects on the waste form will also be minimal. The commercial SNF waste form is surrounded by the oxidized split zirconium cladding and would not be in direct contact with the waste package internals. If the UO_2 did contact the stainless steel fuel boxes and galvanic coupling were to occur, the steel boxes would see the accelerated reaction and not the fuel pellets. As the UO_2 corrodes, it coats itself with reaction products, which will minimize galvanic effects.

Electrophoresis is the movement of an electrically charged element or molecule (e.g., a radionuclide ion) under the influence of an electric field. The WPOB, inner vessel, TAD canister, and waste package internals are in electrical contact with each other and are in contact with the repository ground through the emplacement pallet. The drip shields are also in contact with the repository ground. The possibility of forming significant electric fields within the emplacement drifts owing to galvanic coupling is remote. As discussed earlier, the bulk of the materials in the emplacement drifts are titanium alloys, Alloy 22, and stainless steels that will all have similar corrosion potentials, and contact between these materials will not result in significant galvanic coupling effects. Thus, the movement of charged species such as radionuclides will be insignificant under these small electric fields. Therefore, omission of electrochemical effects (electrophoresis and galvanic coupling) would not have a significant effect on the resulting radionuclide exposures to the RMEI. The development of electric fields due to radiation effects (such as Compton scattering) is addressed in excluded FEP 2.1.09.27.0A (Coupled Effects on Radionuclide Transport in EBS).

Based on the previous discussion, omission of FEP 2.1.09.09.0A (Electrochemical Effects in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.10.0A

FEP NAME:

Secondary Phase Effects on Dissolved Radionuclide Concentrations

FEP DESCRIPTION:

Inclusion of radionuclides in secondary uranium mineral phases, such as neptunium in schoepite and uranium silicates, could affect radionuclide concentrations in water in contact with the waste form. During radionuclide alteration, the radionuclides could be chemically bound to immobile compounds and result in a reduction of available radionuclides for mobilization.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Incorporation/sequestration of certain radionuclide(s) into corrosion products formed during the alteration of SNF may reduce concentrations of radionuclides in water that has contacted fuel and its corrosion products (SNL 2007 [DIRS 177418], Appendix IV). Simple mass-balance calculations (Werme and Spahiu 1998 [DIRS 113466]) on the results of spent fuel dissolution experiments as well as neptunium solubility experiments (Werme and Spahiu 1998 [DIRS 113466]; Quinones et al. 1996 [DIRS 161925]) revealed that the amount of neptunium in aqueous solution was a small portion of what should have been released from the dissolved nuclear fuel. One explanation for this observation is that released neptunium is included in uranyl solids that form during fuel degradation, as discussed in *Dissolved Concentration Limits of Elements with Radioactive Isotopes* (SNL 2007 [DIRS 177418], Appendix IV).

In conclusion, the inclusion of secondary uranyl mineral phases in the TSPA would reduce calculated doses because these solids would sequester actinides such as neptunium.

Based on the previous discussion, omission of FEP 2.1.09.10.0A (Secondary Phase Effects on Dissolved Radionuclide Concentrations) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.11.0A

FEP NAME:

Chemical Effects of Waste–Rock Contact

FEP DESCRIPTION:

Waste (CSNF, DSNF, and HLW) and rock may be placed in direct contact by mechanical failure of the drip shields and/or waste packages. Chemical effects on the waste (e.g., dissolution) may be enhanced or altered in a system where waste, rock minerals, and water are all in physical contact with one another, relative to a system where only waste and water are in physical contact.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The waste forms will have little chance of direct contact with the host rock because the canisters, the waste package stainless steel inner vessel, the Alloy 22 outer barrier, and the drip shield will prevent contact unless they are breached by early failure, or by igneous or seismic events.

For commercial SNF, even if contact of the UO_2 fuel with the rock were to occur, it would have little effect on the fuel corrosion. Uranium in the commercial SNF first oxidizes (U^{4+} to U^{6+}), dissolves, and then precipitates rapidly on the pellet surface as a U^{6+} mineral. Although proximity with the host rock might enhance availability of silicon to precipitate uranyl silicate minerals, this effect is not expected to influence the rate of the fuel's oxidative dissolution process (BSC 2004 [DIRS 169987], Section 6.2.2.3). DOE SNF and defense HLW are also not expected to come into contact with near-field rock. However, the possible direct effects of waste–rock contact, were it to occur, are also considered negligible. For defense HLW, indirect effects that could occur through the water chemistry (e.g., effects on dissolved silicon concentration), which would feed back into the rate of glass dissolution, are expected to be similar to those that will occur due to dissolution of the waste glass itself (BSC 2004 [DIRS 169988], Section 6.5.2.3) in the absence of waste glass and rock contact. The effects, if any, of rock contact would be to inhibit the initial dissolution rate of the glass (i.e., the dissolution rate during the period when the dissolved silicon concentration in the water contacting the glass is increasing due to dissolution of the glass itself). The choice of the k_E parameter value in the HLW glass dissolution model is designed to include the effect of the initial buildup of the dissolved silicon concentration (BSC 2004 [DIRS 169988], Section 6.5.2.6) regardless of whether the source of this silicon is the dissolution of the glass itself or the dissolution of rock with which the glass might come into contact. For DOE SNF (other than naval SNF), an upper-limit model that involves instantaneous degradation of the waste form is used in the TSPA model (see included FEP 2.1.02.01.0A (DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)); direct contact of DOE SNF with the host rock would not affect this model.

Water that contacts SNF will have previously been in contact with the host rock, and therefore rock in physical contact with SNF will not affect the waste–rock–water system chemistry. Furthermore, *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Sections 6.6.2[a], 6.10.1[a], and 6.10.5) demonstrated that variations in the chemistry of the water contacting the waste package internal components, including the SNF, had an insignificant effect on the pH and total carbonate content of the in-package fluids, the two key chemical parameters controlling the dissolution of commercial SNF and HLW.

Waste form and cladding interactions with igneous intrusions are addressed in included FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components).

Based on the previous discussion, omission of FEP 2.1.09.11.0A (Chemical Effects of Waste–Rock Contact) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.12.0A

FEP NAME:

Rind (Chemically Altered Zone) Forms in the Near-Field

FEP DESCRIPTION:

Thermal-chemical processes involving precipitation, condensation, and re-dissolution could alter the properties of the adjacent rock. These alterations may form a rind, or altered zone, in the rock, with hydrological, thermal, and mineralogical properties different from the initial conditions.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The THC seepage model (SNL 2007 [DIRS 177404]) has been used to evaluate thermal-chemical interactions that will occur in the repository environment, and their impact on the composition of seepage entering the drift, and on the mineralogy and hydrologic properties of the host rock. This model captures the effects of changes in temperature, pH, Eh, ionic strength (and other compositional variables), time dependency, precipitation or dissolution effects, and effects of resaturation, and was used to examine near-field and drift seepage flow and chemistry (SNL 2007 [DIRS 177404], Section 6.2). Ion exchange reactions are not explicitly included in the THC seepage model but are represented by dissolution/precipitation of solid solutions for smectites and of pure end-member compositions for other clay minerals and zeolites (SNL 2007 [DIRS 177404], Section 6.2.1.2).

A wide range of fracture permeability data have been measured for the Topopah Spring units, from 10^{-10} to $10^{-13.2}$ m^2 (SNL 2007 [DIRS 181244], Table 7-2[a]). Changes in fracture permeabilities resulting from mineral precipitation or dissolution were found to be on the order of the natural variation in these permeabilities (SNL 2007 [DIRS 177404], Section 6.5.5.3; BSC 2004 [DIRS 170038], Table 6-5 and Section 6.1), with most of the substantial effects limited to regions above and to the side of the drift within about a drift diameter (SNL 2007 [DIRS 177404], Figures 6.5-8 to 6.5-9). The predicted mineral precipitation reduces permeability in the affected regions and leads to a reduction in flow around the drift and therefore less seepage. THC effects on fracture characteristics have been evaluated with the THC seepage model, which explicitly accounts for fracture flow affected by THC parameter alterations (SNL 2007 [DIRS 181244], Section 6.4.4.2). There is no indication that significant precipitation may occur immediately at the drift wall. This means that the local permeability and porosity in the boundary layer above the drift wall, important for the capillary barrier behavior, are not affected by THC processes.

It was demonstrated that the effects of these potential alterations on near-field and drift seepage flow can be excluded in the TSPA because the expected changes would lead to less seepage

(SNL 2007 [DIRS 181244], Section 6.5.1.4). Consequently, omission of this effect is expected to result in a slight increase in seepage and may enhance drift seepage and radionuclide transport.

Based on the previous discussion, omission of FEP 2.1.09.12.0A (Rind (Chemically Altered Zone) Forms in the Near Field) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.13.0A

FEP NAME:

Complexation in EBS

FEP DESCRIPTION:

The presence of organic complexants in water in the EBS could augment radionuclide transport by providing a transport mechanism in addition to simple diffusion and advection of dissolved material. Organic complexants may include materials found in natural groundwater such as humates and fulvates, or materials introduced with the waste or engineered materials.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

In the unexpected event of drip shield failure and waste package failure at the same location, seepage potentially containing organic complexants could enter the waste package. Organic compounds can form soluble complexes with radionuclides, complexes that are not expected to sorb, thereby enhancing their potential for transport. Humic acid and fulvic acid are of particular interest as they have been shown to complex strongly with actinides. Humic acid and fulvic acid are produced as a by-product of biologic activity and might accumulate in seepage. Because humic acid and fulvic acid production in the drift and waste package is expected to be minimal due to the early thermal pulse and long-term limits on nutrient availability (see excluded FEP 2.1.10.01.0A (Microbial Activity in EBS) and included FEP 2.1.11.08.0A (Thermal Effects on Chemistry and Microbial Activity in the EBS)) the analysis that follows focuses on humic acid and fulvic acid carried into the package by seepage. The bulk of the non-actinide radionuclides (e.g., ^{129}I, ^{99}Tc, $^{137,135}Cs$, ^{90}Sr) are predicted to be highly soluble (SNL 2007 [DIRS 177424], Table 6-4), in the absence of humic acid and fulvic acid. The presence of humic acid and fulvic acid that may potentially exist in seepage is, therefore, not expected to elevate their solubility any further (though it may inhibit sorption of cesium and strontium in the invert). The emphasis here is on the low solubility, highly sorbing actinides that might be mobilized by humic acid and fulvic acid.

A total organic carbon content of 0.58 mg/L is reported by Means et al. (1983 [DIRS 100797], Table 1) for well UE25b-1, 33% (0.19 mg/L) of which has a molecular weight greater than 1,000 (Means et al. (1983 [DIRS 100797], Table 3). Using as a maximum a ratio of one humic + fulvic carbon site per complexed actinide, 0.19 mg/L of carbon would correspond to 0.016 mM of complexed actinides.

Solubility limits of plutonium, neptunium, thorium, americium, uranium, and protactinium (SNL 2007 [DIRS 177418]) are much higher than 0.016 mM at high and low pH. Therefore the presence of humic and fulvic acids would have little effect on solubilities under these conditions. The addition of humic acid and/or fulvic acid might elevate actinide solubilities at near-neutral pH values. Humic acid and fulvic acid elevated actinide solubilities are unexpected, however,

because dissolved iron and uranium will compete with actinides for humic acid and fulvic acid complexation sites.

Many organic complexants coordinate with Fe(III), Cr(III), and Ni(II) produced by corrosion of steels (SNL 2007 [DIRS 180506], Table 4-7), and uranium that will leach from the fuels. Competition by Fe(III/II), Cr(III), and Ni(II) and dissolved uranium for binding sites on humic + fulvic acids introduced by seepage waters, or on organic residues in the waste package or EBS is therefore expected to inhibit coordination of actinides with organics, and thereby hinder organic-facilitated transport.In conclusion, because microbial activity in the repository is expected to be low (excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS)), the formation of organic complexants in the EBS will also be low, and the impact of organic materials found in natural groundwater on radionuclide transport will be negligible.

Based on the previous discussion, omission of FEP 2.1.09.13.0A (Complexation in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.15.0A

FEP NAME:

Formation of True (Intrinsic) Colloids in EBS

FEP DESCRIPTION:

True colloids are colloidal-sized assemblages (between approximately 1 nanometer and 1 micrometer in diameter) consisting of hydrolyzed and polymerized radionuclides. They may form in the waste package and EBS during waste form degradation and radionuclide transport. True colloids are also called primary colloids, real colloids, Type I colloids, Eigenkolloide, and intrinsic colloids (or actinide intrinsic colloids, for those including actinide elements).

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Of all the actinides, plutonium has the highest tendency to form stable intrinsic colloids, by virtue of polymerization (Choppin and Stout 1989 [DIRS 168379], p 209). If plutonium intrinsic colloids are shown to be of low importance for radionuclide transport relative to colloids included in system models, colloids of the other actinides of similar abundance should be of even lesser importance. Transport of radionuclides by groundwater colloids is more significant than transport by true colloids In fact, Rai and Swanson (1981 [DIRS 144599], p. 111) show that plutonium-colloidal suspensions (which may be polymers or very fine hydroxide solids) are generally unstable above pH = 5, whereas the pH of the natural system is expected to be higher, even for evolved fluid composition just around the drift (as discussed in excluded FEP 2.2.01.04.0A (Radionuclide Solubility in the Excavation Disturbed Zone)). As true colloids are thermodynamically unstable phases, they are expected to dissolve back into the aqueous phase; the radionuclides will subsequently be sorbed onto pseudocolloids and waste form colloids (or retarded via interaction with immobile substrates). For example, Kersting and Reimus (2003 [DIRS 162421], pp. 88 to 92) describe experiments in which plutonium polymer (an intrinsic colloid) was equilibrated with montmorillonite, silica, hematite, and goethite colloids (pseudocolloids). Sorption coefficients for plutonium onto these pseudocolloids were always at least 10^3 mL/g; and even after aggressive desorption, at least 50% of the plutonium remained bound to the pseudocolloids, demonstrating the dominance of these over the plutonium intrinsic colloids. Thus, plutonium intrinsic colloids, even if they existed after the sorption experiments, were relatively insignificant compared to the plutonium present as pseudocolloids (sorbed onto montmorillonite, silica, hematite and goethite). Near degrading fuel, plutonium may be associated with a zirconium-rich solid phase (conceptually identified as a mixed plutonium-zirconium-rare earth oxide and modeled as "ZrO_2" particles with irreversibly attached plutonium and americium with no additional sorption of other radionuclides), which is expected to transport as a waste form colloid, not as an intrinsic colloid (SNL 2007 [DIRS 177423], Section 6.3.1). Radionuclide transport by colloids formed through coprecipitation in the EBS is

discussed in included FEP 2.1.09.25.0A (Formation of Colloids (Waste-Form) by Co-precipitation in EBS).

Compared to plutonium, uranium shows a lower tendency to polymerize; yet, the much larger mass of uranium requires consideration of its intrinsic colloids. However, for uranium, unlike for plutonium where intrinsic colloids can dominate the mass of plutonium within the solution, the total colloid fraction represents only about 1% to 12% of the uranium dissolved in solution (Wronkiewicz et al. 1996 [DIRS 102047], p. 86). U(VI) hydroxides (polymerized intrinsic uranyl colloids) may initially form, but these will be unstable relative to U(VI) silicates in silica-containing groundwater (Finch and Ewing 1992 [DIRS 113030], Section 4.2.2), and even the U(VI) silicates are expected to be minor contributors to radionuclide transport even if they do not dissolve back into the groundwater over the duration of transport (SNL 2007 [DIRS 177423], Section 7.0).

Again, plutonium is the actinide that is most commonly observed to form true colloids. Because true plutonium colloids are not expected to affect dose, true colloids of the other actinides that are of similar abundance are not expected to affect dose either. For uranium, intrinsic colloids are expected to be neglible contributors to transport and are not expected to affect dose.

Consistent with the previous discussion, omission of FEP 2.1.09.15.0A (Formation of True (Intrinsic) Colloids in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 179394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.16.0A

FEP NAME:

Formation of Pseudo-Colloids (Natural) in EBS

FEP DESCRIPTION:

Pseudo-colloids are colloidal-sized assemblages (between approximately 1 nanometer and 1 micrometer in diameter) of nonradioactive material that have radionuclides bound or sorbed to them. Natural pseudo-colloids include microbial colloids, mineral fragments (i.e., clay, silica, iron oxyhydroxides), and humic and fulvic acids. This FEP addresses radionuclide-bearing pseudo-colloids formed from host-rock materials and all interactions of the waste and EBS with the host rock environment except corrosion.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Natural colloids are modeled as montmorillonite clay colloids as discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.3.1 and 6.3.11). Pseudocolloids generally form as a result of dissolved (aqueous) radionuclides sorbing to existing colloids (SNL 2007 [DIRS 177423], Section 6.3.1). K_d values are developed to model reversible sorption of plutonium, americium, thorium, neptunium, cesium, protactinium, uranium, radium, and tin onto natural groundwater colloids to form pseudocolloids (SNL 2007 [DIRS 177423], Section 6.3.12.1). Colloid stability (including pseudocolloids) is determined based on ionic strength and pH. Colloid concentration (including pseudocolloids) is modeled as an uncertain parameter based on field observations in the Yucca Mountain vicinity (SNL 2007 [DIRS 177423], Section 6.3.11).

In TSPA, seepage water colloids (including pseudocolloids) are modeled with reversible radionuclide attachment using linear sorption coefficients (K_ds) (SNL 2007 [DIRS 177423], Section 6.3.12.1). Model implementation and output parameters used by the TSPA are described in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.5 and 8.1 and Table 8.1). Model parameter uncertainty associated with radionuclide adsorption onto colloids is discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.6.8). The primary uncertainties in the colloid model are the abundances of this colloid type at a given solution composition and the sorption coefficients that are used to partition radionuclides onto this colloid type (SNL 2007 [DIRS 177423], Section 6.6). Laboratory measurement uncertainties are large contributors to both. Uncertainty is captured and propagated in the model by sampling over a range of colloid concentration and radionuclide uptake characteristics.

Natural colloids consisting of iron oxyhydroxides and silica may also be present (SNL 2007 [DIRS 177423], Section 6.3.1). However, these are not modeled. Silica colloids have such low sorptive properties that they can be ignored (SNL 2007 [DIRS 177423], Section 6.3.1), and waste package corrosion products will dwarf the quantity of natural groundwater iron oxyhydroxide colloids. Corrosion product colloids are the subject of included FEP 2.1.09.17.0A (Formation of Pseudo-colloids (Corrosion Product) in EBS) and are not discussed in this FEP.

FEP: 2.1.09.17.0A

FEP NAME:

Formation of Pseudo-Colloids (Corrosion Product) in EBS

FEP DESCRIPTION:

Pseudo-colloids are colloidal-sized assemblages (between approximately 1 nanometer and 1 micrometer in diameter) of nonradioactive material that have radionuclides bound or sorbed to them. Corrosion product pseudo-colloids include iron oxyhydroxides from corrosion and degradation of the metals in the EBS and silica from degradation of cementitious materials.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The model developed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.3.1 and 6.3.8) includes treatment of pseudocolloids associated with corrosion of steel components of the waste package. Silica colloids from the degradation of cementitious material is not treated in the colloids report (SNL 2007 [DIRS 177423], Section 6.3.1) because cementitious materials are not part of the EBS in-drift configuration (SNL 2007 [DIRS 179354], Table 4-1). Colloids formed from the corrosion of steel in the EBS are expected to be iron oxyhydroxides primarily consisting of three mineral species under the anticipated repository conditions: goethite, hematite, and ferrihydrite (also refered to as hydrous ferric oxide) (SNL 2007 [DIRS 177423], Section 6.3.8). Hematite is used in the model for constraining colloid stability, while the sorption properties of iron-oxide surfaces are modeled using hydrous ferric oxide and goethite. Estimated colloidal mass concentrations based on corrosion studies using miniature waste packages under repository-relevant conditions were used to constrain the model (SNL 2007 [DIRS 177423], Section 6.3.8). Iron oxyhydroxide corrosion colloids are subject to concentration and stability constraints controlled by the aqueous chemistry, chiefly determined from the ionic strength and pH of in-package and in-drift fluids (SNL 2007 [DIRS 177423], Section 6.5).

The sorption calculations for iron oxyhydroxide colloids are based on a mechanistic surface complexation-based competitive sorption model, where the sorption coefficients are calculated as a function of dissolved concentration of competing species, pCO_2, and sorption sites (SNL 2007 [DIRS 177407], Sections 6.3.4.2.3 and 6.5.2.4). The results of these calculations are implemented in TSPA by applying reversible sorption of thorium, uranium, and neptunium on iron oxyhydroxide colloids by computing an effective K_d at each timestep. The sorption of plutonium and americium on iron oxyhydroxide colloids is modeled as an irreversible sorption process by kinetic attachment (with no detachment) by applying a forward rate constant as decribed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.3.12.2).

Model parameter uncertainty associated with colloid concentration is discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.6.5). The primary uncertainties in the colloid model are the abundances of the colloid type for a given solution composition and the sorption coefficients that are used to partition radionuclides onto this colloid type. Uncertainty is captured and propagated in the model by sampling over a range of colloid concentrations and by computing the sorption coefficients from surface-complexation modeling performed over a range of dissolved concentrations, surface properties, and chemical conditions.

FEP: 2.1.09.18.0A

FEP NAME:

Formation of Microbial Colloids in EBS

FEP DESCRIPTION:

This FEP addresses the formation and transport of microbial colloids in the waste and EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For microbes to impact near-field performance, microbes must be present in significant quantities, which means that sufficient energy sources and nutrients must be available for microbial activity to be viable. However, due to severe environmental constraints, microbial activity in the EBS is expected to be low, and microbial activity impacts on drift chemistry will be insignificant (excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS), which excludes microbial-activity impacts to the in-drift chemical environment in the TSPA on the basis of low consequence). By inference, the formation of microbial colloids in the EBS would be insignificant, and therefore of low consequence to the performance assessment.

To assess the potential effects on microbial populations within the EBS, *Evaluation of Potential Impacts of Microbial Activities on Drift Chemistry* (BSC 2004 [DIRS 169991]) considered the drift mineralogy; drift physical parameters; metals used in engineered barrier system components; waste dissolution rates and quantities; groundwater compositions and infiltration rates; and compositions and fluxes of gases (e.g., CO_2, water vapor). Environmental limits on microbial activity considered include redox conditions, temperature, radiation, hydrostatic pressure, water activity, pH, salinity, available nutrients, and others. The study evaluated the potential for radionuclide transport facilitated by suspended microbial cells, or biocolloids (BSC 2004 [DIRS 169991], Section 6.5.4). The study concluded that the potential effect of radionuclide-bearing colloids is negligible. The transport of those microbes that do exist will be limited by the scarcity of aqueous pathways. The transport and facilitated radionuclide migration are expected to be limited due to low liquid saturation, high ionic strength and low microbial activity in the EBS (SNL 2007 [DIRS 177423], Section 6.3.13.1). Microbes and organic compounds will not affect the generation of inorganic colloids. Any interactions will tend to destabilize inorganic colloids, possibly decreasing the mobility of associated radionuclides (SNL 2007 [DIRS 177423], Section 6.3.13).

Based on the previous discussion, omission of FEP 2.1.09.18.0A (Formation of Microbial Colloids in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.19.0A

FEP NAME:

Sorption of Colloids in EBS

FEP DESCRIPTION:

Interactions between radionuclide-bearing colloids and the waste and EBS may result in retardation of the colloids during transport by sorption mechanisms.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

As discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.5.2.1), the TSPA considers that colloids with embedded and sorbed radionuclides leave the failed waste package and enter the drift geochemical environment. The colloids exit the in-package chemical environment and enter the invert chemical environment. In the repository, interactions between radionuclide-bearing colloids and the waste and EBS may result in some retardation of the colloid transport by sorption mechanisms as discussed below.

Like physical filtration (see excluded FEP 2.1.09.20.0A (Filtration of Colloids in EBS) and gravitational settling of colloids (see excluded FEP 2.1.09.26.0A (Gravitational Settling of Colloids in EBS)), colloid sorption tends to retard colloid transport in the EBS. In *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.3.1 and 7.2), physical filtration of colloids is not explicitly included in the abstraction. Colloids that leave a failed waste package through the failure opening are not subsequently filtered out or settled out in the surrounding EBS material, including the invert. This assumption overestimates the potential consequences of colloid-facilitated transport of radionuclides and is, therefore, considered bounding. The effect of sorption is similar to filtration and settling, as all three processes result in immobilization of the colloids. Not crediting colloid sorption in the waste package and invert is therefore consistent with not crediting filtration and settling. This produces a bounding estimate of the consequences of colloid-facilitated transport of radionuclides in the EBS.

Based on the previous discussion, omission of FEP 2.1.09.19.0A (Sorption of Colloids in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.19.0B

FEP NAME:

Advection of Colloids in EBS

FEP DESCRIPTION:

Transport of radionuclide-bearing colloids in the waste and EBS may occur by advection.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The formation, stability, and concentration of colloids are addressed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.3.1). Three types of colloids are anticipated to exist in the EBS (SNL 2007 [DIRS 177423], Section 6.3.1): (1) waste form colloids from degradation of HLW glass and commercial SNF, (2) iron oxyhydroxide colloids due to products from the corrosion of steel waste packages, and (3) groundwater or seepage water colloids. On all three types of colloids, radionuclides may undergo reversible, or equilibrium, sorption. The waste form colloids may also contain embedded radionuclides that are not removable. Plutonium and americium can be strongly sorbed onto iron oxyhydroxide; for these radionuclides, sorption is modeled as a kinetic process.

The model developed in *EBS Radionuclide Transport Abstraction* (RTA) (SNL 2007 [DIRS 177407], Section 6.3.4) is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, and water chemistry), and the degradation state of the EBS components (SNL 2007 [DIRS 177407], Section 6.1). Outputs consist of the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The RTA model is implemented directly into the TSPA GoldSim model to compute the radionuclide release rates from the EBS (SNL 2007 [DIRS 177407], Section 6.5.2).

The source of inflow to the EBS is the seepage flux that drips from the crown (roof) of the drift, drift wall condensation, and imbibition flux from the unsaturated zone into the invert. This inflow can flow through the EBS along eight pathways: (1) seepage flux and drift wall condensation, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package into the invert, (7) imbibition flux from the unsaturated zone matrix to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2007 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). Pathways 4, 6, and 8 may cause advective flow of colloids bearing radionuclides.

These pathways are time dependent because drip shield penetrations and waste package penetrations will vary with time and local conditions in the repository.

The conceptual model for flow through the EBS also includes three domains: the waste form (e.g., fuel rods or defense HLW glass), waste package corrosion products, and the invert. The EBS domains are defined in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.5.2). Because no barrier capability is credited to the emplacement pallet with respect to radionuclide transport, the water and radionuclides in this model pass directly from the waste package to the invert.

The total flux entering the invert is equal to: (1) the flux diverted around the drip shield, (2) the flux diverted around the waste package, and (3) the flux leaving the waste package. The concentration of radionuclide-bearing colloids in the invert is determined by the mass of colloids entering the invert and the total flux that leaves the invert (both described earlier). Except for the evaporative fluxes, all fluxes that enter the invert leave the invert to the unsaturated zone.

Radionuclide-bearing colloids are transported through the invert via advection and diffusion. Colloids are transported advectively at approximately the same velocity as the liquid flux leaving the waste package (SNL 2007 [DIRS 177407], Section 6.3.4.4). Longitudinal and transverse dispersion of colloids is ignored because of the short travel distance through the EBS (SNL 2007 [DIRS 177407], Section 6.3.4.4). A summary of the computational model provided to the TSPA, including model parameter uncertainty implementation, is described in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.5.2 and Table 8.1-1).

The advective transport of dissolved radionuclides is addressed in included FEP 2.1.08.08.0B (Advection of Dissolved Radionuclides in EBS).

FEP: 2.1.09.20.0A

FEP NAME:

Filtration of Colloids in EBS

FEP DESCRIPTION:

Filtration processes may affect transport of radionuclide-bearing colloids in the waste and EBS. Filtration includes physical and electrostatic processes in pores and fractures of natural and anthropogenic materials, such as concrete and the joints between invert segments.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Colloid filtration, as discussed here, refers to the physical removal of colloids from a fluid flow system by physical and electrostatic processes. Filtration of colloids generally means the retention of suspended colloids moving with the groundwater in pores, channels, and fracture apertures that are too small or dry to allow passage of the colloids. Like sorption (see excluded FEP 2.1.09.19.0A (Sorption of Colloids in EBS)) and gravitational settling of colloids (see excluded FEP 2.1.09.26.0A (Gravitational Settling of Colloids in EBS)), colloid filtration tends to retard colloid transport in the EBS.

Within the waste package, colloids may form within the defense HLW glass at its outer surfaces (e.g., degraded defense HLW glass), from fuel, and from corroding steel. Colloids could be filtered within fractures in fuel pellets or trapped at the boundaries of disaggregating grains. Colloids forming within SNF rods whose cladding has been breached could be filtered at perforations in the cladding. Additionally, colloids could be filtered at perforations in the stainless steel containers. Colloids reaching the interior of the waste package could be filtered at perforations in the skin of the waste package. In the underlying invert material (crushed tuff), the colloids that do exit the waste package environment could be subjected to filtration in pores and channels that are too small or dry to allow further movement.

In the TSPA, the assumption is made that all stable colloids formed within the waste package (the calculated colloid source term) exit the package and enter the invert without filtration; these colloids will then move through the invert material without being subjected to filtration until they reach the underlying unsaturated zone (SNL 2007 [DIRS 177423], Section 6.3.1). Because filtration within the waste package and the invert will occur to some extent, excluding filtration overestimates the potential impact of colloid-facilitated transport of radionuclides in the TSPA dose calculations.

Based on the previous discussion, omission of FEP 2.1.09.20.0A (Filtration of Colloids in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed

10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.21.0A

FEP NAME:

Transport of Particles Larger than Colloids in EBS

FEP DESCRIPTION:

Groundwater flow through the waste could remove radionuclide-bearing particles by a rinse mechanism. Particles of radionuclide-bearing material larger than colloids could be entrained in suspension and then be transported in water flowing through the waste and EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Colloids by definition have at least one dimension between 1 nm and 1 μm. Particles larger than this inside a breached waste package might include metal and/or fuel fragments, and HLW glass shards. If these particles sorbed radionuclides and were transported from the waste package through the EBS, unsaturated zone, and saturated zone and into the biosphere, they might affect dose. However, transport of radionuclide-bearing particles larger than colloids in the EBS is not expected to have an adverse effect on performance because the size and density of these particles will favor settling from solution. In addition, particles with a relatively large radius are expected to become entrapped in pore throats and attach to immobile air-water interfaces in the EBS. Finally, inorganic particles larger than 1 μm will settle much more rapidly than they diffuse (Reimus 1995 [DIRS 144604], Section 3.2; see also excluded FEP 2.1.09.21.0B (Transport of Particles Larger than Colloids in the SZ)), so diffusion is not expected to contribute significantly to their transport through the EBS.

Although it cannot be ruled out that a small number of particles larger than colloids might transport through the EBS, for the reasons stated above, the number of such particles is expected to be very small compared to the number of colloids transported through the EBS. Colloid transport in the EBS is included in TSPA (FEPs 2.1.09.18.0B (Advection of Colloids in EBS) and 2.1.09.24.0A (Diffusion of Colloids in EBS)) because although colloids are subjected to the same transport processes as larger particles, they settle more slowly, diffuse more rapidly, fit through smaller pore throats, and advectively collide with air-water interfaces to a lesser extent than larger particles. .

Based on the previous discussion, omission of FEP 2.1.09.21.0A (Transport of Particles Larger than Colloids in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.21.0B

FEP NAME:

Transport of Particles Larger than Colloids in the SZ

FEP DESCRIPTION:

Particles of radionuclide-bearing material larger than colloids could be entrained in suspension and then be transported in water flowing through the SZ.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses particles larger than colloids (diameter > 1 μm) that could potentially transport radionuclides in the saturated zone. Particles larger than colloids that are generated in the waste package environment (SNL 2007 [DIRS 177423], Section 1.2) are not considered to move through the EBS (see excluded FEP 2.1.09.21.0A (Transport of Particles Larger than Colloids in the EBS)) or the unsaturated zone (see excluded FEP 2.1.09.21.0C (Transport of Particles Larger than Colloids in the UZ)), so particles larger than colloids with irreversibly sorbed radionuclides that originate in the waste package environment can be excluded from the saturated zone on these bases.

To assess the potential for radionuclide-bearing particles larger than colloids to transport over long distances in the saturated zone, it is convenient to compare the magnitudes of forces and velocities that dictate particle movement in a viscous fluid. Of particular interest are the competing forces that would tend to move particles toward or away from a rough surface upon which a particle is resting. The primary normal forces to be considered are listed below (Reimus 1995 [DIRS 144604], Sections 3.2 and 3.3). Particles will also experience a variety of short-range forces when they come in close proximity to fracture surfaces or collide with these surfaces (Reimus 1995 [DIRS 144604], Section 3.3). However, these short-range forces become less important as particle size increases (Reimus 1995 [DIRS 144604], Section 3.3), and they are expected to play a negligible role in the transport of particles larger than 1-μm diameter.

The primary forces acting on a spherical particle resting on a horizontal surface (these forces also apply to nonspherical particles and non-horizontal surfaces, but the force expressions are more complicated) are:

- Gravity Force (F_g) and Velocity (V_g)—acting toward surface (Reimus 1995 [DIRS 144604], Section 3.2.1):

$$F_g = \frac{4}{3}\pi R^3 \left(\rho_p - \rho_w\right) g \qquad \text{(Eq. 2.1.09.21.0B-1)}$$

$$V_g = \frac{2}{9} R^2 \left(\rho_p - \rho_w\right) \frac{g}{\mu} \qquad \text{(Eq. 2.1.09.21.0B-2)}$$

where, R = particle radius, cm

ρ_p = particle density, g/cm^3

ρ_w = water density, g/cm^3

g = gravitational constant = 980 cm/s^2

μ = water viscosity, g/cm-s (0.007 g/cm-s for water at 1 atm and 35°C (Fetter 2001 [DIRS 156668], Appendix 14)

- Hydrodynamic Drag Force (F_H) and Velocity (V_H)—acting away from surface (Reimus 1995 [DIRS 144604], Section 3.3.6 – Equation 51 of this reference defines the force, and the velocity is the force divided by the frictional drag force, 6πμR (per Equation 18 of this reference); note that the particle surface separation (h in Equation 51) is assumed here to be zero, and the asperity height is defined here as h instead of H):

$$F_H = 43.92 \sqrt{R^2 - (R-h)^2}\, \mu R \left(\frac{dV}{dz}\right)_{z=0} \qquad \text{(Eq. 2.1.09.21.0B-3)}$$

$$V_H = \frac{43.92}{6\pi} \sqrt{R^2 - (R-h)^2} \left(\frac{dV}{dz}\right)_{z=0} \qquad \text{(Eq. 2.1.09.21.0B-4)}$$

where

h = height of asperity on fracture surface, cm

$\left(\frac{dV}{dz}\right)_{z=0}$ = velocity shear at the fracture surface, s^{-1}

$\left(\frac{dV}{dz}\right) = 4V_{center}\left(\frac{1}{b} - \frac{2z}{b^2}\right) = \frac{4V_{center}}{b}$ when $z = 0$

z = distance from fracture surface, cm

V_{center} = water velocity at centerline of fracture (maximum velocity), cm/s

b = fracture aperture, cm.

Note that the expression for $\left(\frac{dV}{dz}\right)$ is calculated assuming a parabolic velocity profile for laminar flow in a parallel-plate channel (Reimus 1995 [DIRS 144604], Section 3.1.2): $V(z) = \frac{4V_{center}}{b^2}\left(bz - z^2\right)$

- Diffusion Force (F_d) and Characteristic Diffusion Velocity (V_d)—can act in both directions, but assumed to act away from the surface (Reimus 1995 [DIRS 144604], Section 3.2.1; note that the diffusion force is the thermal energy causing diffusion kT, divided by the distance over which diffusion acts, which in this case is h, the asperity height (the diffusion force is defined as **B**(t) on p. 28 of the reference); the diffusion velocity is the diffusion force divided by the frictional drag force, $6\pi\mu R$ (per Equations 18 and 26b of the reference)):

$$F_d = kT \qquad \text{(Eq. 2.1.09.21.0B-5)}$$

$$V_d = \frac{kT}{6\pi\mu Rh} \qquad \text{(Eq. 2.1.09.21.0B-6)}$$

where, k = Boltzmann's constant, 1.38×10^{-16} erg/K

T = absolute temperature, K.

Table 2.1.09.21.0B-1 lists the forces and velocities acting on 1-, 2- and 5-μm diameter spherical particles of density = 2.5 g/cm^3 (typical for a silicate) (SNL 2007 [DIRS 177423], Section I.1) at 35°C resting against an asperity with a height equal to half the particle diameter in an otherwise smooth horizontal parallel-plate fracture with an aperture of 1 mm and a flow velocity of 250 m/yr at the fracture centerline (considered to be at the high end of what would be experienced in a 1-mm fracture in the saturated zone). The physical situation is illustrated schematically in Figure 1.

Table 2.1.09.21.0B-1. Forces and Velocities Acting on a Spherical Particle Resting on a Horizontal Surface against an Asperity with Height Equal to Half the Particle Diameter (Figure 2.1.09.21.0B-1)

	Particle Diameter		
Force or Velocity	1 μm	2 μm	5 μm
F_g, dyne (g-cm/s^2)	7.7×10^{-10}	6.2×10^{-9}	9.6×10^{-8}
F_H, dyne	2.4×10^{-11}	9.7×10^{-11}	6.1×10^{-10}
F_d, dyne	8.5×10^{-10}	4.3×10^{-10}	1.7×10^{-10}
V_g, cm/s	1.2×10^{-4}	4.7×10^{-4}	2.9×10^{-3}
V_H, cm/s	3.7×10^{-6}	7.4×10^{-6}	1.8×10^{-6}
V_d, cm/s	1.3×10^{-4}	3.2×10^{-5}	5.2×10^{-6}

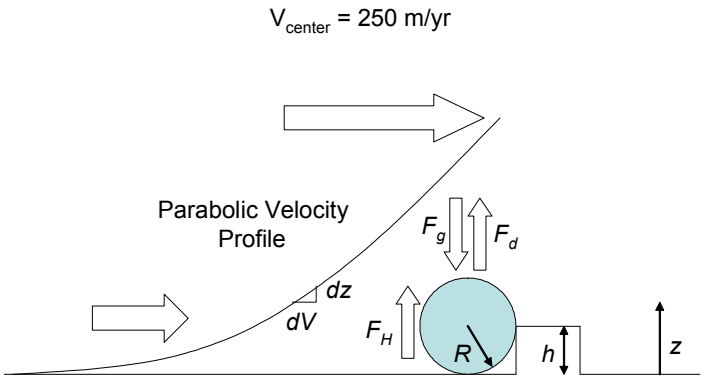

Figure 2.1.09.21.0B-1. Schematic Illustration of the Physical Situation Associated with the Forces and Velocities Calculated for Table 2.1.09.21.0B-1

Table 2.1.09.21.0B-1 shows that a 1-μm diameter particle can experience a diffusion velocity that is capable of freeing the particle from being pinned by gravity behind a 0.5-μm asperity. However, diffusion velocities *decrease* as R^l, while gravitational velocities *increase* as R^2. Thus, for a 2-μm-diameter particle, the gravitational velocity will be over an order of magnitude larger than the diffusion velocity, and for a 5-μm particle, the difference will be nearly 3 orders of magnitude. Therefore, gravity rapidly becomes the dominant force as particle sizes increase above 1-μm diameter. Also, as asperity height, l, increases, the diffusion velocity decreases, so the ability for diffusion to overcome gravity decreases.

It should be noted that the above analysis applies to inclined surfaces as well as horizontal surfaces. The only necessary correction for an inclined surface is that the gravity force vector must be separated into components parallel and perpendicular to the surface, and only the perpendicular component is considered (that is, $F_g(\cos\phi)$, where ϕ = angle between surface and horizontal). Although gravity becomes less important as fractures become more vertical, any particle larger than 1 μm in diameter will be incapable of transporting horizontally over long distances in rough-walled fractures that deviate even slightly from vertical, as expected over long distance scales. Furthermore, any particle that makes it through the volcanics will encounter saturated alluvium, which has numerous pores and asperities capable of trapping particles. Seismic events or flow transients could result in some particle remobilization, but the particle transport distances after remobilization would be limited by the processes described above.

Even if there were laterally extensive vertical fractures in the saturated zone, a sustained upward vertical component of groundwater velocity of ~25 m/yr would be required to keep a 1-μm-diameter particle of 2.5 g/cm^3 density translating horizontally through such a fracture. Upward vertical groundwater velocities this high are not expected in the saturated zone because there is no definitive geochemical signature from the carbonate aquifer in the volcanics or alluvium (SNL 2007 [DIRS 177391], Appendix A, Section A6.3.2) despite the significant upward vertical gradient from the carbonate aquifer to the overlying volcanics (SNL 2007 [DIRS 177391], Section 6.3.1.5). While upward groundwater velocities of ~25 m/yr cannot be completely discounted, they would have to be highly localized with low volumetric flow rates to preclude a geochemical signature.

The preceding paragraphs demonstrate that it is not expected that conditions will exist under which radionuclide-bearing particles larger than 1 μm might transport over long distances in the saturated zone. The number of radionuclide-bearing particles larger than colloids that could travel through the saturated zone to the compliance boundary is expected to be extremely small compared to the number of radionuclide-bearing colloids that travel through the saturated zone to the compliance boundary.

In conclusion, transport of particles larger than colloids is screened out on the basis of low consequence because: (1) the variable orientation and roughness of the fracture and alluvium surfaces along saturated zone transport pathways promote both settling and filtration of particles larger than colloids, and (2) vertical velocity components in the saturated zone are not expected to be large enough to keep particles larger than 1 μm in diameter suspended indefinitely.

Based on the previous discussion, omission of FEP 2.1.09.21.0B (Transport of Particles Larger Than Colloids in the SZ) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.21.0C

FEP NAME:

Transport of Particles Larger than Colloids in the UZ

FEP DESCRIPTION:

Particles of radionuclide-bearing material larger than colloids could be entrained in suspension and then be transported in water flowing through the UZ.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses particles larger than colloids (diameter > 1 μm) that could potentially facilitate the transport of radionuclides in the unsaturated zone. Particles larger than colloids that are generated in the waste package environment (SNL 2007 [DIRS 177423], Section 1.2) are not considered to move through the EBS (see excluded FEP 2.1.09.21.0A (Particles Larger than Colloids in Engineered Barrier System)), so particles with irreversibly sorbed radionuclides that originate in the waste package environment can be excluded from the unsaturated zone on this basis. Transport of other radionuclide-bearing particles larger than colloids in the unsaturated zone is not expected to have an adverse effect on performance because the size and density of these particles will favor settling from solution. In addition, particles with a relatively large radius are expected to become entrapped in pore throats and attach to immobile air-water interfaces in the unsaturated zone. Finally, inorganic particles larger than 1 μm will settle much more rapidly than they diffuse (Reimus 1995 [DIRS 144604], Section 3.2; see also excluded FEP 2.1.09.21.0B (Transport of Particles Larger than Colloids in the SZ)), so diffusion is not expected to contribute significantly to their transport in the unsaturated zone. Indeed, the small diffusivities and large settling velocities of particles will tend to cause particles that are advectively imbibed into the rock matrix from fractures during wetting/drying cycles to remain immobilized in the matrix instead of diffusing back into fractures.

Although it cannot be ruled out that a small number of particles larger than colloids might transport through the unsaturated zone, for the reasons stated above, the number of such particles is expected to be very small compared to the number of colloids transported through the unsaturated zone. Colloid transport in the unsaturated zone is included in TSPA (FEP 2.2.08.10.0B (Colloidal Transport in the UZ)) because although colloids are subjected to the same transport processes as larger particles, they settle more slowly, diffuse more rapidly, fit through smaller pore throats, and advectively collide with air-water interfaces to a lesser extent than larger particles.

Based on the previous discussion, omission of FEP 2.1.09.21.0C (Transport of Particles Larger Than Colloids in the UZ) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate

compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.22.0A

FEP NAME:

Sorption of Colloids at Air-Water Interface

FEP DESCRIPTION:

Colloids may be sorbed irreversibly at the air-water interface under partially saturated conditions.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Colloid sorption at the air-water interface may occur within the waste package and invert, as well as in the unsaturated zone and saturated zone. Both hydrophilic and hydrophobic colloids may be sorbed irreversibly at the air-water interface under partially saturated conditions. Colloid attachment to air-water interfaces commonly occurs in unsaturated environments and may limit mobile colloid generation and migration (SNL 2007 [DIRS 177423], Section 5.8). This phenomenon is dependent on the interface surface area, electrostatic charge on the particles, and the salinity of the aqueous phase (SNL 2007 [DIRS 177423], Section 5.8).

At low water saturations, air-water interfaces are extensive, and although colloid migration is retarded, colloids still diffuse through the adsorbed water films if these films are adequately thick. At intermediate water saturations, there is still an interconnected gas phase, but relative air-water interface areas are lower. The interface is expected to act as a static surface able to irreversibly sorb colloids, although this process is not credited in the model (SNL 2007 [DIRS 177423], Section 7.2). At high water saturations, the air is present as small bubbles, some of which are mobile in groundwater. Trapped bubbles will immobilize some colloids, potentially resulting in a net decrease in colloidal transport.

A number of features are expected to prevent transport of air interface-attached particles under fully saturated conditions. The interfacial area should be low. Increasing hydrostatic pressure with depth in the saturated zone should cause dissolution of small bubbles. Also, buoyant forces would hinder downward bubble movement in the saturated zone. Electrostatic interactions between the rock matrix and particles might likewise slow the transport of the latter.

In partially saturated media, liquid film straining would produce immobile air-water interfaces in confined domains (e.g., pendular rings in pores or fractures) as a result of capillary forces. Therefore, transport of colloid particles attached to these thin film interfaces are not expected to be mobile in unsaturated media (SNL 2007 ([DIRS 177407], Section 6.3.4.4, p. 6-101). Particles attached to air-water interfaces that are part of flowing films would tend to move rapidly through the unsaturated zone. However, flowing films are only expected if the matrix is nearly saturated and if water is tending to flow from the matrix into fractures (BSC 2004 [DIRS 170035], Section 6.1.3). These conditions may occur locally and for short periods of time, but it is not

considered plausible that they would persist over long distances or long times because fracture contact points will disrupt films. Also, continuous films would be difficult to maintain across lithological contacts that exist in the unsaturated zone because of the discontinuities in fractures that often occur at such contacts as well as the changes in matrix properties that give rise to differences in matrix potential and saturation across such contacts. Episodic flow events might cause short-term movement, but each flow event is expected to be followed by matrix imbibition of water and evaporation in the matrix, which will contribute to particle immobilization in pores. Furthermore, such episodic flow below the Paintbrush Tuff nonwelded hydrogeologic unit (PTn), which is above the repository horizon, is excluded in FEP 2.2.07.05.0A (Flow in the Unsaturated Zone from Episodic Infiltration).

Excluding consideration of retention at the air-water interface will overestimate the potential impact to radionuclide releases of colloid-facilitated transport of radionuclides.

Based on the previous discussion, omission of FEP 2.1.09.22.0A (Sorption of Colloids at Air–Water Interface) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.23.0A

FEP NAME:

Stability of Colloids in EBS

FEP DESCRIPTION:

For radionuclide-bearing colloids to affect repository performance, they must remain suspended in the groundwater (i.e., be stable) for time scales that are long relative to the time required for groundwater travel. Further, they must carry significant concentrations of radionuclides. The stability of smectite colloids (applicable for natural groundwater colloids and waste form colloids) is determined primarily by ionic strength but also to an extent by pH. The stability of iron-(hydr)oxide colloids (applicable to corrosion-product colloids) is determined by both ionic strength and pH.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Colloids in the model developed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.3.1) are: waste form colloids (modeled as montmorillonite, "ZrO_2" and meta-autunite); corrosion product colloids (modeled as hematite, hydrous ferric oxide, and goethite); and in-drift/groundwater colloids (modeled as montmorillonite). Their stabilities are determined from ionic strength and pH of the in-package and in-drift fluids, as calculated in the TSPA model.

The colloid stabilities and mass concentrations are determined at each time step executed in the TSPA model calculations taking into account waste package and invert fluid properties (pH and ionic strength) to calculate the colloid mass concentrations entering the invert from the waste package (SNL 2007 [DIRS 177423], Section 6.5.2.1 and Figure 6-29). These determinations are then combined with the sorption analysis to calculate the colloid source term for radionuclides (SNL 2007 [DIRS 177423], Sections 6.5.2.2 to 6.5.2.3 and Figures 6-30 to 6-31). Colloid stability is governed by the Derjaguin-Landau-Verwey-Overbeek theory; which dictates that colloids become unstable at higher ionic strengths. The solution pH and the surface charge are utilized to determine the ionic strength threshold for colloid stability (SNL 2007 [DIRS 177423], Section 6.3.2). Uncertainty associated with colloid stability is discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.6.7). The primary uncertainties in the colloid model are the abundances of the colloid type at a given solution composition and the sorption coefficients that are used to partition radionuclides onto the colloid type (SNL 2007 [DIRS 177423], Section 6.6). Laboratory measurement uncertainties are large contributors to both. Uncertainty is captured and propagated in the model by sampling over a range of colloid concentrations and radionuclide uptake characteristics.

Diffusion of Colloids in EBS

FEP DESCRIPTION:

Colloidal particles, together with any associated actinides, that are sufficiently small may be transported through the EBS by diffusion.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The formation, stability, and concentration of colloids are addressed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423]). Three types of colloids are anticipated to exist in the EBS (SNL 2007 [DIRS 177423], Section 6.3.1): (1) waste form colloids from degradation of HLW glass and commercial SNF, (2) iron oxyhydroxide colloids due to products from the corrosion of steel waste packages, and (3) groundwater or seepage water colloids. On all three types of colloids, radionuclides may undergo reversible, or equilibrium, sorption. The waste form colloids may also contain embedded radionuclides that are not removable. Plutonium and americium can be strongly sorbed onto iron oxyhydroxide; for these radionuclides, sorption is modeled as a kinetic process.

The general colloid-facilitated diffusive transport model and implementation in the TSPA are described in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.4.4). The concentration of colloids in each region of the EBS, specifically in the waste form domain, the waste package corrosion products domain, and the invert domain, is determined in part by the local chemical environment. The diffusion coefficient for colloidal particles (colloid diffusivity) is dependent on temperature and a sampled colloid particle size using the Stokes-Einstein equation (Bird et al. 1960 [DIRS 103524], Equation 16.5-4, p. 514). This is implemented accordingly in the TSPA. A discussion of colloid transport in the EBS is presented in Sections 6.3.4.4 and 6.5.1.2 of *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407]). Other factors involving diffusion areas and path lengths are also specified in the RTA model.

The RTA model developed in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407]) is used to quantify the time-dependent radionuclide releases from a failed waste package and their subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, water chemistry), and the degradation state of the EBS components (SNL 2007 [DIRS 177407], Section 6.1). Outputs consist of the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of

colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials (SNL 2007 [DIRS 177407], Section 8.2). The RTA model is implemented directly into the TSPA model to compute the radionuclide release rates from the EBS (SNL 2007 [DIRS 177407], Section 6.5.2). A summary of the computational model provided to the TSPA, including model parameter uncertainty implementation, is described in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.5.2 and Table 8.1-1).

The source of inflow to the EBS is the seepage flux that drips from the crown (roof) of the drift, drift wall condensation, and imbibition flux from the unsaturated zone into the invert. This inflow can flow through the EBS along eight pathways: (1) seepage flux and drift wall condensation, (2) flux through the drip shield, (3) diversion around the drip shield, (4) flux through the waste package, (5) diversion around the waste package, (6) flux from the waste package into the invert, (7) imbibition flux from the unsaturated zone matrix to the invert, and (8) flux from the invert to the unsaturated zone (SNL 2007 [DIRS 177407], Section 6.3.1.1 and Figure 6.3-1). These pathways are time dependent, because drip shield penetrations and waste package penetrations will vary with time and local conditions in the repository. Diffusive transport may occur via flow pathways 4, 6, and 8 (SNL 2007 [DIRS 177407], Section 6.3.1.2).

The advective transport of colloids in the EBS is discussed in included FEP 2.1.09.19.0B (Advection of Colloids in EBS). The advective transport of dissolved radionuclides is addressed in included FEP 2.1.08.08.0B (Advection of Dissolved Radionuclides in EBS).

FEP: 2.1.09.25.0A

FEP NAME:

Formation of Colloids (Waste-Form) by Co-Precipitation in EBS

FEP DESCRIPTION:

Dissolved radionuclides and other ions may coprecipitate to form colloids. Coprecipitates may consist of radionuclides bound in the crystal lattice of a dominating mineral phase or may consist of radionuclides engulfed by a dominating mineral phase.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Colloids formed via coprecipitation during the degradation of defense HLW glass and SNF have been observed (SNL 2007 [DIRS 177423], Section 6.3.2.2 and Figure 6-2). Colloids produced from degradation of defense HLW glass are modeled as smectite colloids (SNL 2007 [DIRS 177423], Section 4.1) with "embedded" (assumed permanently attached) radionuclides, specifically those of plutonium and americium. These may, in a broad sense, be considered coprecipitates. SNF colloids are modeled as uranophane/meta-autunite and ZrO_2 (SNL 2007 [DIRS 177423], Section 6.3.2.5).

The concentrations of radionuclides associated with these colloids are based on empirical results from YMP-relevant defense HLW glass and SNF corrosion experiments (SNL 2007 [DIRS 177423], Sections 6.3.2.2). Mass concentrations of the particular colloids are based on those experiments with consideration of colloid mineralogy and the effects of ionic strength and pH on the stability of the colloids (SNL 2007 [DIRS 177423], Sections 6.3.2.3 and 6.3.2.4). Plutonium and americium associated with defense HLW colloids are modeled in the TSPA as "irreversibly attached" because they are embedded within the colloid matrix and can only be released upon the dissolution of the colloid. However, other radionuclides (thorium, protactinium, cesium, neptunium, radium, uranium, and tin) within the aqueous environment can reversibly attach to the surfaces of these colloids, and these colloid-radionuclide complexes can therefore be subject to transport in the TSPA model as pseudocolloids (i.e., when radionuclides attach to preexisting colloids) (SNL 2007 [DIRS 177423], Section 6.3.1). Radionuclide sorption onto these pseudocolloids is modeled by assigning K_d values (SNL 2007 [DIRS 177423], Section 6.3.2.5). Similar to natural groundwater smectite colloids, the pseudocolloid stability is controlled by ionic strength and pH.

The primary uncertainties in the colloid model are the abundances of this colloid type at a given solution composition and the sorption coefficients that are used to partition radionuclides onto this colloid type (SNL 2007 [DIRS 177423], Section 6.6). Laboratory measurement uncertainties are large contributors to both. Uncertainty is captured and propagated in the model by sampling over a range of colloid concentrations and radionuclide uptake characteristics.

FEP: 2.1.09.26.0A

FEP NAME:

Gravitational Settling of Colloids in EBS

FEP DESCRIPTION:

Over the relatively short transport distances within the waste package, colloidal particles may experience gravitational settling, thereby inhibiting transport.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The TSPA considers that all radionuclide-bearing colloids generated from waste form degradation within a failed waste package will leave the waste package and enter the drift and EBS minus any radionuclides that decay along the way. Settling of these radionuclide-bearing colloids could result in some retardation of colloid transport. Gravitational settling of colloids is assumed not to occur, resulting in all stable colloids formed within the waste package potentially being able to leave the breach to enter the invert (SNL 2007 [DIRS 177407], Section 5.7). Slow diffusion may limit this movement. Implementation of this assumption results in overestimates of the potential consequences of colloid-facilitated transport of radionuclides (SNL 2007 [DIRS 177407], Section 6.3.4.4, p. 6-101).

Based on the previous discussion, omission of FEP 2.1.09.26.0A (Gravitational Settling of Colloids in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.27.0A

FEP NAME:

Coupled Effects on Radionuclide Transport in EBS

FEP DESCRIPTION:

Repository induced changes to the physical and chemical properties of the EBS and waste form may be important for evaluating radionuclide transport in the EBS. The existence of chemical gradients within the disposal system, resulting from repository material, waste emplacement, and corrosion products, may influence the transport of dissolved and colloidal species. This could include: geochemical reactions that move (pump) radionuclides; effects on advection, diffusion, and sorption within and through failed waste packages; and microbial and electrochemical effects.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Coupled processes refer to two or more physical and chemical processes interacting simultaneously to produce a physical or chemical effect, or to cases where a process is affected by chemical and physical processes at the same time. Onsager couplings refer specifically to chemical transport that is driven indirectly by gradients of thermodynamic state variables (e.g., temperature, pressure, chemical potential, and electrical potential). The coupled processes considered in the TSPA involve the transport of chemicals, including radionuclides, which can affect dose calculations. The bulk of the coupled processes are covered in other FEPs cited below. The present FEP covers the two coupled processes that are not covered elsewhere, specifically, thermal diffusion of water vapor and gas and the development of electric fields around waste packages.

Other FEPs listed here cover various combinations of coupling between thermal, hydrologic, mechanical, chemical, and microbial processes. Thermal-hydrologic processes are addressed in included FEPs 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)) and 2.1.08.11.0A (Repository Resaturation due to Waste Cooling). Thermal-mechanical processes are addressed in excluded FEPs 2.2.01.02.0A (Thermally-Induced Stress Changes in the Near-Field), 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository), 2.2.10.04.0B (Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository), and 2.2.10.05.0A (Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository). Thermal effects on chemical equilibria are examined in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3), *Drift Scale THC Seepage Model* (SNL 2007 [DIRS 177404], Section 6.2.1) and *In-Drift Precipitates/Salts Model* (SNL 2007 [DIRS 177411], Section 6.3). Such effects are also discussed in included FEPs 2.1.09.01.0A (Chemical Characteristics of Water in Drifts) and 2.1.11.08.0A (Thermal Effects on Chemistry and Microbial Activity in the EBS). Thermal effects on chemical reaction rates are explicitly included in *Drift-Scale THC Seepage Model*

(SNL 2007 [DIRS 177404], Section 6.4), as well as in included FEP 2.1.09.07.0B (Reaction Kinetics in Drifts). Coupled effects concerning chemical reactions of the different waste forms are discussed in included FEPs 2.1.02.01.0A (DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)), 2.1.02.02.0A (CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)), and 2.1.02.03.0A (HLW Glass Degradation (Alteration, Dissolution, and Radionuclide Release)). The thermal diffusion effect (Soret effect) on radionuclide transport is discussed in excluded FEP 2.1.11.10.0A (Thermal Effects on Transport in EBS). Hydrologic-chemical processes are discussed in the following FEPs for the unsaturated zone, included FEPs 2.2.07.04.0A (Focusing of Unsaturated Flow (Fingers, Weeps)), 2.2.07.06.0B (Long-Term Release of Radionuclides from the Repository), 2.2.07.08.0A (Fracture Flow in the UZ), 2.2.10.10.0A (Two Phase Buoyant Flow/Heat Pipes), and 2.2.07.18.0A (Film Flow into the Repository); for the EBS, included FEPs 2.1.08.05.0A (Flow through Invert), 2.1.08.07.0A (Unsaturated Flow in the EBS), and excluded FEP 2.2.07.06.0A (Episodic or Pulse Release from Repository); and for the saturated zone, included FEP 2.2.08.08.0A (Matrix Diffusion in the SZ). Microbial effects on sorption in the EBS are considered to be of low consequence in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS). Chemical-hydrologic processes are addressed in excluded FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ) as part of the unsaturated zone and drift near-field analysis. Chemical effects on rock fracture permeability are considered in excluded FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)). Chemical-mechanical processes are addressed in included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages).

Electrochemical processes of electrophoresis and galvanic coupling are considered in excluded FEP 2.1.09.09.0A (Electrochemical Effects in EBS). One additional Onsager coupled process that has not been addressed elsewhere is the development of electric fields around waste packages by Compton scattering and its exclusion is justified here. The generation of electric fields around waste packages is caused by Compton electron scattering was evaluated by Green et al. (1987 [DIRS 170174]). The authors (Green et al. 1987 [DIRS 170174]) calculated the field in direct contact with a wasteform representing a single PWR fuel assembly, assuming completely degraded canisters with no shielding effect by the cladding or the canister wall, and determined that a relatively strong electrical field could form in air, but only very weak fields in rock. Because radionuclide transport pathways from the waste package are through the invert, only weak electrical fields are anticipated. The geometry of the waste forms and waste packages at Yucca Mountain differs from that assumed by Green et al. (1987 [DIRS 170174]); however, their results are bounding for the external surface of a Yucca Mountain waste package. Yucca Mountain waste packages hold up to 21 PWR assemblies; however, the radiation flux at any given point within the package is much less than 21 times the flux on the surface of a single assembly because the flux decreases as a function of the square of the distance; more-distant assemblies contribute much less to the flux than those nearby. Although the net radiation flux within the package is greater than estimated by Green et al. (1987 [DIRS 170174]), the flux on the outside of the waste package, despite the presence of multiple assemblies, is less. In Yucca Mountain waste packages, dose rates will be severely limited by the steel and Alloy 22 waste package wall, which decreases the gamma dose by a factor of 30 to 50, based on a comparison of the gamma dose rate calculated for the inner radial waste package surface to that calculated for the same segment on the outer radial waste package surface (BSC 2004 [DIRS 172227] Tables 6.1-1 and 6.1-2). Furthermore, the Green et al. (1987 [DIRS 170174]) fluxes are overestimates because they assume a line source, resulting in extremely high gamma fluxes close

to the source and a steep radial gradient in flux with distance; this results in large electrical fields relative to those that would be expected around a waste package more than 1.5 m in diameter. Finally, the gamma dose rate decreases exponentially as a function of time making Compton scattering less significant over time. Because the electrical field generated by Compton scattering will be small in the invert, and the effect decreases rapidly with time, the effects of electrical fields generated by Compton scattering are expected to be insignificant and are excluded from the TSPA on the basis of low consequence.

The hydrologic-thermal coupled process that has not been screened above is thermal redistribution of water and gases, which might occur where steep thermal gradients exist. Its exclusion is justified here, and in excluded FEP 2.1.11.10.0A (Thermal Effects on Transport in EBS). In the EBS, areas with steep temperature gradients during the heating pulse will often have temperatures above the boiling point of water. Therefore, there will be little or no liquid available for thermal (Soret) diffusion. When temperatures are below the boiling point of water, the coupled effect of thermo-diffusion and thermo-gravitation (thermal convection of the gas phase) could affect relative humidity distributions. This coupling can cause the separation of water vapor and gas in empty spaces between hot and cold surfaces. This separation may induce the formation of spatially specific relative humidity environments with respect to the geometry of EBS components in the drift, and could therefore affect corrosion of EBS materials through the formation of water condensate. Vidal and Murphy (1999 [DIRS 171801]) conclude that gaps between the relatively hot and cold surfaces (i.e., waste package and drip shield or drip shield and drift wall) of less than 5 cm, coupled with thermal gradients greater than 1°C cm^{-1} can generate significant thermo-gravimetric and thermo-diffusive effects. However, the gaps between waste package and drip shield, and drip shield and drift wall, are very much larger than those considered in their study (SNL 2007 [DIRS 179354], Table 4-1, Parameter Numbers 02-01 and 02-02; Table 4-2, Parameter Number 07-01), and thermal gradients in the EBS are much smaller. Sensitivity analyses in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.11), using different invert hydrologic parameters, indicate that a typical temperature difference just after the drift wall boiling period, from the top to the bottom of the invert (because of the insulating effect of the crushed tuff, thermal gradients in the invert are large relative to those in other parts of the EBS), a distance of approximately 1.3 m (SNL 2007 [DIRS 179354], Table 4-1, Parameter 01-10), is on the order of 5°C. The gradient decreases with time and after a few thousand years is less than a 1°C. Because the thermal gradients are so small within the EBS, this effect is excluded from TSPA on the basis of low consequence.

Based on the previous discussion, omission of FEP 2.1.09.27.0A (Coupled Effects on Radionuclide Transport in EBS) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 6321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.28.0A

FEP NAME:

Localized Corrosion on Waste Package Outer Surface Due to Deliquescence

FEP DESCRIPTION:

Salt-containing dust, which could accumulate on the waste package surface during the preclosure ventilation period, can absorb moisture from the drift atmosphere, even at low relative humidity, dissolving the salt and creating concentrated aqueous solutions. This deliquescence process may result in localized surface chemistry that could cause penetration of the waste package outer barrier by localized corrosion.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The analysis for this FEP discusses the potential for dust deliquescence to influence the localized corrosion of the waste package. An analysis of the general corrosion of the waste package is presented in included FEP 2.1.03.01.0A (General Corrosion of Waste Packages), while an analysis of localized corrosion of the waste package due to other causes (such as seepage) is presented in included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages).

Dust will be deposited on the surfaces of waste packages in emplacement drifts primarily during the operational and the preclosure ventilation periods. After closure of the repository, there is a period of up to 1,000 years in which limited seepage is possible because much of the drift wall temperature is above the boiling point of water (SNL 2008 [DIRS 184433], Figure 6.3-78[a]). During this interval and for as long as the drip shields perform their function, the only aqueous phase that could potentially contact the waste package outer surface is brine that originates by deliquescence of soluble salts in dust residing on the waste package. The potential for brines formed by dust deliquescence to initiate and sustain localized corrosion that results in failure of the waste package outer corrosion barrier has been evaluated in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Sections 7.1 and 7.1[a]). This evaluation shows that dust deliquescence-induced localized (primarily crevice) corrosion of the waste package outer corrosion barrier (Alloy 22) is of low consequence with respect to repository performance (SNL 2007 [DIRS 181267], Sections 7.1.5 and 7.1[a]).

Measured atmospheric and underground dust compositions are the basis of thermodynamic modeling and experimental studies used to evaluate the likelihood of brine formation (SNL 2007 [DIRS 181267], Sections 6.1 and 6.1[a]) and persistence (SNL 2007 [DIRS 181267], Sections 6.2 and 6.2[a]), the volume of brines that may form (SNL 2007 [DIRS 181267], Section 6.4), and the relative corrosivity of the initial deliquescent brines and of brines modified by processes on the waste package surface (SNL 2007 [DIRS 181267], Section 6.3). In addition, several mechanisms are evaluated that could inhibit or stifle localized corrosion should it initiate (SNL 2007 [DIRS 181267], Sections 6.5 and 6.5[a]).

The dust compositions considered include both tunnel and atmospheric dust samples from Yucca Mountain, as well as National Airfall Deposition Program precipitation data representing atmospheric dust compositions in southwestern Nevada. Also considered is the thermal decomposition of ammonium salts, a process that could affect soluble dust quantity and composition prior to deliquescence. Ammonium chlorides, nitrates, and, to some extent, sulfates thermally decompose into ammonia and acid gasses, and will be lost from the surface of the waste package prior to deliquescence (SNL 2007 [DIRS 181267], Section 6.1.2.3).

Justifications are developed using a logical framework approach, considering a wide range of dust and brine compositions, conditions on the waste package, and processes (SNL 2007 [DIRS 181267], Sections 1.1 and 7). Uncertainty or variation in the input parameter values, within a reasonable range, will not change the conclusions drawn in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Section 7). In order for dust deliquescence-induced localized corrosion to significantly affect the performance of the waste package outer corrosion barrier, each of the following five propositions must be answered in the affirmative (SNL 2007 [DIRS 181267], Section 1.1). Analysis does not support an affirmative answer to all of these propositions, as shown below:

(1) *Can multiple-salt deliquescent brines form at elevated temperature?* Yes (see SNL 2007 [DIRS 181267], Table 7-2[a]). As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Section 7.1.1), multiple-salt deliquescent brines can form at elevated temperatures (above 120°C). Ammonium salts can comprise a significant fraction of the salts in atmospheric dust, but most thermally decompose and will not persist long enough to contribute to deliquescent mineral assemblages, thus decreasing the salt load available for deliquescence. Boiling points of saturated salt solutions represent the maximum temperature of deliquescence at a given pressure. For most single-salt phases (nitrates, chlorides, and carbonates), boiling points at one atmosphere are limited to temperatures below 120°C. Saturated multiple-salt mixtures always boil at higher temperatures than the individual salt components. The boiling points for important salt assemblages predicted to occur on the waste package surface have been investigated experimentally. The two-salt mixture $NaCl + KNO_3$ boils at a maximum temperature of 134°C and both the three-salt mixture, $NaCl + KNO_3 + NaNO_3$, and four-salt mixture, $NaCl + KNO_3 + NaNO_3 + Ca(NO_3)_2$, with specific proportions can transition directly to anhydrous melts (i.e., they do not exhibit a maximum boiling temperature).

(2) *If deliquescent brines form at elevated temperature, will they persist?* Sometimes (see SNL 2007 [DIRS 181267], Table 7-2[a]). As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Sections 7.1.2 and 7.1[a]), multiple-salt brines can persist on the waste package surface but are not stable. Acid degassing will occur rapidly at first, increasing the pH to near-neutral or alkaline conditions. Further acid degassing in conjunction with carbon dioxide uptake can result in decreasing brine volume, and will convert the four-salt calcium-containing mixture to the three-salt mixture (SNL 2007 [DIRS 181267], Section 6.2.2[a]). Degassing of HCl and HNO_3 from brines dominated by monovalent salts (e.g., NaCl, $NaNO_3$, KNO_3) also raises the pH, and the potential result is precipitation of less deliquescent salts (e.g., $NaHCO_3$). However, sufficient degassing

to result in complete dryout is not expected for monovalent brines. Should dryout occur, these salts may subsequently deliquesce at lower temperature and higher relative humidity, producing brines with higher pH than the original assemblage. Higher pH brines are generally more benign with respect to localized corrosion (SNL 2007 [DIRS 181267], Section 7.1.2) and the localized corrosion model for Alloy 22 reflects this in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Figures 6-49 and 6-50).

(3) *If deliquescent brines persist, will they be corrosive?* Not expected (see SNL 2007 [DIRS 181267], Table 7-2[a]). As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Sections 7.1.3 and 7.1[a]), brines formed by deliquescence of tunnel dusts or atmospheric aerosols are generally benign, and will remain so as they are modified by processes that occur on the waste package surface. The effects of an added component of cement dust on deliquescent brine composition is discussed in excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Material in EBS). Nitrate is a significant moderator of localized corrosion, as the YMP confirmed at 180°C (SNL 2007 [DIRS 181267], Section 6.4.2.2[a]). This conclusion is also supported by experimental observations by Dunn et al. (2004 [DIRS 173813]), which show that a nitrate-to-chloride ion concentration ratio greater than 0.1 can effectively inhibit localized corrosion of mill-annealed Alloy 22 in 4 M $MgCl_2$-based solutions at 110°C.

Nitrate is a major component of the soluble fraction of atmospheric air (as determined by samples from both cyclonic and rainout collectors). Initial brines formed by deliquescence of multiple-salt assemblages will have near-neutral pH, and they will be relatively nitrate-rich and chloride-poor. Experimental corrosion studies used to develop the localized corrosion model have verified that corrosion will not be initiated by nitrate-rich brines (nitrate-to-chloride ratio at 0.5 or greater) at temperatures below 120°C (SNL 2007 [DIRS 178519], Table 7-6). Higher-temperature data indicate that general corrosion mechanisms do not change up to temperatures of 220°C (SNL 2007 [DIRS 181267], Section 6.3.1.4). This suggests that the same chemical processes (thermodynamics and relative kinetics), which provide nitrate inhibition of localized corrosion, probably continue to be effective at similarly elevated temperatures. Processes occurring after deliquescence, including acid degassing and reactions with silicate minerals, do not result in corrosive brines (SNL 2007 [DIRS 181267], Section 6.3.4). Acid degassing has a beneficial effect, where even small degrees of degassing will result in increases in the brine pH, to values ranging from near-neutral to alkaline. Brine interactions with silicate minerals may also buffer the pH to near-neutral or slightly alkaline values, and may lead to dryout by precipitation of a less deliquescent salt or mineral assemblage.

In addition, as the pH rises due to acid degassing, carbonate and bicarbonate concentrations increase. According to Dunn et al. (2004 [DIRS 173813]) carbonate anions are almost as effective as nitrate anions at inhibiting the initiation of localized corrosion on Alloy 22, while bicarbonate anions inhibit localized corrosion of Alloy 22 to a lesser extent.

(4) *If deliquescent brines are potentially corrosive, will they initiate localized corrosion?* No (SNL 2007 [DIRS 181267], Table 7-2[a]). As stated above, the brines resulting from dust deliquescence are generally nitrate-rich, chloride-poor, with near-neutral pH and are, therefore, not considered to be corrosive. As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Section 7.1.4), the volume of brines formed by deliquescence will be so limited that even if the brines were to be considered corrosive, they are not expected to initiate localized corrosion outside of tight crevices. Considering the effects of ammonium salt removal from dust, and assuming that the soluble component of repository dust derives from atmospheric aerosols, the maximum deliquescence brine volume is calculated to be 1.8 $\mu L/cm^2$ at 120°C or higher (SNL 2007 [DIRS 181267], Section 7.1.4). This value presumes that all salt components in the dust are in mutual contact so that eutectic salt mixtures occur. However, repository dust is heterogeneous and consists mostly of non-deliquescent minerals (e.g., rock-forming minerals) that can physically separate the salt components, so the brine volume estimate is potentially high.

Capillary and surface tension effects in the dust are expected to reduce brine contact with the waste package surface and inhibit brine flow into pores or crevices. Dust samples collected from the Exploratory Studies Facility have been characterized to evaluate the potential for capillary retention of the brine within the dust layer, decreasing the availability of brine for contact with the Alloy 22 surface. The results indicate that the capillary response of the dust is characterized by a typical dimension of about one micron (SNL 2007 [DIRS 181267], Section 7.1.4). This dimension suggests that brine mobility within the dust will be inhibited, and that roughness on the metal surface would need to have similar dimensions in order to compete successfully for the brine.

(5) *Once initiated, will localized corrosion penetrate the waste package outer barrier?* No (see SNL 2007 [DIRS 181267], Table 7-2[a]). Several processes will act to slow or stifle and often arrest localized corrosion before penetration of the waste package outer corrosion barrier can occur.

In order for a propagating crevice to remain active, the critical crevice solution contained within the crevice must be maintained such that the metal surface does not repassivate. As an active crevice propagates, material loss due to corrosion will lead to an increase in the crevice gap. If the resulting crevice gap becomes too large, the mass transport limitation required to maintain the critical crevice solution within the crevice will be lost and the localized corrosion will cease (SNL 2007 [DIRS 181267], Section 6.5.1[a]). Also, as corrosion products accumulate in the corrosion cell, cathodic limitation can result from secondary products that precipitate and coat the metal surface, causing the cessation of localized corrosion in that area.

A power-law description of localized crevice corrosion penetration, which is an alternative conceptual model in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.4.8), is applicable to Alloy 22, as well as many other materials. According to this power law, the corrosion rate slows with time. Laboratory data show that stifling of crevice corrosion in

Alloy 22 occurs (SNL 2007 [DIRS 181267], Section 7.1.5). Thus, the depth of localized corrosion penetration will be limited, with one extrapolation indicating that the localized-corrosion propagation rate would require approximately one-million years to penetrate 20 mm of Alloy 22 (SNL 2007 [DIRS 181267], Section 6.5.1[a]). All of the crevice corrosion stifling experiments to date have been performed under inundated conditions, the solutions representing a near-infinite source of reactive species (e.g., chloride). The brine quantity and the amount of reactive components are extremely limited in the environment produced by dust-deliquescence, and it is expected that stifling will be even more efficient under such conditions.

In summary, brines formed by deliquescence of tunnel and atmospheric dusts are not expected to be aggressive with respect to initiating localized corrosion. Processes that act to modify the brines on the waste package surface are beneficial with respect to corrosivity. Should corrosive brines form, scale factors related to brine volume will inhibit initiation of localized corrosion. Furthermore, should localized corrosion initiate, several processes will act to limit or stifle it, and would ensure that penetration of the waste package outer corrosion barrier will not occur (SNL 2007 [DIRS 181267], Sections 7 and 7.1[a]).

Based on the previous discussion, omission of FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.09.28.0B

FEP NAME:

Localized Corrosion on Drip Shield Surfaces Due to Deliquescence

FEP DESCRIPTION:

Salt-containing dust, which could accumulate on the drip shield surface during the preclosure ventilation period, can absorb moisture from the drift atmosphere, even at low relative humidity, dissolving the salt and creating concentrated aqueous solutions. This deliquescence process may result in localized surface chemistry that could cause penetration of the drip shield surface by localized corrosion.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

The rationale for the exclusion of localized corrosion of the drip shields from the TSPA model under seepage conditions is presented under excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shields). This FEP justifies exclusion from the TSPA model of localized corrosion of the drip shields in the absence of seepage, when the aqueous conditions upon the drip shield are due to deliquescence of material residing on the surfaces of the drip shield.

Dust will be deposited on the surfaces of drip shields primarily during their emplacement. Unlike the waste packages, which will see dust accumulation throughout the operational and preclosure ventilation periods, the drip shields will not be subject to such an extended accumulation period, as they are emplaced upon completion of the ventilation period. As such, the quantity of dust deposited on the surface of the drip shields will be lower than that on the waste package surface and be composed predominantly of tunnel dust, rather than atmospheric aerosols. Tunnel dust is composed primarily of powdered rock and contains a much lower soluble salt concentration (<<1%) than atmospheric aerosols (10% to 20%) (SNL 2007 [DIRS 181267], Section 6.1). As a result, the volume of brine produced by such dusts will be lower on a per mass basis than that present in the atmospheric aerosols that will reside on the surface of the waste packages following the ventilation period. Therefore, as the maximum brine quantity on the waste package surface has been calculated to be 1.8 $\mu l/cm^2$ at 120°C (SNL 2007 [DIRS 181267], Section 6.4.1.2), the quantity on the surface of the drip shields will be much lower due to the lower concentration of soluble salts in the dust on the surface of the drip shields combined with the much lower absolute quantity of dust present per unit area of drip shield surface.

Following closure of the repository, there is a period of up to 1,000 years in which limited seepage is possible because much of the drift wall temperature is above the boiling point of water (SNL 2008 [DIRS 184433], Figure 6.3-78[a]). During this interval, the only aqueous phase that could potentially contact the surface of any given drip shield is brine that originates by deliquescence of soluble salts in dust residing on the drip shields.

Justifications are developed using a logical framework approach, considering a wide range of dust and brine compositions, conditions on the waste package, and processes in the same manner in which this phenomenon was addressed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence) for the waste package outer barrier. For dust deliquescence-induced localized corrosion to affect the performance of the drip shields, each of the following five propositions must be answered in the affirmative. Analysis does not support an affirmative answer to all of these propositions, as shown below:

(1) *Can multiple-salt deliquescent brines form at elevated temperature?* Yes (see SNL 2007 [DIRS 181267], Table 7-2[a]). As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Section 7.1.1), multiple-salt deliquescent brines can form at elevated temperatures (above 120°C). Boiling points of saturated salt solutions represent the maximum temperature of deliquescence at a given pressure. For most single salt phases (nitrates, chlorides, and carbonates), boiling points at one atmosphere are limited to temperatures below 120°C. Saturated multi-salt mixtures always boil at higher temperatures than the individual salt components. The boiling points for important salt assemblages that are expected to occur on the drip shield surfaces have been investigated experimentally. The two-salt mixture $NaCl + KNO_3$ boils at a maximum temperature of 134°C and the three-salt mixture, $NaCl + KNO_3 + NaNO_3$, and four-salt mixture, $NaCl + KNO_3 + NaNO_3 + Ca(NO_3)_2$, with specific proportions can both transition directly to anhydrous melts (i.e., they do not exhibit a maximum boiling temperature).

(2) *If deliquescent brines form at elevated temperature, will they persist?* Sometimes (see SNL 2007 [DIRS 181267], Table 7-2[a]). As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Sections 7.1.2 and 7.1[a]), multiple-salt brines can persist on the waste package surface but are not stable. Acid degassing will occur rapidly at first, increasing the pH to near-neutral or alkaline conditions. Further acid degassing in conjunction with carbon dioxide uptake can result in decreasing brine volume, and will convert the four-salt calcium-containing mixture to the three-salt mixture (SNL 2007 [DIRS 181267], Section 6.2.2[a]). Degassing of HCl and HNO_3 from brines dominated by monovalent salts (e.g., NaCl, $NaNO_3$, KNO_3), also raises the pH, and the potential result is precipitation of less deliquescent salts (e.g., $NaHCO_3$). However, sufficient degassing to result in complete dryout is not expected for monovalent brines. Should dryout occur, these salts may subsequently deliquesce at lower temperature and higher relative humidity, producing brines with higher pH than the original assemblage. Similar processes are expected to occur upon the surfaces of the drip shield. Higher pH brines are not of concern with respect to localized corrosion and the localized corrosion model for Titanium Grade 7 reflects this in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 8.4, and Figures 19 and 20).

(3) *If deliquescent brines persist, will they be corrosive?* No. The environments that may form during the period where there is active deliquescence are predicted to be benign with respect to localized corrosion of the waste package outer barrier as discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Table 7-2[a]) and in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface due to Deliquescence). The postclosure brines initially formed on the drip shield surface are from tunnel (rock) dust and are expected to contain minimal fluoride (SNL 2007

[DIRS 181267], Table 6-3[a]). These brines will become increasingly benign with time due to processes that occur after deliquescence, such as acid degassing and carbonation (SNL 2007 [DIRS 181267], Sections 7.1.3 and 6.2[a]). The model for localized corrosion initiation on titanium was developed to predict the behavior of drip shield materials under seepage conditions. However, the model is based on experiments performed in electrolytes that also represent the dominant constituents of the predicted deliquescent brine chemistries. Tables 19 and 20 in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778]) contain a catalogue of the test solutions used to develop the localized corrosion model for Titanium Grade 7, and Table 6.3-2 in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267]) compares the predicted deliquescent brine chemistries to the corrosion test solutions that have been utilized. The corrosion performance of Titanium Grade 7 in $CaCl_2$-based brines is presented in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Table 21), where the large positive values of ΔE preclude localized corrosion initiation. The localized corrosion model predicts a probability of much less than 1 in 10,000 in 10,000 years of localized corrosion initiation on Titanium Grade 7 across a wide range of chloride concentrations, temperatures, and pH levels, where initiation may occur if ΔE is less than zero (SNL 2007 [DIRS 180778], Figures 19 and 20). This is fully consistent with cyclic polarization tests performed on creviced Titanium Grade 7 specimens in 1 M NaCl over a range of temperatures from 90°C to 165°C by Brossia and Cragnolino (2000 [DIRS 162445]). The authors found that the measured repassivation potential exceeded the corrosion potential (measured at 95°C in aerated 1 M NaCl) by at least 1.2 volts. In another study, the same authors (Brossia and Cragnolino 2001 [DIRS 159840]) evaluated the effect of 0.1 to 10 M NaCl on the crevice repassivation potential of Titanium Grade 7 at 95°C. The potential dropped with increasing chloride content but was still over 4 V_{SCE} in 10 M NaCl, consistent with significant localized corrosion margin even in absence of nitrate. These results are also supported by YMP test results obtained in concentrated $CaCl_2$ and $CaCl_2 + Ca(NO_3)_2$ brines at temperatures up to 150°C, indicating that crevice corrosion is not expected to occur under these conditions (SNL 2007 [DIRS 180778], Table 21). These results demonstrate that localized corrosion of Titanium Grade 7 will not occur in environments representative of predicted deliquescent brine compositions.

According to the drip shield design (SNL 2007 [DIRS 179354], Table 4-2, Parameter Number 07-01), the drip shields will have Titanium Grade 29 structures mounted on the outer surface of the drip shield plates. While the exposed surface area is far less than for the plate material, dust may accumulate on the surface of the structural supports as well. Cyclic polarization testing of uncreviced samples at elevated temperature in multi-ionic electrolytes containing various levels of $CaCl_2$, KCl, KNO_3, $NaNO_3$, NaCl, Na_2SO_4, NaF, and NaBr has shown similar behavior for Titanium Grade 29 and Titanium Grade 7 with no localized attack reported for either grade of titanium following polarization (DTN: MO0705SCCIGM06.000 [DIRS 180869], Table 11 and Figures 46 to 53). Additionally, cyclic polarization testing of creviced samples in concentrated NaCl + KCl with and without KNO_3 and NaF at temperatures at or above 110°C has shown high values for the critical potentials of both Titanium Grade 7 and Titanium Grade 29 (DTN: LL070800612251.197 [DIRS 183159], file: *Ti Gr 7 Gr 29 Electrochemical Developed Aug07*). To evaluate the tabular data for the above tests, the critical potentials

were taken as the point in the polarization curve where the current density exceeds 200 $\mu A/cm^2$, designated as E_{200}. Although attack under the crevice former was noted for Titanium Grade 29 in some of the concentrated salt electrolytes, such attack only occurred after the samples had been polarized to high potentials (greater than 1 V versus SSC, a condition that cannot occur in the repository environment). Based on these experimental results, it is concluded that Titanium Grade 29 will not degrade due to localized corrosion processes when exposed to the anticipated deliquescent brines that may form on the surface of the drip shields.

(4) *If deliquescent brines are potentially corrosive, will they initiate localized corrosion?* No (SNL 2007 [DIRS 181267], Table 7-2[a]). As stated earlier, the brines resulting from dust deliquescence generally contain minimal fluoride with near-neutral pH, and are therefore not considered to be corrosive. As discussed in *Analysis of Dust Deliquescence for FEP Screening* (SNL 2007 [DIRS 181267], Section 7.1.4), the volume of brines formed by deliquescence will be so limited that even if the brines were to be considered corrosive, they are not expected to initiate localized corrosion outside of tight crevices. In the analysis of the dust on the waste package outer barrier, considering the effects of ammonium salt removal from dust, and assuming that the soluble component of repository dust derives from atmospheric aerosols, the maximum deliquescence brine volume is calculated to be 1.8 $\mu L/cm^2$ at 120°C or higher (SNL 2007 [DIRS 181267], Section 7.1.4). However, as discussed above, the dust on the surface of the drip shields will be predominantly tunnel dust. Tunnel dust is composed primarily of powdered rock and contains a much lower soluble salt concentration (<<1%) than atmospheric aerosols (10% to 20%) (SNL 2007 [DIRS 181267], Section 6.1). As a result, the volume of brine produced by such dusts will be lower on a per mass basis than that present in the atmospheric aerosols that will reside on the waste package surface following the ventilation period. Therefore, the quantity on the drip shield surfaces will be much lower than that on the waste package surface (i.e., <<1.8 $\mu l/cm^2$) due to the lower concentration of soluble salts in the dust on the surface of the drip shields combined with the much lower absolute quantity of dust present per unit area of drip shield surface. This value presumes that all salt components in the dust are in mutual contact so that eutectic salt mixtures occur. However, repository dust is heterogeneous and consists mostly of non-deliquescent minerals (e.g., rock-forming minerals) that can physically separate the salt components, so the brine volume estimate is potentially high.

Capillary and surface tension effects in the dust are expected to reduce contact with the drip shield surface and inhibit brine flow into pores or crevices. Dust samples collected from the Exploratory Studies Facility have been characterized to evaluate the potential for capillary retention of the brine within the dust layer, decreasing the availability of brine for contact with the surface of the drip shields. The results indicate that the capillary response of the dust is characterized by a typical dimension of about one micron (SNL 2007 [DIRS 181267], Section 7.1.4). This dimension suggests that brine mobility within the dust will be inhibited, and that roughness on the metal surface would need to have similar dimensions in order to compete successfully for the brine.

(5) *Once initiated, will localized corrosion penetrate the drip shield?* Not applicable. Localized corrosion will not initiate as discussed in proposition 4.

In summary, on the basis of the previous discussion, brines formed by deliquescence of the relevant tunnel dusts are not expected to be aggressive with respect to initiating localized corrosion. Processes that act to modify the brines on the waste package surface are beneficial with respect to corrosivity. Should corrosive brines form, scale factors related to brine volume will inhibit initiation of localized corrosion.

Therefore, significant localized corrosion of the drip shields due to dust deliquescence is not anticipated to occur, and FEP 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces Due to Deliquescence**)** is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319] on the basis of low probability.

FEP: 2.1.10.01.0A

FEP NAME:

Microbial Activity in EBS

FEP DESCRIPTION:

Biological activity is important to consider because of the potential impact on aqueous chemical conditions within the waste and EBS. In deep subsurface environments, biological activity is limited to microbiological activity and may include effects of natural and anthropogenic bacteria (e.g., anaerobic, methanogenic, sulfate reducers, etc.), protozoans, yeast, viruses, and algae. This FEP addresses a broad range of effects of biological impacts, including the effects of microbes on corrosion of waste packages, cladding, and waste form; bioreduction of multivalent contaminants, metals, and sulfate; generation of organic complexants and gases as metabolic by-products; and the formation of biofilms and their impact on transport.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Early high temperatures and long-term nutrient scarcity will sharply limit microbial activity inside Yucca Mountain. Although microbial activity is expected to be insignificant and the effects of microbial activity are generally screened out, models of general waste package corrosion assign a rate-enhancement factor to bound any impact of microbes (BSC 2004 [DIRS 178519], Section 8.1). A more detailed discussion on the potential effect of microbes on corrosion of waste packages is provided separately in included FEP 2.1.03.05.0A (Microbially Influenced Corrosion (MIC) of Waste Packages). MIC of the drip shields is excluded (see excluded FEP 2.1.03.05.0B (Microbially Influenced Corrosion (MIC) of Drip Shields)). MIC of the cladding is addressed in excluded FEP 2.1.02.14.0A (Microbially Influenced Corrosion (MIC) of Cladding).

Evaluation of Potential Impacts of Microbial Activities on Drift Chemistry (BSC 2004 [DIRS 169991]) provides an analysis of in-drift biological activities and their potential impacts on EBS materials and processes. The discussion presented here is based on Sections 6.4, 6.5, and 7.1 of that report (BSC 2004 [DIRS 169991]). The following thermal and chemical factors will severely limit microbial activities in the repository:

Thermal

- The in-drift temperatures during the thermal pulse created by radioactive decay will exceed the temperature tolerance of many microbes in the repository environment for a period of time after repository closure, thus exerting an early sterilization effect on many, if not all, microorganisms.

- Microbial incubation experiments have demonstrated the importance of water availability for Yucca Mountain microbial growth. The relative humidity and the liquid-water saturation in the repository during the thermal period are predicted to be low, thus further limiting microbial activities during the thermal period.

- Evaporation of seepage waters in the low relative humidity environment of the thermal period will result in brine solutions in which only halophiles may be able to survive.

Chemical

- Although sub-oxic environments may persist locally while stainless steel in the waste package and in the ground support corrodes, an oxic environment will ultimately prevail in the repository over the growth-permissive period and prevent the generation and accumulation of reduced inorganic dissolved matter (in addition to nonreduced elements such as phosphate and nitrate) that are the prerequisite for autotrophic metabolism.

- Phosphate and organic carbon are important limiting factors for Yucca Mountain microbial growth. The extremely low organic carbon supply in the repository will limit heterotrophic microbial activities.

In short, thermal effects and water availability will limit microbial activity during, and for a period after, the thermal pulse; nutrient limitations will limit activity throughout. Because of the multiple and overlapping limitations on microbial growth, there will be no significant effects resulting from bio-reduction of multivalent contaminants, metals, or sulfate, nor will there be any significant potential to form organic complexants.

Evaluation of Potential Impacts of Microbial Activities on Drift Chemistry (BSC 2004 [DIRS 169991], Section 6.5) evaluates the potential impacts on repository chemistry, given the limitations of microbial activity. The report concludes that the effects on water chemistry are negligible (BSC 2004 [DIRS 169991], Section 6.5.1). Although microorganisms may release chemicals that complex with radionuclides, either the concentrations of complexing agents are small, or their binding sites will be dominated by iron (and other) ions, or both (BSC 2004 [DIRS 169991], Section 6.5.2). Section 6.5.3 of *Evaluation of Potential Impacts of Microbial Activities on Drift Chemistry* (BSC 2004 [DIRS 169991]) concludes that potential effects on radionuclide solubility are negligible, while Section 6.5.4 examines the potential for enhanced transport by radionuclides binding directly to the surface of unattached bacteria, concluding that long-distance biocolloid transport is not expected in the unsaturated zone. Gas generation from microbial degradation (FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) of Microbial Degradation)) is excluded as is radiological mutation of microbes (FEP 2.1.13.03.0A (Radiological Mutation of Microbes)).

In conclusion, due to severe environmental constraints, microbial activity in the repository is expected to be low, and its impacts on drift chemistry will be insignificant.

Based on the previous discussion, omission of FEP 2.1.10.01.0A (Microbial Activity in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this

FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.01.0A

FEP NAME:

Heat Generation in EBS

FEP DESCRIPTION:

Temperature in the waste and EBS will vary through time. Heat from radioactive decay will be the primary cause of temperature change, but other factors to be considered in determining the temperature history include the in-situ geothermal gradient, thermal properties of the rock, EBS, and waste materials, hydrological effects, and the possibility of exothermic reactions. Considerations of the heat generated by radioactive decay should take different properties of different waste types, including DSNF, into account.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The temperature-time history of the waste and EBS is calculated as part of the model described in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]). The temperatures as predicted by the MSTHM are influenced by not only the heat of radionuclide decay, but also mountain-scale thermal-property stratigraphic variation, edge-cooling effects that result from lateral heat loss at the repository edges, the natural geothermal gradient from the water table to the ground surface, percolation flux, and rock hydrologic properties (SNL 2008 [DIRS 184433], Sections 6.1, 6.2.5, and 6.2.14[a]). Heat generated by exothermic reactions in the EBS is not considered in performance assessment, as discussed in excluded FEP 2.1.11.03.0A (Exothermic Reactions in the EBS).

The different waste packages considered in MSTHM calculations are summarized in Table 6.2-6[a] of the MSTHM report (SNL 2008 [DIRS 184433]). The thermal decay history of each of the waste package types is developed in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472], Section 6.4.3[a]; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-11; SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-11). The different waste packages fall in two major categories: commercial SNF waste packages, which include PWR and BWR waste packages, and codisposal waste packages, which contain both defense HLW and DOE SNF. Temperatures for different types of waste forms are captured in a submodel of the MSTHM. These waste forms include the 21-PWR, the 44-BWR, and long and short versions of the codisposal waste package, all of which produce heat at different rates. These effects are captured in the TSPA model by providing the temperatures as direct inputs. *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2.17[a]) investigates the influence of waste package-to-waste package heat-generation variability on thermohydrologic conditions in the emplacement drifts.

In-Drift Natural Convection and Condensation (SNL 2007 [DIRS 181648]) deals with heat generation in the waste packages in several ways. The condensation analysis developed in that

report (SNL 2007 [DIRS 181648], Sections 6.3 and 6.1.1[a]) uses the thermal decay history of each of the waste package types developed in *Initial Radionuclide Inventories* (SNL 2007 [DIRS 180472], Section 6.4.3[a]) to establish temperatures and mass transfer rates (condensation and evaporation) within the drift. Drift wall and far-field temperatures are calculated by summing the heat contribution from all 108 drifts in the repository layout, each of which is simulated using a time-dependent thermal line load representing the heat of radionuclide decay. Correlations for condensation rates and condensation probabilities on the drift wall and other EBS components are developed for TSPA (SNL 2007 [DIRS 181648], Section 8.3). The convection and condensation model also calculates a dispersion coefficient that includes heat generation from individual waste packages for use in the condensation analysis. Dispersion coefficients are calculated for various cases using a computational fluid dynamics code that allows for mixing of the gasses in the drift to be enhanced by natural convection cells that form between hotter and cooler packages, and between waste packages and the cooler drift wall. An additional analysis presented in the convection and condensation report (SNL 2007 [DIRS 181648], Section 6.4) is used to generate an effective thermal conductivity within the drift for use by the MSTHM. The effective thermal conductivity is calculated using a two-dimensional computational fluid dynamics code that includes a steady-state heat source represented as a constant temperature boundary at the waste package. The feed to TSPA is indirect because it is through the average equivalent thermal conductivity correlation used by the MSTHM.

Heat generation in the EBS, as applied in the convection and condensation model and in the MSTHM, is closely coupled with heat transfer mechanisms. Conservation of energy dictates that all heat generated within the repository during postclosure must leave through the drift wall. Therefore, the temperature on the interior drift wall is dictated by the requirement to dissipate all the heat generated within the repository. The same energy balance applies to heat generated under the drip shield, which must be transferred from the drip shield to the drift wall. In fact, the temperatures on the surfaces of the waste packages, drip shields, and drift walls are all dependent on the heat transfer mechanisms available to satisfy conservation of energy. Heat transfer by conduction, turbulent natural convection, and thermal radiation are all included in the convection and condensation model such that each physical process occurring in the drift cavity during repository postclosure is simulated. The equivalent thermal conductivity, which is calculated in the convection and condensation model and fed to the MSTHM, does not include radiation because radiation is already included in the MSTHM. Heat transfer mechanisms are described in Sections 6.1.5.1 and 6.4.1.1 of *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]) and in Section 6.2.8.5 of *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]).

The preclosure ventilation period is 50 years (SNL 2007 [DIRS 179466], Table 4-2, Parameter Number 06-01). As described in included FEP 1.1.02.02.0A (Preclosure Ventilation), during the ventilation period, a substantial amount of the decay heat generated by the waste packages is removed by the ventilation system. The balance of the heat is transferred into the rock. Ventilation efficiency is described in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862], Section 6.3.5). The waste package powers used by the MSTHM and the convection and condensation model are modified by multiplying them by the complement of the ventilation efficiency over the 50-year ventilation period.

Uncertainties associated with heat generation in the EBS are propagated to performance assessment calculations through the use of different waste package types, different rock thermal conductivities, and a suite of percolation flux values in the MSTHM (SNL 2008 [DIRS 184433], Sections 6.3.15[a] and 6.3.16[a]). In addition, uncertainties in rock hydrologic properties (SNL 2008 [DIRS 184433], Section 6.3.11[a]), ventilation heat removal efficiency (SNL 2008 [DIRS 184433], Section 6.3.12), and the effects of axial vapor transport (SNL 2008 [DIRS 184433], Section 6.3.18[a]) were evaluated using sensitivity analyses and found to be insignificant. Uncertainties in the in-drift natural convection and condensation model are propagated to TSPA through use of bounding values for the axial dispersion rate, for the degree of drip shield ventilation, and for the percolation rate at the repository horizon (SNL 2007 [DIRS 181648], Section 6.1.3[a]).

In performance assessment calculations, temperature and relative humidity conditions derived from the MSTHM (SNL 2008 [DIRS 184433]) are used to extract parameters of the in-drift chemical environment from the lookup tables generated by the in-drift seepage dilution/evaporation model developed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.3). In addition, drift wall temperatures predicted by the MSTHM are used to constrain the timing of potential seepage into the drift. As discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2), seepage cannot occur until drift wall temperatures drop below 100°C.

FEP: 2.1.11.02.0A

FEP NAME:

Non-Uniform Heat Distribution in EBS

FEP DESCRIPTION:

Uneven heating and cooling at edges of the repository may lead to non-uniform thermal effects during both the thermal peak and the cool-down period.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The calculation of the repository thermohydrologic environment, including thermal gradients from the repository center to the edges and corners of the repository, is described in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2.1). The increase in temperature from the ambient geothermal temperature as predicted by the MSTHM is influenced by: (1) the thermophysical properties of the rock and EBS components, and (2) the repository footprint shape, which influences the evolution of the edge-cooling effect (SNL 2008 [DIRS 184433], Section 1). *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Table 1-1) provides postclosure thermal-hydrologic parameters to the TSPA as functions of time and location in the drift or host rock. Uncertainty in MSTHM results is propagated to TSPA calculations through the use of simulation results using different rock thermal conductivities and a suite of percolation flux values (SNL 2008 [DIRS 184433], Sections 6.3.15[a] and 6.3-16[a]). Other sources of uncertainty, including rock hydrologic properties, ventilation heat removal efficiency, and the effects of axial vapor transport, were evaluated using sensitivity analyses and found to be insignificant (SNL 2008 [DIRS 184433], Sections 6.3.11[a], 6.3.12, and 6.3.18[a]).

In-Drift Natural Convection and Condensation (SNL 2007 [DIRS 181648], Section 6.3.5.1.1) includes the effects of heating and cooling at the repository edges. Seven drifts are chosen for the condensation/evaporation analysis. Two sets of three drifts span the width of the repository, capturing the temperature variations between the repository center and the repository edge. The three drifts at the north of the repository footprint reflect the cooler portion of the repository layout. The three drifts in the middle of the repository footprint capture the hotter portion of the layout. The seventh drift is in the narrowest portion of the repository. Condensation rates calculated in the model are influenced by the temperature profiles within each drift. The model implemented in the TSPA calculates a probability of condensate on the drift walls at any location and, if condensation occurs, rate of condensation. The probability of occurrence of condensation and the condensation rate are abstracted as functions of the percolation flux, as described in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 8.3). Uncertainties in the condensation model are propagated to TSPA through use of bounding values for the axial dispersion rate, the degree of drip shield ventilation, and the percolation rate at the repository horizon (SNL 2007 [DIRS 181648], Section 6.1.3[a]).

FEP: 2.1.11.03.0A

FEP NAME:

Exothermic Reactions in the EBS

FEP DESCRIPTION:

Exothermic reactions liberate heat and will alter the temperature of the disposal system and affect the properties of the repository and surrounding materials. Examples of possible exothermic reactions include oxidation of uranium metal fuels such as represented by N Reactor fuels and hydration of concrete used in the underground environment.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP focuses on the effects of excess heat from exothermic reactions (other than pyrophoric reactions) on the properties of the repository and in the surrounding materials. The two exothermic reactions discussed in this FEP are the oxidation of uranium-metal fuel, which is significant because of the rapid O_2-scavenging ability of uranium-metal and the total quantity of specific heat generated is large; and the hydrolysis of cement, which is only significant if large quantities of cement are available to react. The oxidation of uranium-metal is considered to be bounding with respect to potential consequences as this reaction may occur extremely rapidly and thereby release significant heat essentially instantaneously. The N Reactor SNF, which is the uranium metal-based fuel, comprises the majority of DOE SNF by MTHM but only accounts for 6% of the codisposal waste packages and is expected to undergo oxidative degradation upon exposure to oxygen and/or water vapor. The oxidation of uranium-metal to form UO_2 is exothermic with a standard enthalpy of formation of −1,085 kJ/mol (Grenthe et al. 1992 [DIRS 101671], Table III.1). Uranium metal is also known to be pyrophoric under certain conditions. Pyrophoric materials are materials that can spontaneously ignite due to overheating as a result of oxidation, sparks, or mechanical trauma. A pyrophoric reaction is, thus, a rapid exothermic reaction resulting in fire. This FEP does not address pyrophoricity. The effects of pyrophoricity related to N Reactor fuel are addressed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF).

The reaction between uranium-metal and oxygen (as opposed to water vapor) is used in this analysis as it is the bounding case. In the repository, the sources of oxygen that are potentially available to react exothermically in the codisposal waste packages containing N Reactor fuel are:

- Oxygen or air ingress into the waste package through waste package breaches
- Oxygen that could be produced from radiolysis of residual and bound water left in the MCOs after they are dried and closed.

These potential sources of oxygen and how they are expected to influence and limit the exothermic reactions that might occur in the repository are discussed in the following paragraphs.

The breaches in the waste package outer shell through which ingress of oxygen might occur are expected to be SCCs (see included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages)). A more rapid, advective flow of air into the MCOs could result in a pyrophoric event and that case is discussed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF). Following pressure equilibration between the waste package void space and the drift air, it is expected that the SCCs will allow oxygen ingress by a counter diffusion process involving helium, nitrogen, oxygen, and water vapor. Upper bound estimates for the diffusive mass transport rate of oxygen into the waste package through these SCCs can be calculated using the approach described in (SNL 2007 [DIRS 177407], Section 6.6.2). The analysis provided in the RTA report calculated water vapor diffusion through SCCs. Here that analysis is modified to maximize the amount of oxygen available for uranium oxidation by analyzing O_2 diffusion in air. This calculation shows that an upper bound estimate of the rate of diffusive ingress of oxygen into a waste package through SCCs is approximately 2,610 mol/yr. The details of this calculation are provided in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF).

If all of this oxygen is used to covert uranium metal to UO_2, for which the heat of formation is 1,085 kJ/mole uranium (Grenthe et al. 1992 [DIRS 101671], Table III.1), the corresponding heat generation rate is about 90 watts with a reaction time of 18 years. In this analysis, every atom of uranium-metal in the waste packages is oxidized during the 18-year reaction time given the oxygen diffusion rate of 2,610 mol/yr (see details in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF)).

Oxygen ingress by barometric pumping and by flow driven by buoyancy are both discussed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF).

At emplacement, a comparison of the calculated wattage increases due to uranium-metal oxidation to the average thermal power at emplacement for a 2-MCO/2-HLW-Long waste package, which is comprised of two MCOs and two HLW glass canisters, reveals that these values are insignificant to the total waste package heat generation due to radioactive decay (BSC 2004 [DIRS 166941], Table 2). At emplacement, the thermal output is 1,660 watts and the oxidation of uranium-metal contributes an additional 5.4% should a seismic event occur (90 watts ÷ 1,660 watts). Assuming that the MCO thermal output decays at a rate similar to the 5-HLW-Long waste package (Assumption 3.7 in BSC 2004 [DIRS 166941]), at 10,000 years the 2-MCO/2-HLW-Long waste package will have decayed to approximately 2 watts (0.001 × 1,660 watts; where 0.001 is estimated as the fraction of the heat remaining for a 5-HLW-Long waste package at 10,000 years (i.e., $1.42 \times 10^{-3} \div 9.9 \times 10^{-1}$ from SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02)) . At 10,000 years, the additional heat generated by the uranium-metal oxidation (approximately 90 watts) would result in an increase by a factor of 45 should a seismic event occur compared to the heat generated by an unbreached waste package. This increase over the nominal heat generation is considered inconsequential because it is so short lived (less than 20 years) and small relative to the initial heat at emplacement.

The impact of the increased heat generation on the repository performance and the surrounding materials is evaluated by examining the thermal output increase relative to an average thermal load. A comparison of these calculated values to the waste package decay heat generation along a 7-package segment (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02) indicates that their relative contribution is small and their impact negligible. At emplacement, the average heat generation for the 7-packages segment is 51,200 W and the oxidation of uranium-metal should a seismic event occur contributes an additional 0.18% (90 watts ÷ 51,200 watts). At 10,000 years, the average heat generation for the 7-package segment is 603 W and the oxidation of uranium-metal should a seismic event occur contributes less than 15% (90 watts ÷ 603 watts).

The amount of free and bound water that may remain in the MCOs after they are dried and closed is uncertain. The dominant form of this water is bound water in uranium and aluminium oxide hydrates with the estimated amount per MCO ranging up to 4.64 kg or approximately 258 moles (Garvin 2002 [DIRS 169141], Table 4-4). In the repository, this water could be released and converted to free hydrogen and oxygen due to thermal and radiolytic decomposition of the uranium and aluminium oxide hydrates involved. If free oxygen and hydrogen are produced inside the codisposal packages, the oxygen will be scavenged by reaction with exposed uranium metal in the breached fuel because of the rapid kinetics of the uranium-metal/oxygen reactions at temperatures up to 1,440°C and at various O_2 and H_2O pressures (Haschke 1998 [DIRS 174075], Table 1). The fate of the free hydrogen is less clear. In studies of uranium-metal corrosion in moist air, neither hydrides nor hydrogen gas formed (Haschke 1998 [DIRS 174075], pp. 149 to 150), suggesting that any evolved hydrogen is rapidly transformed to water on the U-metal surface under the conditions of this study. The production and fate of hydrogen are discussed further in excluded FEPs 2.1.12.03.0A (Gas Generation (H_2) from Waste Package Corrosion) and 2.1.13.01.0A (Radiolysis). Even if both MCOs in a codisposal package are each assumed to contain 4.64 kg water, and it is also assumed all of the oxygen in this water is available as free oxygen to convert uranium-metal to UO_2 in a rapid exothermic reaction, it would oxidize only a very small fraction (0.5%) of the fuel in the waste package. This is calculated from 1.13×10^7 g uranium-metal per waste package assuming that the waste package contains two MCOs each containing Mark IV fuel and scrap baskets containing the maximum fuel (3,804 kg uranium) and scrap (1,832 kg uranium) loadings ($2 \times (3.804 \times 10^6 + 1.832 \times 10^6) = 1.13 \times 10^7$ g uranium-metal) (rounded)) (Garvin 2002 [DIRS 169141], Table 4-4), which is equivalent to 47,500 moles of uranium by conversion using the atomic weight of uranium = 238 (rounded) from DTN: SN0612T0502404.014 [DIRS 178850] (1.13×10^7 g ÷ 238 g/mol). The total O_2 available from the emplaced water is 258 moles per waste package (derived in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF)). Thus, the fraction of uranium-metal that could be converted is approximately 0.5%. The heat energy released would be about 2.8×10^5 kJ, which would cause a waste package temperature increase of only 21°C even under assumed adiabatic conditions (see details of this calculation in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF)).

Degradation of the uranium metal fuel as a result of its oxidation may cause the radionuclides in the oxidized fuel to be available for dissolution and transport when that fuel is contacted by water. Even in the absence of oxidation, the TSPA model uses a bounding instantaneous degradation rate for the uranium-metal DOE SNF (BSC 2004 [DIRS 172453]), which considers that the radionuclide inventory in this fuel is available for dissolution and transport when the fuel is contacted by water. Therefore, the heat generated during the oxidative alteration of the fuel

will not adversely affect radionuclide release because it will not increase the rate of radionuclide release beyond that already included in the TSPA model. Also, because a bounding estimate of the overall temperature increase (i.e., the adiabatic estimate discussed above) is small, it is not expected to melt or otherwise significantly degrade the HLW waste that is codisposed with the uranium-metal fuel.

An analysis of the impact of even a small temperature increase on the degradation rate of HLW glass is warranted because the rates are temperature dependant above a relative humidity of 44% (BSC 2004 [DIRS 169988], Section 8.1 and Equation 13). Note that this temperature-dependent increase in glass degradation rate affects only a small fraction of the codisposed waste packages. The temperature dependence follows an Arrhenius relationship:

$$\text{Rate} = K_E \text{B} \exp(-E_a/\text{RT})$$

where K_E is the ambient degradation rate, B contains a pH dependence, E_a is the activation energy for the degradation reaction, R is the molar gas constant (8.3145 J/K·mol) (rounded) (Grenthe et al. 1992 [DIRS 101671], Table II.7), and T is temperature in Kelvin. Thus, the increase in degradation rate as a function of temperature is calculated:

$$\text{Log K increase as } f(\text{T}) = \{\text{Log}[(K_E\text{B}) \times \text{EXP}(-E_a/\text{R} \times (1/\text{T}_2 - 1/\text{T}_1)]\}$$

$$- \text{Log}\,(K_E\text{B})$$

The E_a values used by the HLW degradation model are pH dependent with an "acidic" E_a equal to 31 kJ/mol and an "alkaline" E_a value of 69 kJ/mol (BSC 2004 [DIRS 169988], Table 8-1). Over the entire range of pH the faster of the two degradation rates is the rate implemented by the TSPA as described in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.3.1.3.4[a] and Figure 6-2[a]). Minimum (which is the most probable value) and maximum K_E values are provided for both the acidic and alkaline cases in Table 8-1 of the HLW glass degradation report (BSC 2004 [DIRS 169988]):

$$K_{E\_acidic} = 8.41 \times 10^3 \text{ g/m}^2\cdot\text{day to } 1.15 \times 10^7 \text{ g/m}^2\cdot\text{day}$$

$$K_{E\_alkaline} = 2.82 \times 10^1 \text{ g/m}^2\cdot\text{day to } 3.47 \times 10^4 \text{ g/m}^2\cdot\text{day}$$

Uncertainties are applied as a triangular distribution (BSC 2004 [DIRS 169988], Section 8.2.2). Using the most probable value for each set of rates the rate increase owing to a temperature rise of 21°C can be calculated (B cancels out):

$$0.80 = \{\text{Log}[(28.2) \times \text{EXP}(-69{,}000/8.3145 \times ((1/318.15) - (1/297.15))]\} - \text{Log}\,(28.2)$$

and

$$0.36 = \{\text{Log}[(8410) \times \text{EXP}(-31{,}000/8.3145 \times ((1/318.15) - (1/297.15))]\} - \text{Log}\,(8410)$$

Note that the activation energy alone accounts for the temperature-dependent rate increase; therefore, the increases in K_E calculated above are independent of the initial rate and the starting temperature.

For the alkaline case, the rate increase is 0.80 log units. For the acid case, the rate increase is 0.36 log units. The adverse consequences of the HLW glass degradation rate increase are expected to be small because both values are less than the range of uncertainty sampled by TSPA, which spans more than 3 log units for both the acidic and alkaline cases (BSC 2004 [DIRS 169988], Table 8-1).

As indicated in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-4, Parameter Number 05-04), cementitious and other backfill materials are not planned for use in the emplacement drifts, so exothermic reactions from hydration of concrete will not impact emplacement drift thermal conditions.

In conclusion, exothermic reactions in the EBS will not significantly increase heat generation beyond the expected thermal output from other sources.

Based on the previous discussion, omission of FEP 2.1.11.03.0A (Exothermic Reactions in the EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.05.0A

FEP NAME:

Thermal Expansion/stress of In-Package EBS components

FEP DESCRIPTION:

Thermally induced stresses could alter the performance of the waste or EBS. For example, thermal stresses could cause the waste form to develop cracks and create pathways for preferential fluid flow and, thereby, accelerate degradation of the waste.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Commercial SNF and defense SNF are designed for temperatures and the thermal cycles expected in reactors, which are more severe than the conditions that are anticipated to occur in the repository. As discussed in Section 6.2.1 of *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987]), the in-reactor thermal cycles (principally that associated with the initial power escalation) cause stresses that result in extensive cracking of the fuel matrix. The effects of this cracking are included in the commercial SNF waste form degradation model through the specific surface area parameter (BSC 2004 [DIRS 169987], Section 6.4.1.5). Additional thermally induced cracking of the fuel pellets after they are emplaced in the repository is not expected because the temperatures and temperature gradients to which the fuel pellet fragments will be exposed are modest compared to those experienced during reactor operation. The HLW glass logs crack because of the stresses induced during cooldown following pouring into the glass canisters during manufacturing. The cracking that results from this cooldown is included in the defense HLW degradation model via a surface area parameter (see included FEP 2.1.02.05.0A (HLW Glass Cracking)). The cracking that results from this cooldown is included in the defense HLW model surface area parameter. This cooldown and the effects of the associated stresses on glass cracking is more severe than any cooldown anticipated under expected repository conditions; additional thermally induced cracking in the repository is not significant (BSC 2004 [DIRS 169988], Section 6.5.4). Waste form cracking prior to emplacement in the repository and the associated effects on the waste form surface areas available for alteration and dissolution are discussed in included FEPs 2.1.02.02.0A (CSNF Degradation) and 2.1.02.03.0A (HLW Glass Degradation). The effects of thermally induced cracking in the repository on the waste form surface area are not explicitly included in TSPA because these effects are small compared to the preemplacement waste form cracking effects that are included. In the TSPA, DOE SNF degradation (except naval SNF) is modeled as instantaneous degradation or dissolution of the waste form upon exposure of the waste form to groundwater. For all groups of DOE SNF (except naval SNF), the upper-limit model produces complete dissolution of the waste form during a single-code time step upon exposure of the waste form to groundwater (BSC 2004 [DIRS 172453], Section 8.1). Therefore, the impact of thermal expansion of the DOE SNF waste form on calculated dose will be insignificant.

The effects of thermal expansion on the waste of package outer barrier, the waste package inner vessel, the TAD canister, the emplacement pallet, drip shields, and invert are discussed in excluded FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components).

Based on the previous discussion, omission of FEP 2.1.11.05.0A (Thermal Expansion and Stress of In-Package EBS Components) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.06.0A

FEP NAME:

Thermal Sensitization of Waste Packages

FEP DESCRIPTION:

Phase changes in waste package materials can result from long-term storage at moderately hot temperatures in the repository. Stress corrosion cracking (SCC), intergranular corrosion, or mechanical degradation may ensue.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Alloy 22 could be subject to aging and phase instability when exposed to elevated temperatures that are well above the anticipated maxima expected in the repository (BSC 2004 [DIRS 171924], Section 6.3). Aging and phase instability processes involve precipitation of different secondary phases and restructuring of the microstructure. The affected material may exhibit increased brittleness and decreased resistance to corrosion processes such as localized corrosion and stress corrosion cracking (BSC 2004 [DIRS 171924], Section 1.1).

Nominally, control of the heat treatment process and thermal loading of waste packages will avoid exposure to temperature ranges that can lead to degradation of the physical properties of the Alloy 22 WPOB through thermal sensitization (SNL 2007 [DIRS 179394], Table 4-1, Parameter Numbers 03-16 and 06-03; SNL 2007 [DIRS 179567], Table 4-1, Parameter Numbers 03-16 and 06-03). The effects of potential mechanisms leading to early failure of waste packages including improper heat treatment of waste packages are evaluated in *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.3) and discussed in included FEP 2.1.03.08.0A (Early Failure of Waste Packages). Before waste loading, the waste packages (base-metal and fabrication welds) are fully solution annealed (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-16; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-16). After waste loading, the closure lids are welded onto the waste package (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-17; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-17). Possible effects of aging and phase instability on the Alloy 22 WPOB closure lid weld regions are discussed later. *Aging and Phase Stability of Waste Package Outer Barrier* (BSC 2004 [DIRS 171924], Section 8) concluded that no effects of aging and phase instability on the Alloy 22 WPOB would be observed if the waste package were maintained at less than 300°C for a period of 500 years followed by temperatures less than 200°C for a period of 9,500 years. These thermal exposure conditions bound all repository-relevant thermal exposure conditions (SNL 2008 [DIRS 184433], Figure 6.3-76[a]) except in the event of a drift collapse within approximately 90 years after closure (SNL 2008 [DIRS 184433], Figure 6.3-82[a]). For the waste package surface to exceed 300°C, a seismic event of sufficient magnitude must occur within approximately 90 years after closure, result in drift collapse, and affect a waste package with an

unfavorable combination of a high thermal output surrounded by low conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about one in 10,000 within the first 10,000 years after closure (SNL 2008 [DIRS 179962], Section 6.5.1). Therefore, with the exception of early failure-related processes, thermal sensitization of waste packages is not expected.

The ASTM specification for the composition of Alloy 22 is shown in Table 2.1.11.06.0A-1. *Aging and Phase Stability of Waste Package Outer Barrier* (BSC 2004 [DIRS 171924], Section 8.2) recommended the use of a more restricted compositional range based on the compositional range of Alloy 22 heats tested in that report. *Computational Modeling of Phase Stability in Alloy 22 Over a Range of Chemical Compositions for the Yucca Mountain Project* (Hu et al. 2005 [DIRS 181177], Figures 3a and 4a) shows that as the amount of alloying elements (in particular chromium and molybdenum) decrease, the phase stability of Alloy 22 is enhanced. Therefore, it is reasonable to extend the applicability of the conclusions of *Aging and Phase Stability of Waste Package Outer Barrier* (BSC 2004 [DIRS 171924], Section 8.2) to the ASTM specification minimums as shown in Table 2.1.11.06.0A-1. The compositional range of Alloy 22 used for waste package fabrication is constrained to these values (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-19; SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-19).

Sources: [a] ASTM B 575-99a [DIRS 147465], Table 1, p. 2.
[b] BSC 2004 [DIRS 171924], Table 12.

The Alloy 22 WPOB closure lid welds cannot be solution annealed without risking damage to the waste form. Therefore, the closure welds of the WPOB could be more prone to thermal aging and phase instability than the base metal under long-term thermal exposure in the repository. Analyses conducted in *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 6.4.6.1) studied the effect of thermal aging on corrosion of Alloy 22. Three metallurgical conditions of Alloy 22 were studied using creviced specimens: mill-annealed, as-welded, and as-welded plus thermally aged (at 700°C for 173 hours). The samples were tested in 5 M $CaCl_2$ solutions with and without 0.5 *M* $Ca(NO_3)_2$ at test temperatures varying from 30°C to 120°C (as-welded plus thermally aged specimens were tested at 120°C). Comparison of the calculated corrosion rates of the mill-annealed, as-welded, and as-welded plus thermally aged specimens showed no apparent enhancement of the general

corrosion rate (or any intergranular corrosion) due to the presence of welds or thermal aging of the welded specimens for the tested conditions. Also, the localized corrosion resistance of specimens taken from the longitudinal weld seam of a full-diameter, quarter-length mockup waste container that had undergone the fabrication process planned for the full-sized waste packages were evaluated (SNL 2007 [DIRS 178519], Section 6.4.6.2.2). It was concluded that the localized corrosion resistance (i.e., the crevice repassivation potential) of the specimens from the mock-up container was comparable to that of mill-annealed or as-welded specimens prepared from laboratory plates. Based on these results, it is expected that there will be insignificant impact of phase instability on general and localized corrosion of waste package closure lid welds under repository exposure conditions.

Stress corrosion cracking of the WPOB closure welds is discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953]) and included FEP 2.1.03.02.0A (Stress Corrosion Cracking (SCC) of Waste Packages). Data from thermally aged specimens (including welded and thermally aged specimens) were used to develop SCC initiation and crack growth models for the waste package outer barrier closure weld region (SNL 2007 [DIRS 181953], Sections 6.2.1 and 6.4.4). Therefore, although no significant amount of thermal aging is expected in the repository, the effects of potential thermal aging have been incorporated in the SCC models. In this respect, inclusion of an explicit dependence of SCC on thermal aging would not be expected to have a significant effect on predicted radiological exposure to the reasonably maximally exposed individual and radionuclide releases to the accessible environment.

Based on this analysis, insignificant aging and phase instability will occur under the thermal conditions expected in the repository, and the predicted corrosion performance of the waste package outer barrier material is not expected to be affected by aging and phase instability under the thermal conditions expected in the repository (SNL 2007 [DIRS 178519], Section 8).

Based on the previous discussion, omission of FEP 2.1.11.06.0A (Thermal Sensitization of Waste Packages) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.06.0B

FEP NAME:

Thermal Sensitization of Drip Shields

FEP DESCRIPTION:

Phase changes in drip shield materials can result from long-term storage at moderately hot temperatures in the repository. Stress corrosion cracking (SCC), intergranular corrosion, or mechanical degradation may ensue.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

Aging and phase stability of the Titanium Grade 7 drip shield plate material is discussed in *General Corrosion and Localized Corrosion of the Drip Shield* (SNL 2007 [DIRS 180778], Section 6.7.3), which concludes that aging and phase instability will not affect the corrosion performance of the Titanium Grade 7 drip shield material for properly fabricated drip shields. The effects of potential mechanisms leading to early failure of drip shields including improper heat treatment of drip shields are evaluated in *Analysis of Mechanisms for Early WastePackage/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.4) and discussed in included FEP 2.1.03.08.0B (Early Failure of Drip Shields).

Titanium Grade 7 is a stabilized alpha (α) phase alloy and possesses outstanding phase stability. Titanium Grade 7 contains small amounts of alloying elements (DTN: MO0003RIB00073.000 [DIRS 152926]), most notably palladium. The solubility of palladium in Titanium Grade 7 is about 1 wt % at 400°C. The nominal concentration of palladium in Titanium Grade 7 is well below the solubility limit at this temperature (Gdowski 1997 [DIRS 102789], pp. 1 to 8). Titanium –palladium intermetallic compounds capable of being formed in the titanium-palladium system have not been reported to occur in Titanium Grade 7 with normal heat treatments. Hua et al. (2002 [DIRS 160670]) tested the base and welded metals of Titanium Grade 7 in a highly concentrated basic environment at 60°C, 70°C, 80°C, 90°C, 100°C, and 105°C for up to eight weeks (Hua et al. 2002 [DIRS 160670]; Hua and Gordon 2003 [DIRS 163111]). No difference in weight loss and, therefore, in corrosion rate was observed between the base metal and welds. The boundaries between the welds and heat-affected zone, which experienced a range of temperatures during welding, as well as the boundaries between the heat-affected zone and base metal, were not visibly attacked.

Titanium Grade 29 (the drip shield support material) is a ruthenium-containing version of Titanium Grade 5 with extra-low interstitial elements (ASTM B 265-02 [DIRS 162726], Section 1.1.26 and Table 2). Titanium Grades 5 and 29 both contain about 6% aluminum and 4% vanadium, and are α-β alloys (Leyens and Peter 2003 [DIRS 181560], Chapter 1.5). The α-phase in the alloys is stablized by addition of 6% aluminum and β-phase is stablized by 4%

vanadium. The β-transus of Ti-6Al-4V alloys is about 980°C (Leyens and Peter 2003 [DIRS 181560], Chapter 1.5, Figure 1.12). In general, heating to a temperature higher than the β-transus will increase the initial β grain size, and slow cooling from this temperature will reduce the amount of fine acicular α that forms at high temperature. Below the β-transus, no significant β-phase grain growth is observed (Leyens and Peter 2003 [DIRS 181560], Chapter 1.5).

Stability of commercial α-β alloys, such as Titanium Grades 5 and 29, depends on composition and heat-treatment. In the mill-annealed condition, the α-β alloys can be considered thermally stable up to 315°C (600°F) to 370°C (700°F) (ASM 1990 [DIRS 141615], p. 628). Properly fabricated and heat treated, these α-β alloys are thermally stable up to 425°C (800°F) in the heat treated condition for periods of at least 1,000 hours (ASM 1990 [DIRS 141615], p. 628). These thermal exposure conditions bound all repository-relevant thermal exposure conditions (SNL 2008 [DIRS 184433], Figure 6.3-76[a]) except in the event of a drift collapse within approximately 90 years after closure (SNL 2008 [DIRS 184433], Figure 6.3-82[a]). For the waste package surface to exceed 300°C, a seismic event of sufficient magnitude must occur within approximately 90 years after closure, result in drift collapse and affect a waste package with an unfavorable combination of a high thermal output surrounded by a low conductivity rubble (SNL 2008 [DIRS 179962], Section 6.5.1). Analyses have shown that the mean probability of these conditions occurring is about 1 in 10,000 within the first 10,000 years after closure (SNL 2008 [DIRS 179962], Section 6.5.1). Therefore, given that the waste package exposure temperature will bound the drip shield exposure temperature (as the drip shield is further from the heat source (the decaying waste forms)), and that Titanium Grades 5 and 29 are expected to be thermally stable up to 315°C (600°F) to 370°C (700°F) (ASM 1990 [DIRS 141615], p. 628), thermal sensitization of these materials can be considered to be of low probability under repository exposure conditions.

Schutz et al. (2000 [DIRS 177257]) measured the mechanical properties of Titanium Grade 29 after 12 months of exposure at 210°C (410°F) and observed no changes in mechanical properties of Titanium Grade 29 after this long time exposure. Schutz et al. (2000 [DIRS 177257]) also concluded that the fully annealed, equilibrium, two-phase transformed β structure of Titanium Grade 29 exhibited no measurable changes in phases or phase composition after long-term exposure at 210°C. The low-ductility ordered phase α_2 (Ti_3Al) does not form below 400°C (750°F) (Jones 1992 [DIRS 178458], p. 269). No significant α_2 (Ti_3Al) precipitation was observed because of the low aluminum and interstitial content levels in Titanium Grade 29. Based on the previous discussion, it can be concluded that under the repository conditions, the precipitation of detrimental phases (e.g., α_2 (Ti_3Al) or coarsened β) is not expected to be a factor for the integrity of the material.

Therefore, based on the experimental evidence, FEP 2.1.11.06.0B (Thermal Sensitization of the Drip Shield) can be excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability of occurrence under the exposure conditions in the repository.

FEP: 2.1.11.07.0A

FEP NAME:

Thermal Expansion/Stress of In-Drift EBS Components

FEP DESCRIPTION:

Repository heat at Yucca Mountain could result in thermally induced stress changes that would affect the mechanical and chemical evolution of the repository. These stress changes could affect the EBS components, thus causing the formation of pathways for groundwater flow through the EBS or altering and/or enhancing existing pathways. Relevant processes include changes in physical properties of the drip shields, waste packages, pallet, and invert.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Waste Package—According to the current waste package design, all waste forms except the codisposal canisters will be contained in TAD canisters made of 300-series stainless steel (e.g., Stainless Steel Type 316L (UNS S31603)) (SNL 2007 [DIRS 179394], Section 4.1.1.4). The TAD canisters will be placed inside the Stainless Steel Type 316 inner vessel contained inside the Alloy 22 waste package outer shell (SNL 2007 [DIRS 179394], Section 4.1). The codisposal canisters will be placed inside the Stainless Steel Type 316 inner vessel, which will be placed inside the Alloy 22 waste package outer shell (SNL 2007 [DIRS 179567], Sections 4.1.1). Since the thermal expansion coefficient of the TAD canister and the waste package inner vessel is expected to be the same, only stress induced from differing thermal expansion between the inner and the outer vessel is important for this FEP.

The coefficient of thermal expansion for Stainless Steel Type 316L (UNS S31603) (an analogue for the Stainless Steel Type 316 used for the waste package inner vessel) is larger than the coefficient of thermal expansion for Alloy 22 (e.g., Stainless Steel Type 316 NG [nuclear grade]: 17×10^{-6} m/m·K at 260°C, Alloy 22: 12.6×10^{-6} m/m·K from 24°C to 316°C, where K is temperature in Kelvin (BSC 2001 [DIRS 152655], Section 5.1)). Thus, changes in temperature could lead to contact stresses between the waste package inner vessel and outer shell. Consequently, a loose fit between the waste package outer shell and the inner vessel is required to accommodate the differing thermal expansion coefficients between Stainless Steel Type 316 and Alloy 22.

Under thermal expansion loading, tangential stresses are significantly higher than radial stresses (BSC 2001 [DIRS 152655], Section 1.0). The maximum tangential stress at the waste package outer shell inner and outer surfaces was evaluated for several waste package configurations (e.g., 5-DHLW/DOE SNF-Short, 2-MCO/2-DHLW, and naval SNF Long (which is similar to a TAD canister) and Short) as a function of temperature and shell gap size (i.e., difference in radius of the two shells evaluated at room temperature) and results documented in *Waste Package Outer Barrier Stresses Due to Thermal Expansion with Various Barrier Gap Sizes* (BSC 2001

[DIRS 152655], Section 6). These design calculations have shown that a shell gap size of about 1 mm (or greater) would result in no tangential stresses due to thermal expansion. Therefore, current waste package design requires the radial gap between the waste package inner vessel and the waste package outer shell to be a least 1 mm and could be increased to a maximum of 5 mm (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-04). Typical waste package design also requires a relatively large longitudinal shell gap of at least 30 mm (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-05). Therefore, no significant stress is expected to develop between the waste package inner and outer vessels due to differing thermal expansion of waste package components. Although, as discussed in excluded FEP 2.1.03.06.0A (Internal Corrosion of Waste Packages Prior to Breach), residual moisture in the waste packages could result in the formation of a thin (on the order of 0.13 μm) corrosion product layer prior to breach of the waste package outer shell, this small amount of corrosion product is not expected to generate significant stress between the waste package inner vessel and outer shell.

Pallet—The waste package pallet also contains components composed of stainless steel and Alloy 22 (SNL 2007 [DIRS 179354], Section 4.1.3). However, thermal expansion of the pallet would have negligible effect because it is not constrained laterally or longitudinally.

Drip Shields—The drip shield connectors are required to allow for thermal expansion with no impact on drip shield performance at temperatures up to 300°C (BSC 2007 [DIRS 179354], Table 4-2, Parameter Number 07-15). Since the drip shield is farther from the heat source (i.e., the decaying waste forms), its temperature will be lower than the waste package surface temperature. A temperature of 300°C on the waste package surface should bound all repository-relevant thermal exposure conditions (SNL 2008 [DIRS 184433], Figure 6.3-76[a]) except in the event of a drift collapse within approximately 90 years of closure (SNL 2008 [DIRS 184433], Figure 6.3-82[a]). For any waste package surface temperature to exceed 300°C, a seismic event causing drift collapse and subjecting that waste package to a high thermal output in a surrounding of a low thermal conductivity rubble is required to occur within approximately 90 years of closure (SNL 2008 [DIRS 179962], Section 6.5.1). However, analyses have shown that the mean probability of occurrence of such conditions is about one in 10,000 within the first 10,000 years of disposal (SNL 2008 [DIRS 179962], Section 6.5.1). Therefore, thermal expansion of the drip shield segments is expected to have no significant impact on drip shield performance in the repository. The space between the drip shield and waste package is large enough to accommodate deflection due to rockfall as discussed in excluded FEP 2.1.03.07.0B (Mechanical Impact on Drip Shield).

Invert—Any thermal expansion of the invert ballast material will not generate appreciable stress because the material is unconstrained vertically and will expand into the open spaces within the drift (see discussion in excluded FEP 2.1.06.05.0B (Mechanical Degradation of Invert)).

In conclusion, thermally induced stress changes as discussed above will not affect the aforementioned EBS in-drift components causing the formation of pathways for groundwater flow through the EBS or altering and/or enhancing existing pathways.

Based on the previous discussion, omission of FEP 2.1.11.07.0A (Thermal Expansion/Stress of In-Drift EBS Components) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible

environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.08.0A

FEP NAME:

Thermal Effects on Chemistry and Microbial Activity in the EBS

FEP DESCRIPTION:

Temperature changes may affect chemical and microbial processes in the waste and EBS.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Actinide solubilities in carbonate systems, such as those that will prevail in the EBS, decrease with increasing temperature (SNL 2007 [DIRS 177418], Section 6.3.3.3); the actinide solubilities used in TSPA are those calculated at 25°C. Conversely, the solubility of radium (using barium as an analog) increases with temperature (SNL 2007 [DIRS 177418], Section 6.3.3.3), and the radium solubilities used in TSPA are those calculated at 100°C. Tin solubilities are calculated at 25°C due to limited thermodynamic data; other radionuclides are not solubility-limited and their release rate is controlled by the dissolution rate of the waste form (SNL 2007 [DIRS 177418], Table 8-1). Sensitivity runs indicate that temperature influences in-package pH (SNL 2007 [DIRS 180506], Section 6.6.6), but has only a minor impact on ionic strength. To be consistent with the solubility model, and because of greater confidence in the 25°C thermo-kinetic inputs, all in-package pH and ionic strength abstractions are based on calculations performed at 25°C (SNL 2007 [DIRS 180506], Section 6.6[a]).

The effects of temperature on mineral stabilities and chemical reaction rates are included in each geochemical submodel of *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.2), which uses results from *In-Drift Precipitates/Salts Model* (SNL 2007 [DIRS 177411]); which is used to predict the temperature-dependent stabilities of precipitated phases in the drift.

Test data show that the reaction rates for commercial SNF and HLW glass degradation are temperature dependent. Temperature dependence was included in degradation abstraction models implemented in TSPA for both waste forms. Total carbonate concentration, which is an input for commercial SNF degradation, is also temperature dependent.

Evaluation of Potential Impacts of Microbial Activities on Drift Chemistry (BSC 2004 [DIRS 169991], Section 6.4) outlines several repository-specific environmental constraints on microbial activity. The conclusions from that analysis are summarized in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS), which indicates that environmental factors will severely limit microbial activities in the repository. Microbial activity, therefore, need not be considered further.

FEP NAME:

Thermal Effects on Flow in the EBS

FEP DESCRIPTION:

High temperatures in the EBS may influence seepage into, and flow within, the waste and EBS. Thermally-induced changes to fluid saturation and/or relative humidity could influence in-package chemistry. Thermal gradients in the repository could lead to localized accumulation of moisture. Wet zones could form below the areas of moisture accumulation.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Multiscale Thermohydrologic Model (SNL 2008 [DIRS 184433]) calculates the thermohydrologic environment within and around the emplacement drifts. Based on the modeling methodology and inputs described in that report (SNL 2008 [DIRS 184433], Sections 6.2, 6.4, and 6.12[a], and Table 1-1), the MSTHM predicts the temperature, relative humidity, gas- and liquid-phase fluxes, and gas- and liquid-phase saturations in the near-field host rock, as well as within the emplacement drifts (SNL 2008 [DIRS 184433], Section 6.3[a]). The temperature and relative humidity directly affect the in-drift chemical environment calculated in the TSPA.

The thermal effects on flow within and around the drift are also simulated with the TH seepage model in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.2). The TH seepage model evaluates seepage into the drift during the thermal pulse and concludes that (1) the volume of thermal seepage is always less than seepage under ambient conditions, and (2) seepage will not occur at drift wall temperatures over 100°C for the intact drifts. These conclusions are utilized to develop an appropriate seepage abstraction methodology in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2), which conservatively abstracts the larger ambient seepage rates determined by *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.3.6) for use in TSPA. TSPA calculations incorporate seepage model uncertainty by sampling probability distributions for rock capillarity, permeability, and percolation flux (SNL 2007 [DIRS 181244], Section 6.6).

Thermal-hydrologic conditions calculated by the MSTHM (SNL 2008 [DIRS 184433], Section 6.3[a]), together with results described in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 8[a]) and *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Section 8[a]), are implemented in the TSPA and are also used as input by the EBS flow and transport model described in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.1.1). Thus, thermal effects on flow into the EBS are accounted for in TSPA. However, with respect to advective fluxes of water through various EBS components, for the purpose of transporting radionuclides by advection, the potential effects of evaporation

within the drift are conservatively ignored. The total flux through the invert is set equal to the seepage flux into the drift, plus any contributions due to drift wall condensation and imbibition flux from the host rock.

Thermal gradients in the repository could lead to localized accumulation of moisture within the cooler regions of the emplacement drifts. Such effects are addressed in included FEPs 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-scale Cold Traps)) and 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-scale Cold Traps)), and excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield). Locally saturated conditions are considered in the in-package chemistry abstraction provided to TSPA (SNL 2007 [DIRS 180506]).

The effects of evaporation and condensation are addressed in included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-scale Cold Traps)), included FEP 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-scale Cold Traps)), and excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield).

FEP: 2.1.11.09.0B

FEP NAME:

Thermally-Driven Flow (Convection) in Waste Packages

FEP DESCRIPTION:

Temperature differentials may result in convective flow in the EBS. Convective flow within the waste packages could influence in-package chemistry.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Convective flow in the gas phase or the aqueous phase within waste packages could occur as a result of local thermal gradients. Convective flow in the gas phase could affect the relative humidity or oxygen levels in waste packages. In the aqueous phase, such flow could serve to disperse corrosion by-products or dissolved radionuclides, potentially resulting in increased waste package releases. The effects of thermally driven convection in waste packages decrease with time, as the waste cools and temperature gradients within the packages decrease. There are few mechanisms for early waste package failure, limiting the potential occurrence of this process.

In TSPA, in-package chemistry is calculated using the in-drift gas phase composition, which is expected to be in equilibrium with the gas phase within the waste package; this equilibrium is maintained by diffusive and advective processes. The CO_2 partial pressure is set to the in-drift value; conditions are assumed to remain oxic; and the relative humidity at the waste package surface is taken to be representative of the interior relative humidity. Although not quantitatively evaluated, the effect of thermal convection in the gas phase within a waste package would be homogenization, reducing the possibility of compositional gradients. This is consistent with the existing TSPA implementation.

Convection in the aqueous phase is not anticipated to have a large effect on radionuclide releases from the waste package. Huge volumes of uranium secondary phases and steel corrosion products buffer the pH within the package (SNL 2007 [DIRS 180506], Section 6.3.4[a]), so little change in water chemistry can occur. Also, once packages have cooled sufficiently for water to exist in the package, thermal gradients and the resulting convective mixing will be minor. In addition, convection in the aqueous phase requires that water enters a waste package, and for convection to be important relative to advection, ponding must occur within the waste package. Water entry into a waste package requires both drip shield and waste package failure. The drip shield does not fail by localized corrosion (SNL 2007 [DIRS 180778], Section 8.4) or hydride cracking (excluded FEP 2.1.03.04.0B (Hydride Cracking of Drip Shields)), and will not breach by general corrosion within the first 10,000 years (SNL 2007 [DIRS 180778], Section 8.3). Waste packages do not fail by hydride cracking (excluded FEP 2.1.03.04.0A (Hydride Cracking of Waste Packages)), or by general corrosion within the first 10,000 years (SNL 2007

[DIRS 178519], Section 8.1). However, in the event of drip shield failure, waste packages may fail by localized corrosion if contacted by seepage. Seismic events may result in drip shield damage such as buckling, rupture, or displacement, allowing seepage to reach the waste package. Waste packages contacted by seepage may fail by localized corrosion, resulting in corrosion patches, which permit advective flow into the packages and ponding to occur.

If seepage is benign with respect to localized corrosion, ponding inside packages is not anticipated, because the types of waste package damage that occur due to seismic ground motion do not permit ponding of water in the waste package. Seismic ground motion and the resulting dynamic interaction of waste packages, pallets, and the drip shield, can produce waste package damage from end-to-end impacts and package-pallet impacts (SNL 2007 [DIRS 176828], Section 6.5). Breaches resulting from such damage are limited to stress corrosion cracks, and advective flow of liquid water through such cracks is excluded in FEP 2.1.03.10.0A (Advection of Liquids and Solids through Cracks in the Waste Package). Seismic fault displacement may result in shearing of waste packages, potentially allowing for flow into and radionuclide transport out of a damaged package (SNL 2007 [DIRS 176828], Section 6.1.4). However, fault displacement severely damages waste packages. In addition, seismic events sufficiently large to damage a waste package by fault displacement occur with a mean annual exceedance frequency of 2.5×10^{-7} or less (SNL 2007 [DIRS 176828], Section 6.11.4). Only 214 waste packages are intersected by faults in the consequence analyses reported in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.11.2), and, generally, only a small fraction of that number are anticipated to be affected by any single faulting event. Because of the extensive damage to the waste package produced by fault displacement, ponding is not anticipated to occur.

An evaluation of the probability of ponding within waste packages, for several different combinations of drip shield and waste package failure mechanisms including early failures, failures due to seismic ground motion, rockfall and drift collapse, and waste package failure by localized corrosion, is presented in *Waste Package Flooding Probability Evaluation* (SNL 2008 [DIRS 184078], Table 7-4). The analysis concludes that, while ponding can occur if the drip shield fails and the waste package is subject to localized corrosion, the mean probability of ponding occurring in even a single waste package in 10,000 years is less than 10^{-4}.

Waste package failure will occur in the case of an igneous intrusion intersecting the respository. The effects of igneous intrusion are evaluated in *Dike/Drift Interactions* (SNL 2007 [DIRS 177430], Section 8.1.2). The damage to a waste package caused by magma intrusion is extensive, compromising the durability and even the shape of the entire waste package. High magma temperatures compromise the corrosion resistance of the waste package, and the cooling basaltic magma represents a corrosive environment, exsolving volatile gases such as H_2O, H_2, CO_2, CO, SO_2, S_2, HCl, HF, and H_2S, which has a large impact on waste package corrosion rates. Even if the waste package does not breach during the magma intrusion, subsequent rapid and ubiquitous failure will occur. Thus, ponding within the package is not plausible.

To summarize, convection in the gas phase will have little effect on gas-phase compositions, as diffusion and advective flow already provide driving forces for homogenization of the gas phase within a given waste package and with the in-drift gas phase. Convection in the aqueous phase is anticipated to occur only rarely because it requires ponding within a waste package. Should this

unlikely event occur, it will have little effect on water chemistry or radionuclide releases from a waste package.

Based on the previous discussion, omission of FEP 2.1.11.09.0B (Thermally Driven Flow (Convection) in Waste Packages) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.11.09.0C

FEP NAME:

Thermally Driven Flow (Convection) in Drifts

FEP DESCRIPTION:

Temperature differentials may result in convective flow in the EBS. Convective flow within the drifts could influence in-drift chemistry.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Heat generated by decaying radioactive waste will produce temperature differences between the waste package, the drift wall, and other components of the engineered barrier system. Non-uniform heating will produce temperature differences between adjacent waste package locations. These temperature differences will cause natural convection within the open spaces in the drift. The effects of natural and forced convection during preclosure ventilation are addressed in *Ventilation Model and Analysis Report* (BSC 2004 [DIRS 169862], Sections 6.3.3 and 8.2). Natural convection in the drifts after closure is addressed by *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648]).

The convection model presented in *In-Drift Natural Convection and Condensation* (SNL 2007 [DIRS 181648], Sections 6.1 and 6.2) includes explicit representation of two-dimensional and three-dimensional natural convection driven by temperature differences. Results from this model (SNL 2007 [DIRS 181648], Section 6.4) are used to develop an effective thermal conductivity for air that captures the heat transfer effects from natural convection, and is subsequently used in submodels of *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Appendix I[a]). Using this approach, the overall heat transfer rate from the waste package to the in-drift components and the drift wall is maintained. The three-dimensional convection model is also used to develop a dispersion coefficient (SNL 2007 [DIRS 181648], Section 6.2.7) that represents gas-phase mass transport by thermal convective mixing for use in simulating vapor transport in the emplacement drifts (SNL 2007 [DIRS 181648], Section 6.3.5; SNL 2008 [DIRS 184433], Sections 6.3.18[a] and 7.8[a]). Uncertainties in the in-drift natural convection and condensation model are propagated to TSPA through use of bounding values for the axial dispersion rate, for the degree of drip shield ventilation, and for the percolation rate at the repository horizon (SNL 2007 [DIRS 181648], Section 6.1.3[a]).

The output from the ventilation model (BSC 2004 [DIRS 169862], Section 8.2), modified and extended as described in *Thermal Management Flexibility Analysis* (SNL 2007 [DIRS 179196], Section 6.3), and output from the condensation model (SNL 2007 [DIRS 181648], Section 8.3.2) are used in the MSTHM (SNL 2008 [DIRS 184433]), which simulates thermal-hydrologic conditions in the drift. In TSPA calculations, temperature and relative humidity conditions derived from the MSTHM are used to extract parameters of the in-drift chemical environment

from the lookup-tables generated by the in-drift seepage dilution/evaporation model, developed in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.3).

Condensation forming on the roof or other parts of the drift is input to the TSPA as described in included FEP 2.1.08.04.0A (Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)). Condensation forming at the repository edges is discussed in included FEP 2.1.08.04.0B (Condensation Forms at Repository Edges (Repository-Scale Cold Traps)), and condensation forming on the underside of the drip shields is discussed in excluded FEP 2.1.08.14.0A (Condensation on Underside of Drip Shield). Preclosure ventilation is discussed in included FEP 1.1.02.02.0A (Preclosure Ventilation).

Finally, thermal convective mixing is also a factor in dispersion of acid-gas species that may evolve from liquid brines, such as those formed by salt deliquescence (SNL 2007 [DIRS 181267], Section 6.2). Dispersion from convective mixing is part of the justification for excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence).

FEP: 2.1.11.10.0A

FEP NAME:

Thermal Effects on Transport in EBS

FEP DESCRIPTION:

Temperature changes in the repository may influence advection, diffusion, and sorption in the EBS. The Soret effect is a diffusion process caused by a thermal gradient. In liquids having both light and heavy molecules (or ions) and a temperature or thermal gradient, the heavier solute molecules tend to concentrate in the colder region. Temperature differences in the waste and EBS may result in a component of diffusive solute flux that is proportional to the temperature gradient.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses thermal effects on radionuclide transport by Soret diffusion and sorption. Other thermal effects are included in TSPA. In *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Section 6.3.4.1.2), the diffusion coefficient for the invert, corrosion products, and waste form domains is modified for temperature, but not for thermal gradient. The thermal effect on diffusion coefficients for species in an aqueous medium is based on hydrodynamic theory and is approximated by the Stokes-Einstein equation (Bird et al. 1960 [DIRS 103524], Section 16.5). The Stokes-Einstein equation shows that the diffusion coefficient in a liquid medium is directly proportional to the temperature divided by the viscosity of the medium. For aqueous media, the viscosity of water decreases with respect to increasing temperature so that the diffusion coefficient is seen to increase with increasing temperature (SNL 2007 [DIRS 177407], Section 6.3.4.1.2, Figure 6.3-5). The effect of temperature on diffusion rates is further discussed as part of included FEPs 2.1.09.08.0A (Diffusion of Dissolved Radionuclides in EBS) and 2.1.09.24.0A (Diffusion of Colloids in EBS). Diffusion rates in the invert are also indirectly coupled to thermal effects through the invert saturation (SNL 2007 [DIRS 177407], Sections 6.3.4.1, 6.3.4.3, and 6.3.4.6), which is determined by *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2.12.1[a]). This effect is summarized in included FEPs 2.1.08.05.0A (Flow Through Invert) and 2.1.08.07.0A (Unsaturated Flow in the EBS).

In addition, thermal gradients and temperature effects relative to advection are addressed by evaluations of these transport-related processes, as summarized in included FEPs 2.1.11.09.0A (Thermal Effects of Flow in the EBS), 2.1.09.08.0B (Advection of Dissolved Radionuclides in EBS), and 2.1.09.19.0B (Advection of Colloids in EBS).

The Soret effect refers to the development of a concentration gradient in response to a temperature gradient. The magnitude of the effect is described by the Soret coefficient (S_T) (Duhr and Braun 2006 [DIRS 183865], p. 19,678):

$$S_T\,(\mathrm{K}^{-1}) = D_T/D \qquad \text{(Eq. 2.1.11.10.0A-1)}$$

where D_T is the thermodiffusion coefficient, and D is the diffusion coefficient. Because of thermodiffusion, a concentration gradient will develop in response to the temperature gradient, as described by Duhr and Braun (2006 [DIRS 183865], p. 19,678):

$$c / c_o = \exp\left[-S_T\left(T - T_o\right)\right] \qquad \text{(Eq. 2.1.11.10.0A-2)}$$

where the concentration c is normalized to the concentration c_o at temperature T_o. In general, ions diffuse from the hotter region to the cooler; therefore, in the EBS, the Soret effect could potentially result in more rapid diffusion of radionuclides out of the hot waste package or from the hotter top of the invert towards the cooler bottom. The magnitude of the effect is dependent upon, for any given species, the Soret coefficient and the magnitude of the thermal gradient ($T - To$). In general, this effect is small. According to Bird et al. (1960 [DIRS 103524], pp. 565 to 567), "The thermal diffusion term [Soret effect] describes the tendency for species to diffuse under the influence of a temperature gradient; this effect is quite small." This is corroborated by Hirschfelder et al. (1964 [DIRS 171800], p. 8), who state, "Diffusion may also result from a temperature gradient (thermal diffusion or the Soret effect), and the transfer of energy may also result from a concentration gradient (diffusion thermo or Dufour effect). These are small effects."

The small thermal conductivity of the invert results in large temperature gradients relative to other locations in the EBS (SNL 2008 [DIRS 184433], Section 6.3.11). Thermal gradients within the repository will be greatest soon after closure, when the maximum thermal response occurs in the repository. Later in time, as the repository cools, the thermal gradients within the EBS are reduced. Sensitivity analyses in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.3.11), using different invert hydrologic parameters, indicate that a typical temperature difference just after the drift wall boiling period, from the top to the bottom of the invert, a distance of approximately 1.3 m (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-10), is on the order of 5°C. The gradient decreases with time and after a few thousand years is less than a 1°C.

Typical Soret coefficients for aqueous solutions are on the order of 0.001 to 0.01 K^{-1} (Platen 2006 [DIRS 183864], p. 5). These general values are corroborated by data from Snowden and Turner 1960 [DIRS 183867], Table 1), Thornton and Seyfried (1983 [DIRS 183866], Table 1), and Petit et al. (1986 [DIRS 183863], Table II). Using the maximum expected thermal gradient of 5°C, this corresponds to an increase in the diffusion rate through the invert of 0.5% to 5% (Equation 2.1.11.10.0A-1). This is negligible relative to the range of uncertainty in the invert diffusion coefficient that is implemented in *EBS Radionuclide Transport Abstraction* (SNL 2007 [DIRS 177407], Equation 6.3.4.1.1-22 and Figure 6.3-4), which spans a factor of 10. Hence, the Soret effect is considered to be insignificant and is not implemented by TSPA.

An evaluation to determine the potential for sorption coefficients to vary with temperature on substrates (tuff and hematite) relevant to the repository was done, as discussed in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Appendix I). Measurements at various temperatures of K_d for sorption of barium (a proxy for radium), cesium, strontium, and neptunium on Yucca Mountain tuff are reported, respectively, in

DTNs: LA0010JC831341.001 [DIRS 162476], LA0010JC831341.002 [DIRS 153321], LA0010JC831341.003 [DIRS 153322], and LA0010JC831341.007 [DIRS 153319]. It was concluded that the effect of temperature on sorption coefficients is minor, and that sorption generally increases with increasing temperature. Hence, the use of sorption coefficients of the radioelements measured at ambient temperatures should be applicable and generally bounding, and the effect of temperature on sorption coefficients need not be considered in modeling radionuclide transport in the near-field of the repository.

Based on the previous discussion, omission of FEP 2.1.11.10.0A (Thermal Effects on Transport in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.01.0A

FEP NAME:

Gas Generation (Repository Pressurization)

FEP DESCRIPTION:

Gas generation in the repository might lead to pressurization of the repository, produce multiphase flow, and affect radionuclide transport. This FEP addresses repository pressurization.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Gas may be generated in the repository by a variety of mechanisms. Waste form radioactive decay may result in helium gas production (excluded FEP 2.1.12.02.0A (Gas Generation (He) from Waste Form Decay)); waste package corrosion may generate hydrogen gas (excluded FEP 2.1.12.03.0A (Gas Generation (H_2) from Waste Package Corrosion)); microbial degradation of EBS materials may lead to the generation of gases (CO_2, CH_4, H_2S) (excluded FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation)); and gas may be generated by radiolysis (excluded FEP 2.1.13.01.0A (Radiolysis)). After the waste packages are breached, gas release and continuing gas generation could conceivably lead to gas pressurization of the repository and affect radionuclide transport.

Gas is not expected to cause repository gas pressures to increase, given the repository's lithologic setting. As discussed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.1.4), the repository is situated in the Topopah Spring Welded Tuff, which is heavily fractured, allowing gases to escape the repository. Changes to the fluid-flow characteristics of the flow system in the mountain could be produced by thermally driven mechanical and chemical processes. This could produce a condensation cap in the drift (BSC 2005 [DIRS 172232], Section 6.1.1) that may result in gas accumulation under the cap. A condensation cap could form above the repository due to heat-driven reflux processes. With continuous heating, a hot dry zone may develop that is characterized by a continuous process of boiling, vapor transport, condensation, and migration of water back toward the heat source, either by capillary forces or gravity drainage. The dry out zone extends approximately 5 to 10 m from the drift wall. The drift spacing is large relative to the dry out zone, which allows the water above the repository to drain between drifts where the rock remains below boiling. The effects of condensation caps are confined to the thermal period, after which the maximum rock temperatures are always below boiling (BSC 2005 [DIRS 172232], Section 6.2.2.1.3). The relatively short-lived heat-driven reflux potentially resulting in the formation of a condensation cap is a dynamic process that does not preclude the diffusion of gasses through the drift wall, convection of gasses along thermal gradients within the drifts, and movement through fractures laterally and below the drifts. Thus, gases are not expected to accumulate under condensation caps.

Additional corroborative evidence for the relative permeability (with respect to gases) of the repository host unit and of the mountain as a whole is presented in *Hydrogeology of the Unsaturated Zone, North Ramp Area of the Exploratory Studies Facility, Yucca Mountain, Nevada* (Rousseau et al. 1999 [DIRS 102097], p. 55), which describes variations in the pressure of the gas phase in the unsaturated zone due to barometric pumping. Changes in gas and water vapor pressures at the repository level are driven by changes in the atmospheric barometric pressure, and are transmitted primarily through the connected fracture network (Rousseau et al. 1999 [DIRS 102097], p. 56). This shows that any gases generated in the repository horizon will migrate away from the emplacement drift into the unsaturated fractures of the host rock, thus preventing significant gas pressure buildup in the drift.

Based on the previous discussion, omission of FEP 2.1.12.01.0A (Gas Generation (Repository Pressurization)) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.02.0A

FEP NAME:

Gas Generation (He) from Waste Form Decay

FEP DESCRIPTION:

Helium (He) gas production may occur by alpha decay in the waste. Helium production might cause local pressure buildup in cracks in the fuel and in the void between fuel and cladding, leading to cladding and waste package failure.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Commercial SNF and DOE SNF (other than naval SNF) cladding is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the fuel matrix nor the release of radionuclides from the fuel after groundwater contact (included FEPs 2.1.02.12.0A (Degradation of Cladding Prior to Disposal); 2.1.02.23.0A (Cladding Unzipping), and 2.1.02.25.0A (DSNF Cladding)). Therefore, even if gas generation (helium) from waste form decay were to cause cladding degradation, the additional impact of this FEP on cladding (other than naval SNF cladding) performance is of low consequence and will not affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment. Naval SNF cladding is discussed in included FEP 2.1.02.25.0B (Naval SNF Cladding).

For failed rods, the helium would be released into the waste package, possibly increasing the pressure therein. However, as illustrated by the following discussion for a commercial SNF waste package, the potential addition of decay-derived helium gas to the waste package void volume would not have a significant effect on the internal waste package pressure.

The radionuclides that are the major sources of decay-derived helium in SNF are: ^{244}Cm, ^{238}Pu, ^{239}Pu, ^{240}Pu, and ^{241}Am (Piron 2001 [DIRS 162396], Section 5.1.2). The decay-derived helium will accumulate in the fuel pellet matrix because these radionuclides are embedded in the fuel matrix and the because most of the alpha particles from their decay are stopped within the fuel matrix. Because of the long half-lives of some of these radionuclides, the decay-derived helium will continue to accumulate in the fuel matrix for a long time after disposal. Even if the helium accumulated for 10,000 years from alpha decay in a fuel rod with a burnup of 47.5 GWd/MTU is assumed to be completely released from the fuel matrix into the gap region between the fuel pellets and the cladding, the pressure increase in the gap would be about 90 bars at 20°C (Piron and Pelletier 2001 [DIRS 165318], Section 5.3.2.4.1). If this helium were to be released from the fuel rods into the void volume of the waste package, the pressure increase in the waste package would be about one bar at 20°C, assuming that the gap volume is about 13 cm^3 (Piron and Pelletier 2001 [DIRS 165318], Section 5.3.2.4.1) and the available void volume for helium expansion in the waste package is about 4,737 liters (SNL 2007 [DIRS 180506], Table 6-3[a]).

This result is obtained when the ideal gas law is used to estimate the pressure in the waste package assuming release of the decay-derived helium that has accumulated for 10,000 years from the 4,368 fuel rods in a commercial SNF waste package containing 21 fuel assemblies each containing 208 fuel rods (i.e., 13 cm^3/rod × 4,368 rods = 56.8 liters). The pressure increase at 20°C is given by: 90 bar × 56.8 liters/waste package / (56.8 liters + 4,737 liters) = 1.1 bar. The corresponding pressure increase at a more relevant 10,000-year temperature of 50°C would be less than 1.2 bar or (1.2 bars × 14.504 psia per bar (Perry et al. 1984 [DIRS 125806], Table 1-6)) 17.4 psia. Such a pressure increase is small compared to the design pressure limit (140 psia at 707°F) (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-06) and would therefore have a negligible effect on the waste package. The combined effects of decay helium and other gasses on the internal waste package temperatures are addressed in included FEP 2.1.03.07.0A (Mechanical Impact on Waste Package). Because the codisposal waste packages containing HLW glass and DOE SNF (other than naval SNF) have a much smaller inventory of the radionuclides that can produce decay-derived helium compared to the commercial SNF waste packages (SNL 2008 [DIRS 180472], Table 7-1[a]), the potential pressurization effects of decay-derived helium on the codisposal waste packages is also expected to be negligible.

Helium is an inert gas and will not chemically react with in-package components (internals, cladding or UO_2 pellets). The effects of microcracking due to pressure buildup in gas bubbles within the fuel matrix on the rate of matrix corrosion are expected to be negligible. As described in Sections 6.2.1 and 6.2.2 of *CSNF Waste Form Degradation: Summary Abstraction* (BSC 2004 [DIRS 169987]), evidence from commercial SNF testing indicates that the corrosion process is a general corrosion process occurring predominantly at the periphery of the fuel fragments; the rate of the process is not significantly influenced by microcracks in the fuel matrix.

Based on the previous discussion, omission of FEP 2.1.12.02.0A (Gas Generation (He) from Waste Form Decay) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.03.0A

FEP NAME:

Gas Generation (H_2) from Waste Package Corrosion

FEP DESCRIPTION:

Gas generation can affect the mechanical behavior of the host rock and engineered barriers, chemical conditions, and fluid flow, and, as a result, the transport of radionuclides. Gas generation due to oxic corrosion of waste packages, cladding, and/or structural materials will occur at early times following closure of the repository. Anoxic corrosion may follow the oxic phase if all oxygen is depleted.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP discussion involves the potential impact of hydrogen gas generation on the waste package, cladding, and internal structure of the waste package through chemical processes. The screening justification is based on the kinetic aspect of hydrogen gas production due to metal corrosion, and the possible interaction of generated hydrogen with the waste package and cladding materials, and the surrounding atmosphere.

The waste package outer barrier material, Alloy 22 (UNS N06022) (SNL 2007 [DIRS 179567], Table 4-1, Parameter Number 03-03), is extremely corrosion resistant because it forms a highly protective oxide film that protects it from further corrosion, and the observed general corrosion rate of the waste package outer barrier under repository-relevant environments is very low, on the order of nanometers per year (SNL 2007 [DIRS 178519], Section 8.2, and Figures 6-26 to 6-27). The low general corrosion rate of Alloy 22 will lead to a very low rate of hydrogen gas generation in the oxic repository.

A fraction of the total amount of hydrogen produced will be adsorbed and then absorbed by the metals in the emplacement drift as atomic hydrogen (the extent of absorption will depend on the hydrogen absorption efficiency of the metal under the prevailing environmental conditions) potentially forming metal hydride phase(s), and the balance will evolve as hydrogen gas (i.e., as molecular hydrogen) into the surrounding environment. Almost all of the evolved hydrogen gas (i.e., undissolved molecular hydrogen) is expected to be diffused out (under a concentration gradient) and barometrically pumped out of the drift via fractures in the host rocks of the repository. Under this situation, hydrogen buildup leading to internal pressurization of the drift is not expected to occur (see also excluded FEP 2.1.12.01.0A (Gas Generation (Repository Pressurization)). Since the internal pressure of the repository remains unaltered, and there are no known chemical reactions between hydrogen and host rock materials, mechanical properties of the repository host rocks and hence fluid flow through these rocks will not be impacted. Further, due to lack of hydrogen pressure buildup in the repository, absorption of waste package general corrosion-produced hydrogen into the drip shield will be negligible. This is expected per

Sievert's law, which states that the concentration of absorbed hydrogen in a metal is directly proportional to the square root of hydrogen gas pressure outside the metal (ASM International 1987 [DIRS 103753], p. 329). Hydrogen incorporation into the waste package and drip shield materials is further evaluated in excluded FEPs 2.1.03.04.0A (Hydride Cracking of Waste Packages) and 2.1.03.04.0B (Hydride Cracking of Drip Shields).

In the event of waste package failure, water will gain access to the stainless steel inner vessel. If the inner vessel also breaches, then water will contact the waste package contents (e.g., TAD canister, structural components, and cladding). Corrosion of these materials will also produce hydrogen at a rate controlled by their corrosion rates and likely limited by the amount of water available, but with low consequence. Hydrogen production from aqueous corrosion of waste package materials (the TAD canister, waste package internals, and the cladding) will not have a significant impact on in-package chemistry, particularly in terms of radionuclide release from the waste form This is because the hydrogen gas is expected to quickly exit the through the openings of the failed waste package, also because a more-reducing environment (due to the presence of hydrogen gas) is expected to inhibit the dissolution of fuel (SNL 2007 [DIRS 177418]). In addition, corrosion-generated hydrogen will be consumed through the following physicochemical processes:

- A portion of the total hydrogen produced from aqueous corrosion of the waste package metal(s) will be first adsorbed onto the metal surface and then absorbed in the metal as atomic hydrogen, and the balance will be evolved as molecular hydrogen.

- A portion of molecular hydrogen evolved may exit the waste package without reacting with anything within the waste package and diffuse (under concentration gradient) out of the drift via fractures of the host rocks.

- As molecular hydrogen is slightly soluble (a few parts-per-million) in water (Lide 2006 [DIRS 178081], p. 8-81), a small portion of molecular hydrogen retained in the waste package will remain dissolved in water.

Commercial SNF and DOE SNF (other than naval SNF) cladding is considered to be breached upon emplacement in the repository and will neither inhibit groundwater contacting the fuel matrix nor the release of radionuclides from the fuel after groundwater contact (included FEPs 2.1.02.12.0A (Degradation of Cladding Prior to Disposal); 2.1.02.23.0A (Cladding Unzipping), and 2.1.02.25.0A (DSNF Cladding)). Furthermore, following waste package failure, immediate exposure of bare fuel to the waste package environment is assumed to take place (included FEP 2.1.02.23.0A (Cladding Unzipping)). Therefore, the incremental impact of corrosion-generated hydrogen gas on cladding will be insignificant.

The effect of hydrogen produced from radiolysis of water is discussed in excluded FEP 2.1.13.01.0A (Radiolysis).

In summary, hydrogen gas production due to oxic and anoxic corrosion of waste package materials is not expected to cause repository gas pressure to increase because the repository's fractured host rock is connected to the atmosphere. Pressurization of the repository due to gas pro duction is further discussed in excluded FEP 2.1.12.01.0A (Gas Generation (Repository

Pressurization)). Any credible potential for hydrogen gas leading to explosion is excluded by FEP 2.1.12.08.0A (Gas Explosions in EBS).

Based on the previous discussion, omission of FEP 2.1.12.03.0A (Gas Generation (H_2) From Waste Package Corrosion) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.04.0A

FEP NAME:

Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation

FEP DESCRIPTION:

Microbes are known to produce inorganic acids, methane, organic byproducts, carbon dioxide, and other chemical species that could change the longevity of materials in the repository and the transport of radionuclides from the near-field. The rate of microbial gas production will depend on the nature of the microbial populations established, the prevailing conditions (temperature, pressure, geochemical conditions), and the organic or inorganic substrates present. Initial analysis indicates the most important source of nutrient in the YMP repository will be metals. Other possible nutrients include cellulosic material, plastics, and synthetic materials. Minimal amounts of organics are mandated by regulation.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The unsaturated zone communicates with the atmosphere, which will prevent any gas produced at the repository horizon from accumulating. This is discussed in more detail in excluded FEP 2.1.12.06.0A (Gas Transport in EBS). Microbiological activity inside the EBS, as discussed in excluded FEP 2.1.10.01.0A (Microbial Activity in EBS), is excluded from TSPA because early temperatures and long-term nutrient constraints will limit microbial activity. The presence of organic/cellulosic materials in the waste packages will be limited by design controls. Control and specification of technical information needs on the organic content of sealed waste form canisters (DOE 2007 [DIRS 169992], Sections 4.2.6, 5.4.1B(4), and 5.4.3.C) and waste form and TAD canister design parameters (SNL 2007 [DIRS 179394], Table 4-1) will be used to confirm consistency between the contents of the waste form canisters emplaced in the repository and the technical basis for the TSPA. Moreover, requirements have been established to prevent undesirable materials (e.g., organics/cellulosics) that could have an adverse impact on postclosure performance from being left in the drift. These requirements are discussed in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 02-03) and excluded FEP 1.1.02.03.0A (Undesirable Materials Left).

CO_2, CH_4, H_2S, and ammonia are gases that are produced by microbial activity. Under the oxidizing conditions of the repository, carbon dioxide would be most prevalent. Any generation of CO_2 by microorganisms present inside of breached waste packages would tend to be dissipated by diffusion and/or advection from waste packages. Moreover, calculations in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.6.3[a]) indicate that order of magnitude variations in carbon dioxide partial pressures have minor effects on in-package chemistry (i.e., pH and ionic strength). The CO_2 ranges over which TSPA calculates probability distributions for radionuclide solubilities (maximum values are 100 times

atmospheric levels) correspond to maximal levels seen in organic-rich soils. Therefore, any additional effects on radionuclide solubilities from high carbon dioxide levels from microbial degradation are expected to be minor.

Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry (BSC 2004 [DIRS 169991], Section 6.5) suggests that the low levels of organic carbon in the system will limit any CO_2, CH_4, and H_2S elevation in the drift (BSC 2004 [DIRS 169991], Section 6.1.3 and Table 6.1-2). Furthermore, the oxidizing conditions in the repository will limit the formation of substantial quantities of H_2S (BSC 2004 [DIRS 169991], Section 6.4.2).

All waste packages will be dried and backfilled with helium, then sealed (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04). This will result in low water availability, which will limit microbial activity inside the waste package prior to breach. Any postbreach microbial degradation of waste form and waste package materials will produce gases that will diffuse and disperse in the drift atmosphere.

Gas pressurization of the repository due to the production of gases such as CO_2, CH_4, and H_2S is discussed in excluded FEP 2.1.12.01.0A (Gas generation (Repository Pressurization)), which is excluded on the basis of low consequence. The possibility of chemical reaction between methane (and/or hydrogen sulfide) gas with atmospheric oxygen is discussed in excluded FEP 2.1.12.08.0A (Gas Explosions in EBS).

Based on the previous discussion, omission of FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.06.0A

FEP NAME:

Gas Transport in EBS

FEP DESCRIPTION:

Gas in the waste and EBS could affect the long-term performance of the disposal system. Radionuclides may be transported as gases or in gases. Gas bubbles may affect flow paths, and two-phase flow conditions may be important.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is focused on gas transport in the EBS. Related to this FEP is excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere), which is concerned with the low consequence of gas transport in the geosphere. Gas pressurization of the repository is discussed under FEP 2.1.12.01.0A (Gas Generation (Repository Pressurization)), which is excluded on the basis of low consequence.

Several potential sources of gas in the waste package and EBS include: (1) air (O_2, N_2, Ar, CO_2, H_2, etc.), present at closure and circulated through convection and diffusion during the life of the repository; (2) gases produced from microbial processes (CO_2, CH_4, H_2S) (excluded FEP 2.1.12.04.0A (Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation)); (3) gases produced from waste form and EBS component degradation; (4) fission product gases (argon, xenon, krypton); (5) helium from initial fuel rod manufacture and waste form decay (excluded FEP 2.1.12.02.0A (Gas Generation (He) from Waste Form Decay)); (6) H_2 from waste package corrosion (excluded FEP 2.1.12.03.0A (Gas Generation (H_2) from Waste Package Corrosion)); and (7) gas generated by radiolysis – e.g., H_2 (excluded FEP 2.1.13.01.0A (Radiolysis)) – and radioactive decay ($^{14}CO_2$ and radon).

The following discussion is in two parts: (1) gas and performance; and (2) gas bubbles and two-phase flow.

Gas and performance—The results of THC seepage model simulations and the evidence for barometric pumping indicate that the minor gas generation that results from microbial respiration, corrosion, radiolysis, and other in-drift processes will not accumulate to the point of having any impact on long-term performance. Gases that may be present in the repository or formed from various processes are expected to convect and diffuse into the drift walls, become diluted, and disperse throughout the surrounding rock (gas transport in the geosphere is discussed under excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere)). Despite the large volume change associated with the phase transition from liquid water to vapor (a factor of ~1,600 at 100°C and 1 atmosphere, as given by Keenan et al. (1969 [DIRS 134666]), THC seepage model simulations show that pressures in fractures adjacent to the drift (which are nearly identical to

pressures in the drift) do not significantly increase during the boiling period. This is documented in THC seepage model outputs (SNL 2007 [DIRS 177404], Table 6.5-5; spreadsheets "*fract_81_162_dr_wn.xls*" (n = 0, 8, 9, 10, for different starting waters), worksheets "data1" and "data2"), and points to the high permeability of the host rock to gases.

Additional corroborative evidence for the relative permeability with respect to gases of the repository host unit and of the mountain as a whole is presented in *Hydrogeology of the Unsaturated Zone, North Ramp Area of the Exploratory Studies Facility, Yucca Mountain, Nevada* (Rousseau et al. 1999 [DIRS 102097], p. 55), which describes variations in the pressure of the gas phase in the unsaturated zone due to barometric pumping. Changes in gas and water vapor pressures at the repository level are driven by changes in the atmospheric barometric pressure, and are transmitted primarily through the connected fracture network (Rousseau et al. 1999 [DIRS 102097], p. 56).

High early repository temperatures, the primarily oxic environment, and a relative scarcity of water and organic carbon will combine to limit microbial activity and biogenic gases in the emplacement drifts, as demonstrated in *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 6.4).

Aqueous transport will fully encompass any dose effects of gas-phase transport in the geosphere. The only radionuclides that would have a potential for gas transport are $^{14}CO_2$ and ^{222}Rn as discussed in excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere). An analysis of the potential dose from gas-phase geosphere transport of $^{14}CO_2$ has been done for the individual maximum radiological dose rate. It was found that the dose from aqueous geosphere transport of $^{14}CO_2$ bounds the dose from gas-phase geosphere transport pathways. Aqueous geosphere transport pathways will also bound the dose from ^{222}Rn, primarily through aqueous transport of uranium and generation of ^{222}Rn as a decay product at the accessible environment (excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere)).

Gas bubbles and two-phase flow—If the waste package and invert were to become largely saturated, gas bubbles in advecting water in the waste package and invert could potentially affect advective and diffusive flow paths. The most plausible situation is one in which bubbles could lodge in pore spaces or fractures, forcing diversion of flow to neighboring flow paths. However, this would occur on a very localized scale, given the very small quantities of gas anticipated. Bubble effects in the unsaturated zone are described in excluded FEP 2.2.11.02.0A (Gas Effects in the UZ).

As discussed in part of included FEP 2.2.10.10.0A (Two-phase Buoyant Flow/heat Pipes), two-phase buoyant flow may occur as a result of waste-generated heat. Two-phase circulation continues until the heat source is too weak to provide the thermal gradients required to drive it. Therefore, this process would be temporary and would shut down at some point during cooldown.

Note that included FEP 2.1.11.09.0C (Thermally Driven Flow (Convection) in Drifts) describes thermally driven flow (convection) in drifts.

Based on the previous discussion, omission of FEP 2.1.12.06.0A (Gas Transport in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.12.07.0A

FEP NAME:

Effects of Radioactive Gases in EBS

FEP DESCRIPTION:

Radioactive gases may exist or be produced in the repository. These gases may subsequently escape from the repository. Typical radioactive gases include ^{14}C (in $^{14}CO_2$ and $^{14}CH_4$ produced during microbial degradation), tritium, fission gases (Ar, Xe, Kr), and radon.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Generation of radioactive gases due to activation of emplacement drift air and host rock is estimated to be low. By correcting the calculated activity in *Radiological Releases Due to Air and Silica Dust Activation in Emplacement Drifts* (BSC 2003 [DIRS 164562], Table 5-10) for an infinite irradiation time for stagnant air, activation of emplacement drift air generates approximately 9.0×10^{-11} μCi/mL of ^{16}N and 7.4×10^{-9} μCi/mL of ^{41}Ar. The ^{16}N activity is identical to the value in Table 5-10 of *Radiological Releases Due to Air and Silica Dust Activation in Emplacement Drifts* (BSC 2003 [DIRS 164562]) at the exhaust shaft inlet because it represents the saturation activity (the maximum activity produced by activation without radioactive decay). The ^{41}Ar activity includes a correction factor of $1/(1\text{-}e^{-0.3787*0.252}) = \sim 11.0$ (BSC 2003 [DIRS 164562], Section 5.7.1, example) for the saturated activity. The resulting ^{41}Ar activity is estimated as: 6.7×10^{-10} μCi/mL (BSC 2003 [DIRS 164562], Table 5-10, at the exhaust shaft inlet) $\times$ 11.0 = 7.4×10^{-9} μCi/ml. Activation of host rock produces a saturation activity of 2.1×10^{-7} μCi/mL of ^{16}N at the drift wall (BSC 2003 [DIRS 164562], Table 5-11).

In units of g/mL, this amounts to 9.0×10^{-28} g/mL of ^{16}N and 1.7×10^{-22} g/mL of ^{41}Ar from neutron activation of air, and 2.1×10^{-24} g/mL of ^{16}N from neutron activation of host rock. These concentration values are for onset of waste package emplacement and will be less at the time of closure and will decrease further with time. These estimated quantities are negligible (compare to the density of air - 1.204×10^{-3} g/mL; (Weast 1985 [DIRS 111561], p. F-10, for 20°C and 760 mm mercury) and are, therefore, considered to be non-contributors to in-drift conditions and to radionuclide releases to the accessible environment.

The major gas constituents trapped inside a waste package prior to disposal will be the result of fission and neutron-activation, predominantly radioactive isotopes of the noble gases argon, xenon, and krypton (Manaktala 1993 [DIRS 101719], Section 3.3.6). Gasses in the gap fraction will be available for release upon clad failure. There are several arguments that support the exclusion of radioactive gases from TSPA calculations, based on low consequence to waste package internal pressures (see excluded FEP 2.1.03.07.0A (Mechanical Impact on Waste Package)) and low consequence with respect to radionuclide releases from the EBS, discussed

further here. Radioactive gases residing in fuel rods and waste packages prior to postclosure or produced after postclosure times will either decay rapidly or quickly become negligible. Argon, krypton, and radon were screened out due to short half-lives or low activity (Baum et al. 2002 [DIRS 175238], pp. 53 and 54; see also SNL 2007 [DIRS 177424], Table 4-3). Likewise, xenon is also negligible, since the half-lives of the xenon isotopes are on the order of just a few days at most (Parrington et al. 1996 [DIRS 103896], p. 35). Specifically:

A. Xenon (^{135}Xe), a fission yield-product, is short-lived (with a half-life of 9.1 hours) and will not be produced during the regulatory time period. It will undergo decay to its long-lived daughter ^{135}Cs by the time of waste emplacement.

B. Argon (^{39}Ar) has a low activity and is screened out due to low consequence. It will not be produced during the regulatory time period.

C. Of the noble gases, ^{85}Kr has a significant initial inventory, but because of its short half-life (approximately 11 years), its concentration and radioactivity level would rapidly become insignificant.

D. Radon gas (^{222}Rn and ^{219}Rn) is short-lived (with half-lives of approximately 3.8 days and 4 seconds, respectively), as are its gaseous daughters (^{218}Po, half-life approximately 3.1 minutes and ^{215}Po, half-life of microseconds) and, thus, will be in secular equilibrium with, respectively, radium (^{226}Ra) and actinium (^{227}Ac). Geosphere transport of radon has been excluded as discussed in excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere) because the radon will decay to insignificant levels before reaching the accessible environment.

E. Tritium may be present in SNF as a result of neutron activation of impurities present in the fuel assemblies. Tritium has a half-life of about 12 years (Dean 1992 [DIRS 100722], Table 4.16), and because of its short half-life, its concentration and radioactivity level would rapidly become insignificant.

F. ^{14}C is formed from nitrogen in reactors through neutron capture and proton decay. The generation of the radioactive gases $^{14}CH_4$ and $^{14}CO_2$ from microbial activity (BSC 2004 [DIRS 169991], Sections 6.4, 6.5, and 7.1) is not significant because organic levels in the waste are expected to be low, and microbial activity in the waste package and the EBS is expected to be negligible (see excluded FEP 2.1.10.01.0A (Microbial Activity in EBS)). Moreover, methane as $^{14}CH_4$ is not expected to be produced by microbes as sustained anaerobic conditions would be required (BSC 2004 [DIRS 169991], Section 6.1.3; and excluded FEP 2.1.12.04.0A (Gas generation (CO_2, CH_4, H_2S) from Microbial Degradation)) yet oxidizing conditions will prevail in the in-drift environment over the long-term (SNL 2007 [DIRS 177412], Section 6.7.1).

Once a waste package is breached, an oxidizing environment is created within the waste package enabling $^{14}CO_2$ to be formed via chemical oxidation of any ^{14}C species present in the waste form. The limited amount of ^{14}C remaining in the inventory limits the potential creation of $^{14}CO_2$ to small amounts. Furthermore, the dose from ^{14}C transported as a gas to the accessible

environment will be extremely small, so the risk consequence is negligible (see excluded FEP 2.2.11.03.0A (Gas Transport in the Geosphere)).

In summary, the effects of radioactive gases in the EBS are negligible compared to overall radionuclide releases to the accessible environment.

Based on the previous discussion, omission of FEP 2.1.12.07.0A (Effects of Radioactive Gases in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.
