FEP: 2.1.12.08.0A

FEP NAME:

Gas Explosions in EBS

FEP DESCRIPTION:

Explosive gas mixtures could collect in the sealed repository. An explosion in the repository could have radiological consequences if the structure of the repository were damaged or near-field processes enhanced or inhibited.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP focuses on potential flammable gas generation in the EBS external to the waste package. Potential flammable gas generation inside of waste packages is considered in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF), excluded FEP 2.1.13.01.0A (Radiolysis), and excluded FEP 2.1.02.29.0A (Flammable Gas Generation from DSNF).

Flammable gases that may be produced in the EBS include hydrogen (H_2) and methane (CH_4). Hydrogen would be produced from the radiolysis of water (H_2O) (Glass et al. 1986 [DIRS 105021]) or oxidation of metals under anaerobic conditions. Methane could be produced from the microbial action on organics or the metal containers under anaerobic conditions.

However, negligible quantities of methane and hydrogen could be maintained in the EBS atmosphere because the necessary anaerobic conditions will only exist in the earliest stages of the repository (SNL 2007 [DIRS 177412], Section 6.7.1). Moreover, because the repository is located in unsaturated rock units that are connected by a pervasive fracture network to the ground surface (BSC 2004 [DIRS 166107], Section 6.1.4), flammable gases will be dispersed into the much larger gas volume residing in and above the rock mass surrounding the drift. The lower explosive limits are 4.1vol % and 5.3 vol % for hydrogen and methane, respectively, in air at 25°C and one atmosphere total pressure (Dean 1992 [DIRS 100722], Table 5.22). Because gas concentrations in the drift will largely reflect those in the atmosphere, the likelihood of exceeding the lower explosive limits (Dean 1992 [DIRS 100722], Table 5.22) is insignificant. Therefore, the probability of an explosion occurring is zero.

This FEP is therefore excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319] on the basis of low probability.

FEP: 2.1.13.01.0A

FEP NAME:

Radiolysis

FEP DESCRIPTION:

Alpha, beta, gamma, and neutron irradiation of water can cause disassociation of molecules, leading to gas production and changes in chemical conditions (potential, pH, and concentration of reactive radicals).

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Potential pressurization and/or fire caused by gases generated from radiolytic decomposition of water inside a waste package is excluded on the basis of low consequence, because the small amount of water in a dried and inerted TAD canister-bearing waste package will not generate sufficient gas to cause a problem. Enhanced corrosion of waste packages and drip shields due to the effects of beta-gamma radiolysis is excluded because beta-gamma radiation is intense enough to cause a problem only while the repository temperature is above boiling when little or no liquid water will be present on waste package or drip shield surfaces. The effects of radiolysis on the corrosion of commercial SNF and other internal waste package components is excluded on the basis of low consequence, since neither nitric acid nor hydrogen peroxide (H_2O_2) are expected to have a significant impact on in-package chemistry. The potential influence on radionuclide concentrations and mobilities due to H_2O_2 accumulation caused by long-term alpha radiolysis is excluded on the basis of low consequence.

Background

Strong radiation fields (alpha, beta, gamma, and neutron) originating from HLW can cause radiolysis (molecular disintegration caused by radiation) of water and other molecules (e.g., molecular nitrogen in the air). These effects have the potential to adversely affect repository performance in several ways. Radiolysis of water leads to formation of ions, radicals, and other potentially reactive species that can alter water chemistry (e.g., pH), radionuclide speciation, and effective redox potential. Such changes can accelerate corrosion of metals (e.g., drip shields and waste packages) and waste forms (e.g., commercial SNF and HLW glass), as well as enhancing solubilities and/or mobilities of radionuclides (and other potentially toxic elements). This FEP addresses the aqueous-chemical effects of radiolysis (including gas generation). Direct radiation damage to solids is discussed in excluded FEP 2.1.13.02.0A (Radiation Damage in EBS).

Radiolysis of water leads to the production of charged and uncharged species, with proportions depending largely on radiation type (alpha, beta-gamma, or neutron). The number of radiolytic species produced is described by a radiation-specific "G-value," which expresses the number of

molecules produced as a function of energy deposited (in air or water). Note that beta and gamma radiations are not distinguished experimentally (because one can generate the other) and a single G-value applies to the beta-gamma field. Radiolysis of air can produce water-soluble nitrogen oxides that can form aqueous nitric acid. In the absence of a compensating acid-consuming reaction (e.g., dissolution of certain solids), nitric acid production can lower pH, potentially increasing corrosion rates (Reed and Bowers 1990 [DIRS 113577]) and enhancing solubilities of radionuclide-bearing solids. Hydrogen peroxide (H_2O_2) is a strong oxidant under most conditions and has the potential to accelerate corrosion of drip shields and waste packages, as well as enhancing the degradation rate of spent fuel. Under aqueous conditions (in bulk solutions), anodic shifts in the open-circuit potential of stainless steel in gamma-irradiated solutions have been observed experimentally, and these shifts in potential have been shown to be due to the formation of hydrogen peroxide (SNL 2007 [DIRS 180778], Section 6.7.1), which means that H_2O_2 might also enhance corrosion of stainless-steel TAD canisters.

Whereas beta-gamma radiation tends to produce large quantities of highly reactive free radicals and ionic species, alpha radiation tends to produce primarily molecular species, predominantly H_2 and H_2O_2. Thus, in addition to chemical changes, radiolytic production of hydrogen gas poses the risk of potentially flammable quantities of H_2 being generated.

Much of the discussion that follows focuses on the effects of radiolysis associated with commercial SNF because commercial SNF constitutes the vast majority of waste packages destined for disposal and contains most of the radionuclide inventory on a per-package basis (SNL 2007 [DIRS 180472], Table 7-1[a]). Furthermore, most commercial SNF waste packages are thermally hotter (SNL 2008 [DIRS 184433], Table 6.2-6[a] and Section 6.3.16[a]) and are more radioactive (BSC 2004 [DIRS 172227], Section 6.4.2) than most codisposal packages containing HLW glass and DOE SNF. Moreover, failure of an MCO-type codisposal package due to a pyrophoric event is addressed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF) and is shown to be of low consequence. The MCO canisters containing N Reactor fuel may contain considerably more water at emplacement than commercial SNF waste packages, and potential gas generation and pressurization of MCO-containing waste packages is addressed separately at the end of the following section.

Radiolytic Gas Production

Radiolysis of water has the potential to pressurize storage containers through the accumulation of radiolytically generated hydrogen and oxygen. The rate at which these gases are produced by radiolytic decomposition of water (and, potentially, of hydrous solids) will depend on a number of chemical and physical features and processes (e.g., exposed reactive metal surface area, radiation field, etc.). Perhaps most important is the availability of water, which limits the overall extent of H_2 and O_2 production. Even without an early breach, it is expected that TAD canister-bearing commercial SNF waste packages will contain some residual water upon emplacement (possibly including adsorbed, occluded, and chemically bound water, as well as water vapor). The potential consequences of hydrogen generation by radiolysis and a subsequent conflagration (either deflagration or detonation) in a waste package are discussed in more detail in Appendix I of *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]). From the standpoint of this FEP, the most serious effect due to

over-pressurization of the waste package is rupture and possible damage to one (or possibly two) neighboring waste packages.

Excluded FEPs that calculate pressure effects (e.g., FEPs 2.1.03.07.0A (Mechanical Impact on Waste Package) and 2.1.12.02.0A (Gas Generation (He) From Waste Form Decay)) use a TAD canister void volume of 4,737 L (from DTN: SN0702PAIPC1.001 [DIRS 180451], file: *CSNF WP Design Cell 1.xls*, worksheet: "TAD WP Total Moles and SA," cell: B48). This volume is based on a chemical "cell" inside a TAD canister-bearing waste package (c*ell 1* intended for in-package chemical calculations), and does not correspond to a physically defined volume that is potentially larger by as much as 70% (see SNL 2007 [DIRS 177407], Section 6.3.4.3.4.2, p. 6-90). There is uncertainty in estimating pressures inside a TAD canister-bearing waste package. Nevertheless, in order to help maintain consistency among FEPs, so that pressure calculations might be compared more directly, the in-package chemistry "cell 1" TAD canister void volume of 4,737 L (DTN: SN0702PAIPC1.001 [DIRS 180451]) is used in this FEP to estimate pressure inside a TAD canister-bearing waste package. All calculations of pressure performed in this document were conducted in units of atm and converted to psia according to 1 atm = 14.7 psia. No attempt was made to convert the resulting pressure in atm to psig (gauge pressure), although some specifications may be given in this unit (notably, the design pressure for an MCO canister from Garvin 2002 [DIRS 169141], Section 2.2.6.2). Because gauge pressure (psig) is less than or equal to absolute (psia), there is approximately a 1 atm (or less) margin of error in all calculated values when compared to psig (where applicable), such that the effect of this uncertainty on conclusions reached in this document is negligible.

The potential for over-pressurization and rupture of a TAD canister-bearing (commercial SNF) waste package due to waste package pressurization by several relevant processes (including gas generation by radiolysis) is addressed in excluded FEP 2.1.03.07.0A (Mechanical Impact on Waste Package). This FEP concludes that, even considering the upper limit of expected waste package temperatures (approximately 350°C for the drift-collapse case), rupture of a waste package due to over-pressurization is not expected to be a concern before 10,000 years after closure (pressure at 350°C is approximately 114 psia, from excluded FEP 2.1.03.07.0A (Mechanical Impact on Waste Package)). The safety margin is such that, in the absence of water or gases generated by radiolytic decomposition of water, the maximum expected pressure achievable inside a TAD canister-bearing (commercial SNF) waste package is on the order of 114 psia (0.8 MPa) at 350°C, whereas the design pressure for a commercial SNF waste package is 140 psia (0.97 MPa) at 375°C (SNL 2007 [DIRS 179394], Section 4.1.2.6; note that the temperature specified is 707°F rather than 375°C). In fact, a more reasonable maximum pressure – at 200°C – is not expected to exceed 70 psia (0.47 MPa), about one-half the design pressure.

According to *Total System Performance Assessment Data Input Package for Requirements Analysis for Transportation Aging and Disposal Canister and Related Waste Package Physical Attributes Basis for Performance Assessment* (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04), "all TAD canisters and waste packages shall be dried and backfilled with Helium [sic] to achieve less than 0.43 mole (7.7 g) of H_2O in a 7 m^3 TAD canister after drying in a manner similar to *Standard Review Plan for Dry Cask Storage Systems* (NRC 1997 [DIRS 101903], Section 8.V.1)." The value of 0.43 mole in 7 m^3 is taken from Knoll and Gilbert (1987 [DIRS 123682] Table 3, p. 12), refers to the amount of H_2O in the gas phase only. The procedure described in NUREG-1567, *Standard Review Plan for Spent Fuel Dry Storage*

Facilities (NRC 2007 [DIRS 149756], Section 9.5.4.1) cites NUREG-1536 (NRC 1997 [DIRS 101903], Section 8.V.1) for moisture removal and is therefore acceptable. It is expected that compliance with this requirement will be accomplished according to specifications, and that there is no need to evaluate the potential for failing to meet that requirement, consistent with excluded FEP 1.1.08.00.0A (Inadequate Quality Control and Deviations from Design).

As discussed in excluded FEP 2.1.03.07.0A (Mechanical Impact on Waste Package), the complete conversion of 0.43 moles of water to 0.65 moles of H_2 and O_2 gas results in a pressure increase of only about 0.08 psia at 211°C (the temperature of the analysis). Water in the gas phase does not preclude (and in fact implies) some small quantity of adsorbed and potentially chemically bound water inside a properly dried and inerted TAD canister. To this vapor-phase water must be added any additional pressure that might be achieved if all adsorbed and chemically bound water (if present) were to also be converted to H_2 and O_2 gas. However, because the amount of water in the vapor phase is so small, only a few monolayers of water is expected to be adsorbed (e.g., less than about 10 to 15 nm). Spread over the approximately 1,200 m^2 surface area inside a 21-PWR waste package (SNL 2007 [DIRS 177407], Table 6.3-10) means that, at most, about one mole of additional water needs to be accounted for. Converting this to 1.5 moles of gas by radiolysis increases the pressure inside a TAD canister by only about 0.6% (0.2 psia). Thus, a reasonable assumption is that the potential pressure increase due to complete radiolytic conversion of water into gas might increase in-package pressure by less than one percent (at 211°C), so that the maximum expected pressure will still be approximately one-half the design pressure. The potential conservatism of this calculation should also be emphasized because, due to the high reactivity of radicals generated by radiolysis (many of which must recombine, rather than react with solids, in order to produce molecular O_2), it is highly doubtful that it will be possible to completely convert water into gas at a ratio of 1:1.5. Nevertheless, even if all water is converted into gas at a ratio of 1:1.5, the net effect on pressurizing a TAD canister-bearing waste package can be excluded on the basis of low consequence.

The maximum pressure that could be generated inside an MCO in the absence of a hydrogen fire can be estimated by assuming that one MCO in a codisposal waste package contains the maximum amount of free and bound water, as reported for all MCOs loaded to date: 4.3 kg or 239 moles H_2O (Sexton 2007 [DIRS 184742], Table 2-1). If pressurized at 25°C to 1.5 atm (0.15 MPa or 22 psia) with helium (24.5 mole helium in 400 L void volume; DTN: SN0702PAIPC1CA.001 [DIRS 180451], file: *CDSP – 2MCO Cell 1.xls*, worksheet: "Void Space," cell C51) and assuming all residual water is converted into H_2 and O_2 gas (358 mole gas = 1.5 × 239 mole H_2O) the design pressure of 450 psi (at 132°C; Garvin 2002 [DIRS 169141], Section 2.2.6.2) will be exceeded at about 117°C for a single MCO. The pressure inside the MCO at 211°C would reach 559 psia) (38 atm = 3.8 MPa), well beyond the design pressure. Therefore, it can be expected that an MCO containing the maximum amount of water will fail due to over-pressurization.

Failure of an over-pressurized MCO canister is not expected to damage the inner stainless-steel liner (two inches thick) and outer corrosion barrier (one inch thick) sufficiently to diminish the overall pressure rating of the codisposal waste package (140 psia; SNL 2007 [DIRS 179394], Section 4.1.2.6). Rather, a failed MCO is expected to vent into the surrounding codisposal waste package, which has a net void volume of 3,000 L (7,400 L minus the net volumes of two MCO

canisters at 1,000 L each and two HLW glass canisters at 1,200 L each; volumes from DTN: SN0702PAIPC1CA.001 [DIRS 180451], file: *CDSP – 2MCO Cell 1.xls*, worksheet: "Void Space"). It is assumed further here that the codisposal waste package will have also been pressurized to 1.5 atm with helium at 25°C (184 mole helium in 3,000 L of void volume). Combining the void volumes of the codisposal waste package and one MCO canister (3,000 + 400 = 3,400 L) indicates that the design pressure for the waste package will not be exceeded for temperatures below about 425°C, and that the pressure at 211°C would only be about 93 psia (6.3 atm = 0.64 MPa). Including the void volumes for both MCOs in the calculation increases the attainable pressure by only about 7% (e.g., 104 psia (7.1 atm = 0.71 MPa) at 211°C) if one MCO canister is assumed to contain the maximum amount of water (4.3 kg) and the second MCO canister is assumed to contain the average value of 1.03 kg (57 moles) total water (Sexton 2007 [DIRS 184742], Table 2-1). It should be noted that an MCO with only an average mass of water (1.03 kg; Sexton 2007 [DIRS 184742], Table 2-1) will not exceed its design pressure of 450 psig below about 1,000°C, so that the preceding calculation might tacitly assume damage to the second MCO canister caused by failure of the first.

The minimum hydrogen concentration that can support flammability varies, depending on the major constituents of the gaseous environment. A minimum hydrogen concentration of approximately 4 vol % in an air-hydrogen atmosphere at nominal (0.1 MPa) pressure is required to propagate a flame front (Coward and Jones 1952 [DIRS 182138], Figure 7). For a helium-hydrogen environment, the minimum hydrogen concentration that can support flammability is approximately 8 vol % (Coward and Jones 1952 [DIRS 182138], Table 3). A reasonably conservative estimate of the maximum concentration of hydrogen gas that could be generated inside a TAD canister due to radiolysis can be calculated by assuming that a TAD canister that has been dried according to procedure (no more than 0.43 moles H_2O in 7 m^3 volume of cover gas) has an estimated one mole of water that remains sorbed or chemically bound inside the TAD canister after backfilling with helium to 1.5 atm and sealing (moles of helium given by the ideal gas law: $n = PV/RT = \{1.5\ \text{atm} \times 4{,}737\ \text{L}\} \div \{0.082\ \text{L·atm·mol}^{-1}\ \text{K}^{-1} \times 298.15\ \text{K}\} = 291$ mole-helium). It is further assumed that all water inside the TAD canister (0.43 mole + 1 mole ≅ 1.5 moles H_2O = 27 grams H_2O) is converted to hydrogen and oxygen gas by radiolysis. Such a calculation demonstrates that, in the absence of any failure of the cladding, the maximum concentration of hydrogen is about one-half of one percent (0.005 ≅ 1.5 moles-H_2 ÷ [291 moles-He + 0.75 moles-O_2 + 1.5 moles-H_2]). Back-filling a TAD canister to 2 atm and potential rupture of cladding only reduces this concentration further, as does He generated due to alpha decay. Thus, as demonstrated by this bounding analysis, it is not possible to attain conditions capable of supporting a hydrogen fire inside a TAD canister-bearing waste package.

The average mass of residual water (free and bound) that has been determined to remain in an MCO after being dried and inerted is approximately 1.03 kg (57 moles H_2O) (Sexton 2007 [DIRS 184742], Table 2-1). Nearly all this water is present as chemically bound water in corrosion products (the most abundant corrosion product being aluminum hydroxide, $Al(OH)_3$, with lesser amounts of uranium oxy-hydroxides and aluminum and iron hydrates; Garvin 2002 [DIRS 169141], Table 4-4 and p. 4-30). This water could be released and converted to free hydrogen and oxygen due to thermal and/or radiolytic decomposition of these hydrated oxides. If free oxygen and hydrogen are produced inside an MCO, much of the oxygen may be scavenged by reaction with exposed uranium metal in the breached fuel because of the rapid kinetics of the uranium-metal/oxygen reactions (Haschke 1998 [DIRS 174075], Table 1), as well

as more moderate consumption by oxidation of iron in stainless steel and lower Fe alloys. The potential fate of free hydrogen is less clear. One experimental study of uranium-metal corrosion in moist air reported formation of neither hydrides nor hydrogen gas (Haschke 1998 [DIRS 174075], p. 150), suggesting that any hydrogen evolved was rapidly transformed to water on the uranium-metal surface under the experimental conditions. This study, however, was conducted using clean uranium-metal, and the reaction of hydrogen with partially oxidized uranium metal (as would be expected in an MCO with degraded fuel) is less certain (Plys and Duncan 1999 [DIRS 184687]).

A simplistic calculation, as outlined above for a TAD canister, demonstrates that, in the absence of mitigating reactions, ample gas could be generated in an MCO to support a hydrogen fire (400 L MCO void space, pressurized with 1.5 atm fill gas gives 24.5 moles helium at 25°C, from the ideal gas law), assuming the mean value of residual water (1.03 kg). That is, 48% ≅ 57 moles H_2 ÷ [24.5 moles-He + 29 moles O_2 + 57 moles H_2]. In fact, a hydrogen concentration in excess of 4% could be achieved inside an MCO canister if as little as 25 g residual water remains. Thus, a conflagration due to radiolytic generation of hydrogen and oxygen cannot be ruled out, and the potential consequences of such an event must be evaluated.

The consequence of a hydrogen fire inside an MCO would be to raise the temperature and pressure inside that MCO. The maximum achievable temperatures and pressures for such an event were calculated for a mixture of hydrogen in a mixture of oxygen (21%) and helium (79%) by Plys and Duncan (1999 [DIRS 184687], Figure 5-1), who assumed a conservative adiabatic, constant volume (isochoric) complete combustion ("AICC") model. Using the mean value for expected water content (1.03 kg = 57 moles) in an MCO canister inerted to 1.5 atm helium at 25°C (24.5 moles) and assuming complete conversion of all water to H_2 and O_2 gas (57 and 29 moles, respectively), gives a mixture of 48% H_2, 24% O_2, and 28% helium. This level of oxygen will be reduced due to reaction with uranium metal. To achieve a mixture comparable to that evaluated by Plys and Duncan (1999 [DIRS 184687], Figure 5-1) with 21% O_2 and 79% helium (ignoring H_2) requires that roughly 70% of this oxygen be consumed by oxidation reactions with, for example, uranium metal. In fact, highly reactive oxidizing radicals produced by radiolysis might be expected to reduce this oxygen content even further, suggesting this is a conservative estimate of O_2 concentration. Plys and Duncan (1999 [DIRS 184687], p. 6-7) also considered the fact that as H_2 pressures increased inside an MCO canister, this gas would be consumed by reaction with (primarily) uranium metal; however, due to insufficient data on the reactivity of partially corroded uranium metal to form hydrides, they ignored potential reduction in hydrogen concentration. They did note, however, that as H_2 pressure increases, the reaction of H_2 with even partially oxidized uranium metal should increase, becoming significant when the partial pressure of H_2 reaches between 10 and 20 atm, which is achievable for the mean residual mass of water in an MCO (1.03 kg) at temperatures near the upper limit of this analysis (i.e., greater than approximately 190°C).

Even if both MCOs in a codisposal waste package were assumed to contain the maximum 4.3 kg water each (Sexton 2007 [DIRS 184742], Table 2-1), and it is also assumed that all of the hydrogen in this water becomes available to burn, the heat energy released would be about 14×10^7 J, which would cause a waste package temperature increase of about 6°C, even under conservatively assumed adiabatic conditions. For the purposes of the following calculation, it is assumed that both MCOs in the waste package contain intact fuel elements, because these are

less susceptible to reacting with (and therefore consuming) radiolytically generated gases (as well as radicals and other reactive species) than are MCOs with scrap baskets (see excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF)).

The temperature increase is calculated by dividing 4,300 g H_2O by the approximate molecular weight of water, 18 g/mol to obtain 239 moles per MCO, and then multiplying by two to get 478 moles H_2O, which could produce 478 moles H_2 per codisposal waste package. Then, 478 moles × 285.83 kJ/mol (standard enthalpy of formation of water; Grenthe et al. 1992 [DIRS 101671], Table IV.1) equals 14×10^7 J. By assuming adiabatic conditions (all energy is available to increase the waste package temperature (i.e., no radiative heat losses)), a maximum temperature increase for the waste package can be calculated as follows. Each defense HLW glass canister will contain approximately 3×10^6 g HLW glass, which is calcuated by using the density (2.7 g/cm^3) and volume (1.1 m^3 = $\pi \times [0.3 \text{ m}]^2 \times [3.9 \text{ m}]$) from DTN: MO0502ANLGAMR1.016 [DIRS 172830], Table 8-1, making a total of 6×10^6 g defense HLW glass per waste package. Each MCO will contain approximately 6.34×10^6 g uranium-metal fuel and 4.43×10^5 g zirconium cladding (Garvin 2002 [DIRS 169141], Table 4-4, column 2), for a total of approximately 8.9×10^5 g zirconium cladding and 1.27×10^7 g uranium metal per waste package. Each waste package will also contain approximately 2.3×10^7 g steel. This includes 1.6×10^6 g steel in the (unloaded) waste package (SNL 2007 [DIRS 179567], Table 4-10), approximately 2.45×10^6 g steel in two HLW glass canisters (4.2×10^6 g per defense HLW glass canister, from SNL 2007 [DIRS 179567], Table 4-10, minus the mass of defense HLW glass noted above) plus approximately 4.8×10^6 g steel in the two MCOs (9.172×10^6 g per MCO, from SNL 2007 [DIRS 179567], Table 4-10, minus the mass of uranium fuel and zirconium cladding noted above). In addition, each waste package will contain approximately 1.6×10^7 g Alloy 22 (SNL 2007 [DIRS 179567], Table 4-10). A weighted average, or "net" heat capacity, is used here for calculating the temperature increase of a 2-MCO/2-DHLW codisposal waste package in the event of a hydrogen fire. The weighted-average heat capacity of 0.39 J/g·°C is calculated from the heat capacities of austenitic steels (0.5 J/g·°C; ASM International 1990 [DIRS 106780], p. 871), Alloy 22 (0.414 J/g·°C; DTN: MO0107TC239938.000 [DIRS 169995], p. 13), uranium metal (0.11 J/g·°C; Grenthe et al. 1992 [DIRS 101671], Section V.1.1), zirconium metal (0.278 J/g·°C; Lide 2006 [DIRS 178081] p. 4-127), and of sodium-aluminum silicate glass ($NaAlSi_3O_8$) as an analogue for borosilicate waste glass (0.78 J/g·°C; Robie et al. 1979 [DIRS 107109], p. 414). The maximum temperature increase for the waste package due to a hydrogen fire in two MCOs can now be calculated as follows: 14×10^7 J/waste package ÷ (5.8×10^7 g solids/waste package × 0.39 J/g·°C) equals 6°C, which is a negligible change.

In fact, any increase in temperature would only degrade the uranium-metal fuel, as discussed in excluded FEP 2.1.02.08.0A (Pyrophoricity from DSNF), which demonstrated that because this simply makes radionuclides from the DOE SNF available for immediate release (a consequence already assumed for DOE SNF inside a breached codisposal package because of the essentially instantaneous degradation rate already used for DOE SNF by TSPA), exclusion of such an event is of low consequence.

In the event of a hydrogen fire, the pressure increase in an MCO is expected to be considerably less than that calculated above, despite the heat of reaction (note that 1.5 moles of gas (H_2 plus O_2) are converted to one mole H_2O). For example, using their "AICC" model, Plys and Duncan

(1999 [DIRS 184687]) calculated pressures for the flammable gas mixtures noted above and found that the maximum pressure that can be achieved is approximately eleven times the initial pressure (i.e., ~16 atm or 235 psia) for a hydrogen concentration of about 30% (Plys and Duncan 1999 [DIRS 184687], Figure 5-1), also well below the design pressure for an MCO. Again, if this MCO canister were to fail, it would vent into the larger volume of the codisposal waste package, reducing the pressure substantially, as shown for the more conservative estimates calculated earlier.

Exclusion of Potentially Negative Effects on the EBS

As noted previously, radiolysis of air can produce water-soluble nitrogen oxides that can form aqueous nitric acid if sufficient water is present on the outer surfaces of waste packages and/or drip shields. However, a key limitation as to whether radiolysis might adversely affect waste package corrosion rates is the spatial extent (penetration) of radiation throughout the EBS. Radiolysis-enhanced corrosion can only occur if water is present and exposed to a radiation field. Therefore, the potential impact of beta-gamma radiolysis on the outer layers of waste packages will not be significant until relative humidity exceeds 95% (the threshold for forming a water film on surfaces) (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]), or until after seepage water penetrates the drip shield. Maximum dose rates achievable within the drifts will be at the surfaces of a waste package that contain a bounding inventory of spent fuel (i.e., highest burnup). Because alpha and primary beta radiation cannot penetrate waste packages, gamma and secondary beta radiation will be the dominant contributor to dose rate at the waste package outer surface. Neutron-radiation levels are calculated to remain less than gamma levels by more than an order of magnitude for a 21-PWR commercial SNF waste package (BSC 2004 [DIRS 172227], Table 6.3-2).

For a waste package that contains 21 PWR high-burnup SNF assemblies (80 GWd/MTU burnup, and 5-year decay during storage), the maximum level of total radiation at the outer surface of the waste package has been estimated to be approximately 1,160 rad/hr (1,570 rad/hr at the outer surface of the waste package lid; BSC 2004 [DIRS 172227], Section 6.4.2 and Table 6.4-5). After 50 years (the anticipated ventilation period), this will have decreased by an order of magnitude to about 100 rad/hr at the outer surface of the waste package, and 100 years after emplacement the maximum calculated gamma dose will have dropped another third to less than 40 rad/hr at the outer surface of the waste package (BSC 2004 [DIRS 172227], Figure 6.4-1). The temperatures of even the coolest commercial SNF waste packages in the central region of the repository are currently estimated to remain above boiling, and the relative humidity to remain below about 95%, for approximately 1,000 years or more (SNL 2008 [DIRS 184433], Section 6.3.16[a]), so that, in the absence of deliquescent salts, no liquid water will be present on waste package or drip-shield surfaces exposed to high levels of gamma radiation (and secondary beta radiation).

Potential deliquescence of salts contained in dust that may settle on the waste package or drip-shield surfaces is discussed in excluded FEP 2.1.09.28.0A (Localized Corrosion on Waste Package Outer Surface Due to Deliquescence), although that FEP did not address potential radiation effects. Such effects were examined for Alloy C-4 and Titanium Grade 7 during long-term experiments (1 to 4 years) in especially corrosive Mg-Cl brines. These studies showed no observable influence on the corrosion behavior of Alloy C-4 (an analogue for Alloy 22) when

contacted by Mg-Cl brines exposed to gamma radiation doses of less than about 100 rad/hr (Shoesmith and King 1998 [DIRS 112178], p. 29); however, Alloy C-4 undergoes extensive pitting and crevice corrosion when contacted by brine exposed to a gamma dose above 100 rad/hr (Shoesmith and King 1998 [DIRS 112178], pp. 30 to 31). Titanium Grade 7 alloy showed exceptional corrosion resistance under these conditions, and even at dose rates above 1,000 rad/hr, only minor enhancement of film growth rates on Titanium Grade 7 was observed, and its passivity was not compromised (Shoesmith and King 1998 [DIRS 112178], p. 30). Based on these data and the discussion above, it is concluded that radiation levels in the repository after about 50 years will not be sufficiently high to significantly enhance corrosion of Alloy 22 or Titanium Grade 7, even in the presence of especially corrosive brines. (see excluded FEP 2.1.03.03.0B (Localized Corrosion of Drip Shield) for discussion of localized corrosion of Titanium Grade 29). Furthermore, most potentially corrosive deliquescent brine compositions are unstable in the drift environment, and those few that may be stable will degas acid phases in the presence of reactive products of radiolysis (SNL 2007 [DIRS 181267], Sections 7.2.1, 7.2.2, and 7.2.3, pp. 7-2 to 7-3).

Taken together, these conclusions suggest that radiation levels at the outer surface of a commercial SNF waste package, even for fuels with the highest potential burnups (considered here to be a bounding case for all waste packages), will be well below those for which radiolysis effects have been observed to negatively impact the corrosion of waste package or drip-shield metals. Furthermore, these maximum radiation levels are expected early, when most of the repository is anticipated to be dry. Later on, when liquid water is expected to be present (e.g., beyond several thousand years), beta-gamma radiation levels will have decreased enough that significant water radiolysis is not expected outside intact waste packages.

For those waste packages at the perimeter of the repository, exterior waste package and drip shield temperatures may never exceed boiling, so that liquid water (as condensate) may be present on those packages, and the potential that radiolytically generated nitric acid might accumulate in this condensate during the first few thousand years after closure cannot be excluded. However, as noted previously, even in relatively aggressive Mg-Cl brines, corrosion rates of Titanium Grade 7 are not substantially enhanced in a strong gamma field, and corrosion rates of Alloy 22 are negligible for dose rates below about 100 rad/hr in such brines (Shoesmith and King 1998 [DIRS 112178], pp. 29 and 30), which are not expected to exist, especially in lower-temperature regions of the repository. Furthermore, because beta-gamma dose decreases exponentially with time, even those few waste packages and drip shields that might not experience above-boiling temperatures are not expected to experience significant radiolytically enhanced corrosion during the period when beta-gamma dose rates are high. Thus, radiolytically enhanced corrosion of waste packages and drip shields is not expected to have a significant effect on repository performance.

The potential accumulation of radiolytically generated nitric acid inside a waste package is discussed separately in the following paragraphs.

Generation of Radiolytic Products within Waste Packages

Breaches to waste packages are the most common, but not the only way for water to exist within a waste package; because commercial SNF (and several types of DOE SNF) is cooled and stored

under water immediately after being removed from the reactor, water may be retained in fuel elements when loaded into TAD canisters and/or waste packages before being sealed for disposal. Radiolytically produced nitric acid can form only when both water and nitrogen are present, which would require failure to both dry (remove water) and inert (remove nitrogen) a TAD canister properly.

While most of the cladding is physically present (even if defective), alpha and beta radiation due to radioactive decay will be shielded and unable to affect internal steel corrosion of the TAD canister. Only after large-scale rod failure can substantial quantities of actinides and their decay products contact the interior of the steel TAD canister. If a waste package breaches while the temperature in the waste package is above boiling, any liquid water remaining in the TAD canister will evaporate and be unable to participate in further corrosion, and without liquid water, transport of dissolved radionuclides out of the waste package is impossible.

Under strongly oxidizing conditions, the effect of radiolysis on the degradation rate of spent fuel is most pronounced under the influence of beta-gamma radiation, since beta-gamma radiation produces the most reactive radiolytic products; however, as noted previously, the beta-gamma radiation field decreases exponentially to near-negligible levels (i.e., small fractions of a percent of initial levels) after a few thousand years (when waste package breaches are still unexpected and relative humidity is below 95%).

Nitric acid production is primarily a consequence of beta-gamma radiation, waste packages that breach later than about 1,000 years after closure will not be exposed to beta-gamma radiation fields strong enough to generate enough nitric acid to be of concern. According to *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], p. 6-53[a]), the acid-neutralizing capacity within a breached commercial SNF waste package can be described as the number of moles (of an acid-neutralizing component, specifically, the Ni-Fe spinel, trevorite, $NiFe_2O_4$) produced each year due to corrosion of waste-package internals (especially stainless steel). Because schoepite and iron corrosion products dominate the composition of the alteration products from about 500 years on (SNL 2007 [DIRS 180506], Section 6.7.2, p. 6-101) and the Stainless Steel Type 304L inside a 2-MCO/2-DHLW codisposal waste package is completely degraded after approximately 500 years (SNL 2007 [DIRS 180506], p. 6-46[a]), the following analysis considers the acid-neutralizing component inside a waste package at 500 years.

For example, the estimated production of acid-neutralizing capacity for a breached commercial SNF waste package at about 500 years after closure is 0.039 moles per kilogram of solution (molal) annually, and for a codisposal HLW glass-containing cell, it is about 0.0006 molal annually (SNL 2007 [DIRS 180506], p. 6-53[a]). This value can be converted to molecules·yr^{-1}·cm^{-3} of gas-filled porosity by using Equation 2.1.13.01.0A-1:

$$ANC\left(\frac{molecules}{yr \cdot cm^3(void)}\right) = ANC\left(\frac{molal}{yr}\right) \cdot \rho_w s_w A_v \qquad \text{(Eq. 2.1.13.01.0A-1)}$$

where A_v is Avogadro's constant (6.022×10^{23} molecules/mole), s_w is the base-case volumetric ratio of gas-filled porosity to total porosity (i.e., 50%; SNL 2007 [DIRS 180506], Table 6-1[a] and p. 6-4[a]), and ρ_w is the approximate density of the solution (for this calculation a density of 0.001 kg/cm^3 is used; however, a more concentrated aqueous solution will have a greater density,

so this may slightly underestimate acid-neutralizing capacity). This calculation gives an acid-neutralizing capacity production rate of 1.2×10^{19} molecules·yr^{-1}·cm^{-3} in a commercial SNF waste package and 1.8×10^{17} molecules·yr^{-1}·cm^{-3} in a codisposal waste package, for a 50% porous waste form. Therefore, the rates at which acid-neutralizing capacity is generated are several orders of magnitude higher than the annual rate of nitric acid production due to gamma radiolysis for the same time (BSC 2004 [DIRS 172017], Tables 19 and 22, and Figure 5). For comparison, the amount of nitric acid potentially generated by gamma radiolysis in a waste package breached 500 years after closure corresponds to about 3.6×10^{13} molecules·yr^{-1}·cm^{-3} of moist air. Furthermore, the rate of radiolytic nitric acid production decreases with decreasing beta-gamma field, which falls off exponentially over the first 500 years, after which the annual rate of nitric acid production (normalized fuel-rod surface area) remains fairly constant (BSC 2004 [DIRS 172017], Figure 5). Thus, the relatively small amount of nitric acid that will form due to radiolysis inside a waste package at early times will be neutralized by reaction with stainless steel and/or fuel, and the acid-neutralizing capacity of the waste-package corrosion products is expected to outpace the acid produced by radiolysis for all time.

As noted previously, hydrogen peroxide (H_2O_2) is a potentially strong oxidant that can enhance corrosion of many metals and spent fuel, and it is produced by both alpha and beta-gamma irradiation of water. However, the solubility in water of H_2O_2 decreases with increasing temperature. By using data from Stefanic and LaVerne (2002 [DIRS 166303]) the exponential decrease in H_2O_2 concentrations for temperatures between 25°C and 100°C was calculated (BSC 2004 [DIRS 170019], Section 6.2.5 and Table 6-3). At 25°C, the calculated "half-life" is 34 days; 3.79 days at 50°C, and 0.11 days at 100°C. Decomposition and/or degassing of dissolved H_2O_2 at elevated temperature is also implied by results of spent-fuel corrosion experiments, in which the uranyl peroxide solid, studtite, has been observed only in experiments conducted at near-room temperatures, but not in experiments conducted above about 60°C (McNamara et al. 2003 [DIRS 172673]). Because the temperature of waste packages is expected to remain above 100°C for several hundred years, and above 50°C for about 10,000 years or more (SNL 2008 [DIRS 184433], Figure 6.3-82[a]), a significant portion of H_2O_2 produced by radiolysis during the first 10,000 years is expected to decompose. Furthermore, and perhaps most important, elevated H_2O_2 concentrations have little influence on commercial SNF corrosion rates under the strongly oxidizing conditions expected in the repository (Shoesmith 2000 [DIRS 162405]). Finally, *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.6.5[a], Figures 6-32[a] and 6-33[a]) reports on the influence to pH and ionic strength due to enhanced rates of steel and fuel oxidation. While the effect of higher degradation rates on predicted trajectories for pH and ionic strength can be discerned, higher degradation rates are not expected to significantly change the range of pH expected inside the waste package.

Based on the previous discussion, the effects of radiolysis on the corrosion of SNF and other internal waste package components are excluded from the TSPA on the basis of low consequence.

Potential Effects on Radionuclide Speciation and Transport

The potential that radiolysis may change in-package chemistry sufficiently to increase solubilities of radionuclide-bearing solids, alter the speciation of radionuclides, or otherwise enhance radionuclide concentrations and/or transport to the invert and unsaturated zone, must

also be considered. Generation of nitric acid during beta-gamma irradiation was shown above to have no significant effect on in-package pH, due to the buffering capacity (specifically acid-neutralizing capacity) of waste package corrosion products; besides, as noted previously, generation of nitric acid is most pronounced at early times when liquid water is not expected to be present. Although radiolytic decomposition of water produces an equal number of oxidizing and reducing species, H_2 gas (the most abundant reductant produced by alpha radiolysis) has a low solubility in water and is expected to diffuse rapidly out of a breached waste package to the drift environment, where it is expected to be diluted and to diffuse out through fractures in the surrounding rock. For this reason, once a waste package is breached, any change in the oxidation potential of water due to radiolysis is expected to be in a positive direction (i.e., more oxidizing), primarily due to radiolytic production of hydrogen peroxide. Hydrogen peroxide (H_2O_2) is considerably more soluble in water than H_2 gas; it is a potentially strong oxidant and is known to form stable solution species with certain actinides (notably plutonium; Katz et al. 1986 [DIRS 106312]).

It is first noted that concentrations of radiolytically produced H_2O_2 will be mitigated by at least four processes: (1) H_2O_2 will react with reduced iron in the stainless steel and in ferrous corrosion products, as well as with reduced uranium in the fuel (provided sufficient quantities of these reduced elements remain in waste packages); (2) even after complete oxidation of all waste package components, H_2O_2 will be catalytically decomposed by ferric iron in steel corrosion products such as goethite (Kremer 1985 [DIRS 184684]; Abbot and Brown 1990 [DIRS 184686]); (3) as noted, elevated temperatures promote decomposition of H_2O_2; and (4) the stability of H_2O_2 decreases with increasing pH. Such decomposition reactions will prevent H_2O_2 concentrations from increasing indefinitely. In fact, for a given alpha dose, the concentration of H_2O_2 generated by radiolysis is established within a few days and remains very nearly constant over time spans of hundreds to thousands of years, only gradually decreasing (on the order of thousands of years or more) as radiation levels decrease. Even during the first 10,000 years after closure, alpha-radiation levels change by little more than an order of magnitude between about 100 and 10,000 years, so that H_2O_2 concentrations will decrease by less than about 50% between 5,000 and 10,000 years (provided that decomposition reaction rates also remain approximately constant). It is this (poorly known) quasi-steady-state concentration of H_2O_2 that is of potential concern, and the reason it is expected to have little or no negative impact is addressed in the following paragraphs.

Once breached, a waste package is modeled as being fully exposed to the ambient drift atmosphere (i.e., partial pressure of oxygen equal to about 0.2 atmospheres, or $pO_2 = 0.2$ atm), and the dissolved concentrations of nearly all radionuclides are calculated by assuming equilibrium between the drift atmosphere, solubility-controlling solids, and water. The potential for increasing the oxidation potential (also known as the Eh) of water in equilibrium with 0.2 atm oxygen by increasing the dissolved concentration of radiolytic H_2O_2 will be negligible, because such a water is already close to the upper stability limit of water. Even so, most radionuclides are already assumed to be in their most oxidized valence states. However, two radionuclides are given somewhat special treatment: neptunium and plutonium (SNL 2007 [DIRS 177418], Appendix V). In the case of neptunium, the more reduced of two possible oxides, NpO_2, is used to calculate limits on dissolved neptunium concentrations inside a waste package until all waste-package internals are fully oxidized, at which time Np_2O_5, is assumed to limit dissolved neptunium concentrations. Therefore, as long as reductants (i.e., electron donors) exist in the

waste package, these can be assumed to be available to react with H_2O_2, and NpO_2 will remain the stable solubility-limiting solid for neptunium (although the rate at which radiolytic H_2O_2 might oxidize waste package internals is not considered, so that the time at which the TSPA model switches from the lower-solubility NpO_2 to higher-solubility Np_2O_5 may occur later than if radiolytic oxidation of waste package internals were accounted for; however, this delay is not expected to significantly impact calculated concentrations of dissolved neptunium downstream of the waste package because solubility limits on neptunium concentrations differ by just over an order of magnitude for either neptunium-bearing solid in equilibrium with the atmosphere in the pH range of concern).

Similar to the case for neptunium, radiolytic production of H_2O_2 is not expected to increase the dissolved concentration of plutonium releases under anticipated repository conditions. The treatment of plutonium differs from that of neptunium because limits on dissolved plutonium concentrations are calculated by using an "adjusted Eh" model, in which a lower-than-ambient oxidation potential is used to calculate dissolved concentrations of plutonium limited by PuO_2 solubility (SNL 2007 [DIRS 177418], Appendix V). This raises the question as to whether solubility is affected by radiolytically produced H_2O_2. The chemistry of H_2O_2 with plutonium means that H_2O_2 is not expected to adversely affect plutonium solubility, as discussed in the following paragraph.

Hydrogen peroxide (H_2O_2) is an oxidant; however, for certain elements H_2O_2 acts as a reducing agent (Stumm and Morgan 1996 [DIRS 125332], Chapter 11). This is the particular case for the reaction of H_2O_2 with plutonium, as demonstrated by well-documented studies using H_2O_2 to reduce Pu(V) and Pu(VI) to Pu(IV) (Katz et al. 1986 [DIRS 106312]). The vast majority of such work applies to highly acidic solutions containing high-levels of dissolved H_2O_2; that is, for solution chemistries not expected to exist within the repository under any scenario. One study, however, confirms the reduction at more representative conditions reporting reduction of Pu(V) to Pu(IV) in basic solutions with H_2O_2 concentrations closer to those that might be expected to occur due to alpha radiolysis ($7.9 \leq pH \leq 10.8$ and $0.00001 \leq [H_2O_2] \leq 0.04$ moles per liter (Morgenstern and Choppin 1999 [DIRS 184023], pp. 109 to 111). The authors found that not only was Pu(V) gradually reduced to Pu(IV), but the concentration of dissolved plutonium decreased as an unidentified plutonium solid was precipitated. The authors derived a redox half-life for Pu(V) as a function of pH and dissolved H_2O_2 that suggests 50% of Pu(V) would be reduced to Pu(IV) in about 55 years for $[H_2O_2]$ equals 10^{-7} moles per liter and a pH of 8 (and essentially 100% is reduced after 550 years). These experiments were conducted in high ionic-strength solutions (1.0 mole NaCl per kilogram of solution), and it is uncertain how quantitatively the results can be extrapolated to more dilute waters. Also, the pH range studied is on the high end and is above what is expected inside breached waste packages. The range of pH expected in a waste package should, in fact, stabilize H_2O_2 relative to the range reported by Morgenstern and Choppin (1999 [DIRS 184023]), potentially making plutonium reduction by radiolytic H_2O_2 somewhat more effective. Given that the qualitative chemistry demonstrates reduction of plutonium, it is not expected that radiolytic addition of H_2O_2 will increase the dissolved concentration of plutonium under the anticipated repository conditions.

Based on the previous discussion, the effects of radiolysis on the speciation and transport of radionuclides are not included in the TSPA on the basis of low consequence.

In summary, potential pressurization and/or fire caused by gases generated from radiolytic decomposition of water inside a waste package is excluded on the basis of low consequence: (1) the small amount of water in a dried and inerted TAD canister-bearing waste package will not generate sufficient gas to cause a problem; (2) although an MCO containing upwards of 4 kg residual water may fail, it would vent into the larger codisposal waste package, which would not fail; (3) a hydrogen fire in an MCO will not increase pressure sufficiently to fail the canister, and the maximum possible increase in temperature to the waste package would be negligible. Enhanced corrosion of waste packages and drip shields due to the effects of beta-gamma radiolysis is excluded because beta-gamma radiation is intense enough to cause a problem only while the repository temperature is above boiling when little or no liquid water will be present on waste package or drip-shield surfaces. The effects of nitric acid production by radiolysis on the corrosion of commercial SNF and other internal waste package components is excluded on the basis of low consequence because of the acid-neutralizing capacity of the waste package internal corrosion products. Similarly, potential generation of H_2O_2 by radiolysis and its potential enhancement of commercial SNF corrosion rates is excluded on the basis of low consequence, because increased H_2O_2 concentrations have little influence on commercial SNF corrosion rates under strongly oxidizing conditions. The potential influence on radionuclide concentrations and mobilities due to H_2O_2 accumulation caused by alpha radiolysis is excluded on the basis of low consequence.

Based on the previous discussion, omission of FEP 2.1.13.01.0A (Radiolysis) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.13.02.0A

FEP NAME:

Radiation Damage in EBS

FEP DESCRIPTION:

Radiolysis due to the alpha, beta, gamma-ray, and neutron irradiation of water could result in enhancement of the radionuclide migration from the surface of a degraded waste form into groundwater. When radionuclides decay, the emitted high-energy particle could result in the production of radicals in the water or air surrounding the spent nuclear fuel. If these radicals migrate (diffuse) to the surface of the fuel, they may then enhance the degradation/corrosion rate of the fuel (UO_2). This effect would increase the dissolution rate for radionuclides from the fuel material (fuel matrix) into the groundwater. Strong radiation fields could lead to radiation damage to the waste forms (CSNF, DSNF, DHLW), waste packages, drip shield, seals, and surrounding rock.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Radioactive decay can cause damage to the EBS directly and indirectly. Excluded FEP 2.1.02.04.0A (Alpha Recoil Enhances Dissolution) describes the enhancement of dissolution due to direct effects of alpha recoil. In addition, radiation can cause indirect damage to EBS components. For example, alpha-recoil nuclei can also cause damage (e.g., atom displacements, helium and oxygen bubble formation, and microcracking) particularly to the waste forms. Alpha, beta, and gamma radiation fields can also cause radiolysis of water and humid air, leading to the build-up of radicals, oxidizing species, and acids in the fluid surrounding the EBS, which may accelerate corrosion rates and may also lead to enhanced release rates (see excluded FEP 2.1.13.01.0A (Radiolysis)).

In general, the degree of irradiation in the EBS is highest in the waste form. Until the waste packages are breached, the waste forms degraded, and a major fraction of the radionuclide inventory is released, the radiation fields will decrease with distance from the waste form. In addition to the effects of distance from the source, each successive layer of the EBS (such as the waste package) will provide radiation shielding to EBS components that are further away from the waste. This screening justification addresses components of the EBS from the waste form outwards.

In the TSPA, DOE SNF degradation (except naval SNF) is modelled as instantaneous degradation or dissolution of the waste form upon exposure of the waste form to liquid water. For all groups of DOE SNF (except naval SNF), the upper-limit model produces complete dissolution of the waste form during a single-code time step upon exposure of the waste form to liquid water (BSC 2004 [DIRS 172453], Section 8.1). Radiation damage to the DOE SNF is inconsequential for this bounding modeling approach.

Effects of irradiation damage in commercial SNF freshly discharged from reactors are addressed within the scope of included FEP 2.1.02.02.0A (CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)) and are included in the TSPA in so far as data used for the commercial SNF model development and validation were obtained from freshly discharged commercial SNF samples (BSC 2004 [DIRS 169987]). This FEP addresses the effects of radiation damage due to long-term self irradiation of commercial SNF in the repository. Review of the relative importance of the various types of self-irradiation (i.e., irradiation by α, β, γ, fast neutrons, and spontaneous fission) that can cause damage in CSNF indicates that most of the damage will be due to α-decay (Pelletier 2001 [DIRS 164034], Section 5.4.6.3). Unlike other ceramics, the UO_2 fuel matrix does not eventually become amorphous due to the atom displacements induced by radiation (Matzke 1992 [DIRS 113269]). However, accumulation of defect clusters, vacancies, and interstitials in the crystal lattice together with damage relaxation processes can lead to microstructural changes as exemplified in the fine-grained recrystallized structure seen in the peripheral region of high burnup commercial SNF (Dehaudt 2001 [DIRS 164019], Section 5.2.8.1.2.4). Potential effects of the commercial SNF recrystallized rim region on the effective specific surface area available for dissolution are within the scope of included FEP 2.1.02.02.0A (CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)) and are included within the uncertainty range for this parameter in the commercial SNF model (BSC 2004 [DIRS 169987], Section 6.4.1.5). Self-irradiation damage in commercial SNF after it is emplaced in the repository will enhance the rate of diffusion of fission products in the fuel's matrix (Pelletier 2001 [DIRS 164034], Section 5.4). A recent assessment of the potential effect of radiation damage enhancement of fission product mobility in the commercial SNF matrix concluded that the effects on the commercial SNF gap and grain-boundary inventories are limited (Johnson 2005 [DIRS 178773]). This conclusion was based on calculations that showed that use of an upper estimate for the very uncertain radiation-enhanced diffusion coefficients indicates that self irradiation could cause about 5% of the inventory in the fuel matrix to migrate to the grain boundaries over 10,000 years (Johnson 2005 [DIRS 178773], Section 5). The theoretical approaches that have been used to estimate the alpha self-irradiation enhanced diffusion coefficients give estimates that range over three orders of magnitude (Johnson 2005 [DIRS 178773], Section 5); the effect of alpha self-irradiation on radionuclide migration in the fuel would be negligible if a value near the middle of the estimate range is used. Because the initial release fractions in the commercial SNF model (BSC 2004 [DIRS 169987], Section 6.3.2) are based on experimental data that are believed to already overestimate the gap and grain boundary inventory fractions (BSC 2004 [DIRS 169987], Sections 6.3.1 and 6.3.2), exclusion of explicit consideration of alpha irradiation damage effects is warranted. Other commercial SNF radiation damage effects (evolution of the fuel's chemical state, helium generation and accumulation, and evolution of the fuel's physical state including microcracking and grain decohesion) may accumulate in commercial SNF (Piron 2001 [DIRS 162396]). These effects are excluded from explicit inclusion in the TSPA because they are not expected to be significant given that the commercial SNF model considers that all of the gap and grain boundary inventories are part of the instantaneous release fraction (BSC 2004 [DIRS 169987], Section 6.4).

Radiation levels in the repository may damage defense HLW glass causing bond dissociation and atomic displacements, which may lead to devitrification, swelling and cracking, and consequently, enhanced degradation rates. Corrosion tests conducted on irradiated glasses have shown up to four-fold increases in the release rates of glass components (Wronkiewicz 1993

[DIRS 171709], Abstract). However, other authors have reported no significant change in the dissolution rate between actinide-doped and nonradioactive glasses (Advocat et al. 1998 [DIRS 160446]; Werme et al. 1990 [DIRS 163346]). While the experimental evidence indicates that there may be some effect, the effect appears to be small and the contribution to uncertainty in dissolution rate is small compared to the two orders of magnitude range of uncertainty in dissolution rates (BSC 2004 [DIRS 169988], Table 8-1). For these reasons, the effects of irradiation damage on defense HLW glass degradation are excluded from explicit inclusion in the TSPA.

For the TSPA, all commercial SNF and DOE SNF cladding (with the exception of naval SNF) is considered to be breached on emplacement in the repository, as discussed in included FEP 2.1.02.12.0A (Degradation of Cladding Prior to Disposal). Following waste package failure, commercial SNF cladding unzipping is assumed to result in immediate exposure of bare fuel to the waste package environment (included FEP 2.1.02.23.0A (Cladding Unzipping)). It is also considered that DOE SNF (with the exception of naval SNF) degrades instantaneously upon exposure to liquid water (included FEP 2.1.02.01.0A (DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)). No credit is taken for retardation of radionuclide release by fuel cladding. Therefore, the impact of radiation damage to the cladding (with the exception of naval SNF cladding) is of low consequence and will not affect the magnitude or timing of calculated radiological exposures to the RMEI or radionuclide releases to the accessible environment.

The Waste Package Materials Performance Peer Review Panel addressed the possibility of radiation damage in the repository in its final report (Beavers et al. 2002 [DIRS 158781], Section 3.10). They stated that the waste package will be subjected to a flux of neutrons and gamma rays from the stored radioactive waste (Beavers et al. 2002 [DIRS 158781]). These fluxes could cause the following: (1) neutrons could produce atomic displacement damage in the metal, (2) neutrons could produce atomic displacement damage and gamma rays could cause electron-hole pairs in the protective oxide layer on the metal, and (3) gamma rays could cause radiolysis of the surrounding environment (Beavers et al. 2002 [DIRS 158781], Section 3.10). The report concluded that there is no evidence to suggest that radiation damage to the waste package will alter its mechanical properties or that radiation damage would alter the protective properties of the passive film on Alloy 22 (Beavers et al. 2002 [DIRS 158781], Section 3.10). The effects of radiolysis on waste package corrosion are addressed in excluded FEP 2.1.13.01.0A (Radiolysis).

The cumulative neutron fluence at the waste package emplacement pallet as a function of years after emplacement is determined in *Dose Rate Calculation for 21-PWR Waste Package* (BSC 2004 [DIRS 172227], Section 6.4.1). At 290 years and 340 years after emplacement (the two longest times reported), the cumulative neutron fluence at the emplacement pallet location was determined to be 3.83×10^{14} neutrons/cm^2 and 3.95×10^{14} neutrons/cm^2, respectively (BSC 2004 [DIRS 172227], Table 6.4-1). The cumulative neutron fluence at the emplacement pallet location can therefore be approximated to be increasing at a rate of 2.4×10^{11} neutrons/cm^2/yr. Using this approximation, the maximum cumulative neutron fluence at the emplacement pallet location after 10,000 years would be about 2.4×10^{15} neutrons/cm^2 (taking no account of the reduction in neutron irradiation due to radioactive decay). Due to the close proximity of the waste package and the waste package emplacement pallet, it is reasonable

to equate the cumulative neutron fluence at the emplacement pallet location to the cumulative neutron fluence at the waste package location. *Nuclear Engineering Handbook* (Etherington 1958 [DIRS 164789], p. 10-107) identifies neutron fluence levels below which there is no change in the mechanical properties of Stainless Steel Type 316, nickel, and molybdenum. These neutron fluence levels are 5×10^{19} neutrons/cm^2, 10^{20} neutrons/cm^2, and 10^{20} neutrons/cm^2, respectively. Because the estimated neutron fluence is many orders of magnitude below the neutron fluence thresholds for changes in the mechanical properties of stainless steel, nickel, and molybdenum, significant neutron-induced radiation damage is not expected for either the waste package or pallet. This conclusion is consistent with that presented for Alloy 22 in the preceding paragraph.

The drip shield is located farther away from the major source of radiation (the waste form) than the waste package. On this basis, the drip shield material will be subject to smaller neutron and gamma radiation fields than the waste package. Radiation damage is expected to be of even less consequence to drip shield performance than it is to waste package performance. The effects of radiolysis on corrosion of the drip shield are addressed in excluded FEP 2.1.13.01.0A (Radiolysis).

Gamma radiation will have a negligible effect on the host rock. This conclusion is based on data presented in *Effect of Radiation on the Mechanical Properties of Topopah Spring Tuff* (Blair et al. 1996 [DIRS 129637]), where tuff specimens were irradiated with large doses (9±1 MGy) of gamma radiation and uniaxially tested to measure maximum strength and Young's modulus. A cumulative dose of 9 MGy in 10,000 years corresponds to an average dose rate of 90,000 rad/yr. To put this dose rate in perspective, the calculated gamma dose rate at the outer surface of a waste package containing 21 high-burnup (80 GWd/MTU) assemblies at 100 years after emplacement in the repository is about 35 rad/hr or 306,600 rad/yr (BSC 2004 [DIRS 172227], Figure 6.4-1). The tuff irradiation results show that there is no dicernible difference in the peak strengths and Young's modulus between the irradiated and unirradiated samples (Blair et al. 1996 [DIRS 129637], Table 5).

Closure of the repository subsurface facilities requires closing and sealing all openings from the surface to the underground facilities. These openings consist of the north ramp, south ramp, north construction ramps and portals, ventilation shafts/raises, and exploratory boreholes within the repository footprint (the waste emplacement area projected vertically to the surface), and in a buffer zone around the footprint boundary. Radiation is not expected to damage seals within the repository because the seals are remote with respect to the radiation sources (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-02).

Based on the previous discussion, omission of FEP 2.1.13.02.0A (Radiation Damage in EBS) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.13.03.0A

FEP NAME:

Radiological Mutation of Microbes

FEP DESCRIPTION:

Radiation fields could cause mutation of microorganisms, leading to unexpected chemical reactions and impacts.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry (BSC 2004 [DIRS 169991], Section 6.4) considers the repository-specific environmental constraints of: temperature, pressure, oxic and anoxic conditions, relative humidity, water availability, pH, salinity, nutrient availability, and radiation on microbial activity. These are summarized in excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS). High temperatures, low water availability, and high ionic strengths are predicted to limit microbial activity during the thermal pulse, while nutrient availability will limit microbial activity after the pulse has passed. These are fundamental controls over microbial growth that apply not only to those microbes found in the Yucca Mountain repository presently, but to any mutated forms that might potentially form in the future as well.

Based on the previous discussion, omission of FEP 2.1.13.03.0A (Radiological Mutation of Microbes) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.1.14.15.0A

FEP NAME:

In-Package Criticality (Intact Configuration)

FEP DESCRIPTION:

The waste package internal structures and the waste form remain intact. If there is a breach (or are breaches) in the waste package that allows water to either accumulate or flow-through the waste package, then criticality could occur in-situ.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

A prerequisite for any of the SNF waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. Mechanisms considered that may lead to damage or failure of the waste package and allow water into the system have been idenitified in included FEPs 2.1.03.08.0A (Early Failure of Waste Packages) and 2.1.03.08.0B (Early Failure of Drip Shields). All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, or fissile materials) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

As stated in Section 1 of *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), an evaluation of the criticality FEP scenarios

from *Configuration Generator Model* (BSC 2004 [DIRS 172494], Section 7) for configurations with potential for criticality has identified two dominant sequences of events that must occur for a criticality event to be credible, and which are common to each of the in-package scenario classes. The two independent events are: (1) improper manufacturing, resulting in the absence and/or loss of efficacy of the neutron absorber material, and (2) improper loading of fuel assemblies. These independent events, coupled with the probability of an initiating event that could result in breaching the waste package are evaluated in *Screening Analysis of Criticality Features, Event, and Processes for License Application* (SNL 2008 [DIRS 173869]), and provide an upper-bound estimate for the probability of achieving a configuration with potential for criticality. An upper bound is provided because, for independent event (1), absorber material misload–the probability of criticality is conservatively set to the maximum value (i.e., 1.0) within the sequence of events that make up the scenario. For independent event (2), waste form misload–the calculated probability of a criticality from a waste form misload is based on a bounding design basis configuration that maximizes reactivity potential, whereas the actual scenario class limiting configuration would be a less reactive configuration than the design basis configuration, thus having a lower increase in reactivity from a waste form misload.

The processes that are relevant to this FEP that can breach a waste package during the first 10,000 years after repository closure are: (1) stress corrosion cracking initiated from manufacturing defects and (2) misplaced drip shields allowing advective seepage onto waste packages leading to breaching. Radiolytic gas generation is discussed in excluded FEP 2.1.13.01.0A (Radiolysis) and is not considered a potential mechanism for breach. The TAD canisters and DOE SNF MCO canisters are expected to be loaded in spent fuel pools. Intact TAD and DOE canisters and waste packages are expected to contain little moisture, per requirements for drying (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 04-04), but retention of water in a canister could possibly occur if the drying and inerting process is incomplete. The process controls for the drying and inerting process for commercial SNF and DOE SNF canisters are expected to be similar to NUREG-1536, *Standard Review Plan for Dry Cask Storage Systems* (NRC (1997 [DIRS 101903], Section 8.V.1) and, thus, sufficiently rigorous to reduce the likelihood of leaving residual water in the TADs to levels that, if quantified, would not significantly increase the overall probability of criticality in the repository.

Fabrication defects in the waste package OCB that can lead to stress corrosion cracking have been analyzed in *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6). Such events include, for example, improper material selection, improper heat treatment, and waste package OCB lid closure weld flaws. The probabilities associated with the set of fabrication defects in the waste package OCB have been evaluated individually from the respective event tree/fault tree diagrams and collectively with the exception of the weld flaws in the latter case. Thus, probability values from the collective evaluation are used, for example, in the scenario where a waste package OCB breach could result from any one of several SCC initiators. Probability values from the individual evaluations are used where a waste package OCB breach could result from a specific SCC initiator such as failure of the low plasticity burnishing process for stress mitigation.

Certain DOE SNF waste forms have sufficient quantities of fissile material to support unmoderated (fast) criticality if the fissile material is concentrated beyond its design concentration in the waste form and the neutron absorber materials are removed. While

concentration of the fissile material beyond its nominal design concentration could result from degradation of the waste form by either water ingress or a disruptive event, removal of the neutron absorber materials from a DOE SNF waste package would require a breach of the waste package and a removal mechanism. Degradation in the presence of water would result in a moderated system. Likewise, there is no known mechanism that could reconfigure non-degraded fissile material into a compact configuration with unmoderated criticality potential. The most plausible neutron absorber material removal mechanism is through water ingress resulting in degradation of the waste package internal components, dissolving of the neutron absorber material in the water, and flushing of the material from the waste package. This mechanism is not expected to result in a critical configuration since the corrosion rate of the neutron absorber material is very low. In addition, the gadolinium absorber in the DOE SNF canisters forms phosphate or carbonate corrosion products (SNL 2007 [DIRS 181165], Section 6.3.16) that have very low solubility.

Sources of corrosion of the waste package OCB have been considered in the screening of processes affecting waste package degradation in included FEP 2.1.03.02.0A (Stress Corrosion Cracking of Waste Packages). This FEP identifies the propagation of incipient cracks that can occur on the waste package outer barrier closure welds (as these cannot be annealed to relieve tensile stress but stress mitigation processes will be employed (i.e., low plasticity burnishing)) and/or fabrication flaws in the waste packages as possible initiating mechanisms for the development of stress corrosion cracking of the waste package outer barrier. These mechanisms are discussed in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 8.4.2.1) and *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.3). SCCs can be initiated on a smooth weld surface (with incipient cracks) or at existing weld flaws if the tensile stresses exceed the threshold stress for SCC nucleation that is taken to be 90% to 105% of the yield strength. Because weld flaws are already formed, they do not require a stress threshold to nucleate. However, most of the weld flaws are embedded within the material and not initially exposed to the environment. Thus, such flaws will not propagate until exposed to the environment. As general corrosion proceeds, some initially embedded weld flaws may be exposed to the environment while others are corroded away.

All regions of the Alloy 22 waste package outer barrier, except the outer-closure lid welds, are solution-annealed before the waste packages are loaded with SNF assemblies. Thus, the waste package OCB will not be expected to develop residual stresses or stress intensity factors sufficiently high for SCC to occur provided that fabrication defects in the waste package OCB are not present that can lead to stress corrosion cracking.

The criticality potential of the in-package intact configuration scenario is negligible since the EBS components and neutron absorber materials are designed to maintain their function in nominal repository environments over the first 10,000-year period after repository closure by specifying a corrosion allowance or minimum thickness (SNL 2007 [DIRS 179394], Table 4-1, Parameter Numbers 03-07 and 03-10). Although configurations not conforming to design specifications are applicable to both intact and degraded scenarios, configurations with potential for criticality require sufficient water for moderation.

Evaluation of the neutron absorber material misload failure mechanism is an important consideration for the determination of a configuration criticality potential. The probability that proper neutron absorber material is not used in the waste package (or waste form if integrally connected) or becomes separated from the fissile material must then be evaluated for configurations where absorber material is necessary for criticality control. Misloading of the waste forms is also an important consideration for the determination of a configuration criticality potential for commercial SNF that requires restricted loading configurations (i.e., specified loading curves). The probability that such waste forms are not loaded as required must then be evaluated.

The neutron absorber misload event represents the absence and/or loss of efficacy of the neutron absorber plates due to fabrication-related errors (e.g., incorrect material installed during fabrication, absorber content of plates outside specified range). These types of events can only occur during fabrication and/or loading of a canister due to process or procedural errors and are similar to waste package and drip shield early failure mechanisms (SNL 2007 [DIRS 178765], Section 6.2). Errors in fabrication and operational processes are primarily due to human factors that are common to the various processes. Surrogate fabrication and operational processes with associated human factor errors have been evaluated in *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765]) and results are used for such initiating events for the waste package and drip shield early failure mechanisms. The surrogate processes are:

1. Improper performance of the neutron absorber plates represented as a material selection error in the waste package component fabrication processes (SNL 2007 [DIRS 178765], Section 6.3.2)

2. Failure of the waste package and canister drying/inerting process represented as an operational process error (SNL 2007 [DIRS 178765], Section 6.3.5)

3. Drip shield misplacement allowing the possibility of advective seepage flow directly on a waste package OCB (SNL 2007 [DIRS 178765], Section 6.4.4)

4. Fabrication flaws allowing increased susceptibility to SCCs (SNL 2007 [DIRS 178765], Section 6.3).

Waste package fabrication and operational process error probabilities have been obtained from DTNs: MO0701PASHIELD.000 [DIRS 180508] and MO0705EARLYEND.000 [DIRS 180946]. The probability values assigned to absorber plate misloads due to material selection errors, waste package and canister operational process failures, waste package SCC mitigation process failures, and the occurrence of OCB closure lid weld flaws for this analysis are listed in Table 2.1.14.15.0A-1. The operational process failures include the drying and inerting process and OCB outer lid weld stress mitigation process. These processes are conceptually similar since each requires operator actions and the human error failure rate from the OCB outer lid weld stress mitigation process is assigned to each one in Table 2.1.14.15.0A-1.

Table 2.1.14.15.0A-1. Undetected Errors in Waste Package Fabrication and Operational Processes

Waste Package Operations	Probability per Canister
Absorber material selection error [a]	1.25×10^{-7} per canister
Outer closure lid weld stress mitigation process failure [a]	3.8×10^{-5} per canister
Emplacement error for drip shield [a]	4.36×10^{-9} per drip shield
Fraction of waste package OCB lid weld flaws oriented normally to surface [b]	0.008
Probability of undetected fabrication defects in a waste package OCB [b]	1.13×10^{-4} per waste package
Probability of at least one flaw in waste package OCB lid closure weld [c]	0.156

Sources: [a] DTN: MO0705EARLYEND.000 [DIRS 180946], file: *Table 1.doc*, Table 1.
[b] DTN: MO0701PASHIELD.000 [DIRS 180508], file: *Tables for DTN Readme.doc*, Table 1.
[c] DTN: MO0701PASHIELD.000 [DIRS 180508], file: *EarlyFail-WeldDefects.zip*, Section A.7.

The mean value for the probability that a waste package OCB has at least one such defect was estimated using a Monte Carlo sampling process on the collective set of waste package OCB fabrication flaws (excluding OCB closure lid weld flaws) resulting in a value of 1.13×10^{-4} per waste package (Table 2.1.14.15.0A-1).

The outer closure lid weld is plasticity burnished to produce a layer of compressive stress that prevents SCC initiation until general corrosion removes this layer. The probability of having at least one undetected flaw in the outer closure lid weld is 0.156 from Table 2.1.14.15.0A-1. However, such flaws are preferentially oriented in the circumferential direction along the weld, and as such they will not propagate when under residual hoop stress that would parallel most flaws. Only a small fraction (i.e., 0.008 from Table 2.1.14.15.0A-1) of these flaws would be oriented sufficiently normal to the residual hoop stress direction to permit propagation once the compressive stress layer is removed by corrosive action. Thus, the probability of a closure lid weld having a flaw that can propagate is given by $0.156 \times 0.008 = 1.25 \times 10^{-3}$. Specifications for controlled or low-plasticity burnishing of the waste package OCB closure lid call for the outer lid weld to be stress mitigated to a compressive depth of at least 3 mm (SNL 2007 [DIRS 179394], Table 4-1, Parameter Number 03-17). The upper values for the range of general corrosion rates for Alloy 22 from *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Figure 6-10) is 15 nm/yr, which implies that the compressive layer will survive for $\geq 2 \times 10^5$ years in nominal repository conditions provided the low-plasticity burnishing process is properly performed.

The initiating events where the OCB is potentially breached include the failure of the low-plasticity burnishing process such that the compressive stress layer in the waste package OCB closure lid is not produced, failure of the waste package OCB stress mitigation processes to function properly, weld flaws in the waste package OCB lid, and failure to properly emplace drip shields. Weld flaws in the waste package OCB lid or a failure of the stress mitigation processes can lead to a waste package breach from either weld flaw propagation or SCCs initiated by the residual stresses. A drip shield emplacement error could result in an advective flow path to the waste package OCB, creating an environment for subsequent localized corrosion processes that

could breach the waste package OCB (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)).

Events requiring probability values for the screening calculation are listed as follows:

1. Probability of a failure for the low-plasticity burnishing process on the waste package OCB closure lid, or a failure of processes for stress mitigation for the waste package OCB, or a drip shield emplacement error

2. Probability of improper absorber material in a canister

3. Probability of a loading curve violation for a 21-PWR TAD canister.

The probabilities of events in this scenario are derived from preclosure activities, making those values independent of the postclosure period. The mean value of the probability distribution for failure of the low-plasticity burnishing process is given in Table 2.1.14.15.0A-1 as 3.8×10^{-5}. The probability that a waste package OCB closure weld has a flaw that can propagate through the OCB was estimated previously as 1.25×10^{-3} per waste package. The mean probability of waste package OCB fabrication defects as 1.13×10^{-4} per waste package and the mean probability value for improper emplacement of a drip shield is given in Table 2.1.14.15.0A-1 as 4.36×10^{-9} per drip shield. The probability of localized corrosion breaching the waste package OCB from advective seepage flow is conservatively set to 1.0. The probability of installing improper absorber plate material in a TAD or DOE canister is a fabrication related error. This type of error was evaluated in *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765], Section 6.3.2). The mean value of the probability distribution for a fabrication failure is given in Table 2.1.14.15.0A-1 as 1.25×10^{-7} per canister.

An analysis of commercial SNF misload probabilities was documented in *Commercial Spent Nuclear Fuels Waste Package Misload Analysis* (BSC 2003 [DIRS 166316]). Results from this analysis establish that the probability of a loading curve violation in a 21-PWR waste package is 1.18×10^{-5} (BSC 2003 [DIRS 166316], Table 41). The TAD canister specifications require the canisters for PWR SNF to contain 21 assemblies similar to the 21-PWR waste package (SNL 2007 [DIRS 179394], Section 4.1.1.2). The cited analysis is used as a surrogate for misloading waste forms in a TAD canister since the misloading of an assembly into a TAD canister requires the same improper selection of an assembly with characteristics (burnup and enrichment) in the unacceptable range of the loading curve. Thus, the probability of a loading curve violation for TAD canisters is expected to be similar in magnitude to the 21-PWR waste package value. However, neighboring assemblies that have low reactivity values may provide partial compensation for the excess reactivity from the incorrectly loaded assembly. Given that a misloading curve violation occurs, the likelihood of the misloaded configuration having potential for criticality has been shown to be 0.014 from results of a probabilistic calculation of that potential (SNL 2008 [DIRS 182788], Section 7). The probability of a potentially critical configuration resulting from an assembly misload of a 21-PWR TAD canister is $0.014 \times 1.18 \times 10^{-5} = 1.65 \times 10^{-7}$ per TAD canister.

The probability of misloading assemblies in the 44-BWR TAD canister is insignificant since the BWR waste stream inventory for the repository is in the acceptable region of the loading curve

map (SNL 2008 [DIRS 182788], Section 6.1.1.1.3). Misloading of waste forms in DOE SNF canisters is considered very improbable because the shape and size of the defense HLW glass canisters and the various DOE SNF canisters differ significantly and can be readily distinguished by visual inspection. Thus, the waste form misload probability for DOE SNF waste packages is considered to be sufficiently low such that, if quantified, would not significantly increase the overall probability of criticality in the repository.

The probability for the occurrence of configurations with potential for criticality is evaluated from a number of independent sets of sequences of events where all of the events in any specific sequence must happen for that configuration to occur. Since the events in any one sequence can also be considered as independent entities, the probability of the sequence is the product of the probability of each individual event. The expected probability of having a particular sequence occur in exactly *k* waste packages in the repository is a binomial process described by the binomial probability distribution, $P_B(k; p, N)$, with probability "p" for occurrence in a waste package and "q = 1 − p" for non-occurrence. The probability of having the sequence occur in at least "*k + 1*" waste packages is given by:

$$P(\text{at least } k+1 \text{ waste packages}) = 1 - \sum_{l=0 \text{ to } k} P_B(l; p, N) \quad \text{(Eq. 2.1.14.15.0A-1)}$$

where

k = number of items affected (e.g., waste packages, drip shields)

p = probability for occurrence of the event

N = number of possible items involved.

For large N and small "p" where N × p ≅ λ, the binomial distribution converges to the Poisson distribution (P_P) with a mean of λ = N × p. Then Equation 2.1.14.15.0A-1 can be rewritten as:

$$P(\text{at least } k+1 \text{ waste packages}) = 1 - \sum_{l=0,k} P_P(l; N \times p) = 1 - \sum_{l=0,k} \frac{\lambda^l \times \exp(-\lambda)}{l!}$$

(Eq. 2.1.14.15.0A-2)

The criterion for screening criticality scenarios from consideration in the repository as having a low probability for the occurrence of a criticality event sequence for any waste package in the repository (which can be stated as the probability of having at least one such sequence occur) is given by Equation 2.1.14.15.0A-2 with $k = 0$. For the case where $k = 0$ and λ is small, Equation 2.1.14.15.0A-2 can be approximated by λ. Then the probability of at least one waste package configuration with criticality potential occurring in the repository is given by λ ($= N \times p$).

Evaluating the event sequences for commercial SNF and DOE SNF with potential for criticality using the number of PWR TAD canisters as 4,568, the number of 44-BWR TAD canisters as 2,915, and DOE SNF canisters that require neutron absorber plates (DOE1, DOE2, and DOE7 groups) as 1,223 (SNL 2008 [DIRS 173869], Section 6.3.2), and setting the number of drip shields equal to the number of waste packages gives:

PWR TAD canister loading curve violation:

$$\{1 - P_B (0; ((3.8 \times 10^{-5} \times 1.25 \times 10^{-3} + 1.13 \times 10^{-4} + 4.36 \times 10^{-9} \times 1.0) \times 1.65 \times 10^{-7}), 4568)\} = 8.5 \times 10^{-8}$$

PWR TAD canister absorber misload:

$$\{1 - P_B (0; ((3.8 \times 10^{-5} \times 1.25 \times 10^{-3} + 1.13 \times 10^{-4} + 4.36 \times 10^{-9} \times 1.0) \times 1.25 \times 10^{-7}), 4568)\} = 6.5 \times 10^{-8}$$

44-BWR TAD canister absorber misload:

$$\{1 - P_B (0; ((3.8 \times 10^{-5} \times 1.25 \times 10^{-3} + 1.13 \times 10^{-4} + 4.36 \times 10^{-9} \times 1.0) \times 1.25 \times 10^{-7}), 2915)\} = 4.1 \times 10^{-8}$$

DOE SNF canister absorber misload (DOE1, DOE2, and DOE7):

$$\{1 - P_B (0; ((3.8 \times 10^{-5} \times 1.25 \times 10^{-3} + 1.13 \times 10^{-4} + 4.36 \times 10^{-9} \times 1.0) \times 1.25 \times 10^{-7}), 1223)\} = 1.7 \times 10^{-8}$$

Thus, a conservative estimate for the probability of achieving a configuration with criticality potential in the repository due to the presence of weld flaws in the OCB closure lid or other early failure mechanisms, based on summing this set of events, including the DOE1, DOE2, and DOE7 contributions is 2.1×10^{-7} for 10,000 years. Since the events in the above evaluation are all associated with operations during the preclosure period, the probabilities are constant over the postclosure time period. It should be noted that the other DOE criticality SNF groups do not pose a criticality concern because they do not need to rely on neutron absorber plates for criticality control. These evaluations are demonstrated in *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482]), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935]), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926]).

Summary—As documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for the in-package location is much less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]) the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.1.14.16.0A

FEP NAME:

In-Package Criticality (Degraded Configurations)

FEP DESCRIPTION:

The waste package internal structures and the waste form may degrade. If a critical configuration (sufficient fissile material, and neutron moderator, lack of neutron absorbers) develops, a criticality event could occur in-situ. Potential in-situ critical configurations are defined in figures 3.2a and 3.2b of *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505]).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP is analogous in content to excluded FEP 2.1.14.15.0A (In-Package Criticality (Intact Configuration)) with the exception of the configuration.

As noted in excluded FEP 2.1.14.15.0A (In-Package Criticality (Intact Configuration)), for a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, or fissile materials) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration.

Since this FEP considers degraded internal configurations, the cladding is considered breached within a damaged or failed waste package and the interior of the fuel rods are assumed to be exposed to the repository environment allowing the fissile material to convert to the mineral schoepite (UO_3:$2H_2O$) (SNL 2008 [DIRS 173869], Section 6.3.2). The criticality potential of the in-package degraded configuration scenario is negligible provided that waste packages are fabricated and loaded according to design specifications, as sensitivity studies have shown that the PWR SNF waste form in various degraded configurations, such as saturated porous schoepite, does not result in a more reactive configuration than the design basis configuration (SNL 2007 [DIRS 181373], Table A-12; SNL 2008 [DIRS 182788], Section 6.2.5). Although configurations not conforming to design specifications are applicable to intact and degraded scenarios, configurations with potential for criticality require sufficient water for moderation. These were considered in excluded FEP 2.1.14.15.0A (In-Package Criticality (Intact Configuration)) and show that the probability of criticality for the in-package location is much less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. Accordingly, FEP 2.1.14.16.0A (In-Package Criticality (Degraded Configurations)) is excluded from the

performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

YMP 2003	*Disposal Criticality Analysis Methodology Topical Report*	165505

FEP: 2.1.14.17.0A

FEP NAME:

Near-Field Criticality

FEP DESCRIPTION:

Near-field criticality could occur if fissile material-bearing solution from the waste package is transported into the drift and the fissile material is precipitated into a critical configuration. Potential near-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3a).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the near-field location for those conditions that may lead to damage or failure of the waste package and allow water into the system, as identified in included FEPs 2.1.03.08.0A (Early Failure of Waste Packages) and 2.1.03.08.0B (Early Failure of Drip Shields). A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form, as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, or fissile materials) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Near-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the near-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in a favorable geometry. The probability of an external criticality event is expected to be lower than the probability of an in-package criticality event. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the near-field environment.

Because the quantity of material released by diffusion would be small due to the tortuousity of the path, advective flow of water is necessary for transporting fissile materials from the waste package to the near-field in any appreciable quantities to be considered for criticality (SNL 2007 [DIRS 181165], Section 6.2). An advective seepage flow path to a waste package for nominal repository conditions would occur due to misplacement of a drip shield leading to breaching of the waste package from localized corrosion. However, the probability of this type of event is very low (4.36×10^{-9} per drip shield; DTN: MO0705EARLYEND.000 [DIRS 180946], file: *Table 1.doc*, Table 1). Since this type of event occurs during the preclosure time period, it is independent of the postclosure time period. Using the total number of waste packages (11,162; DTN: MO0702PASTREAM.001 [DIRS 179925], file: *DTN-Inventory-Rev00.xls*, worksheet "Unit Cell") as a conservative estimate for the number of drip shields (it is conservative because not all waste packages have sufficient quantities of fissile material to result in a criticality event) and multiplying by the probability of misplacing a drip shield results in an initiating event probability of 4.9×10^{-5}. This value is already below the regulatory screening criterion of 1 chance in 10,000 (10^{-4}) of occurrence within 10,000 years after disposal prior to consideration of probabilities (which would be less than 1.0) associated with the amount of degradation and accumulation into a favorable geometry for criticality that would only result in lowering the sequence probability.

As indicated in excluded FEP 2.1.14.26.0A (Near-Field Criticality Resulting from an Igneous Event) and excluded FEP 2.1.14.20.0A (Near-Field Criticality Resulting from a Seismic Event), the amount of fissile material accumulation in the near-field location is insufficient to pose a criticality concern. Note that the material degradation of the internals and subsequent accumulation in the near-field based on the seismic and igneous scenarios are bounding for nominal repository conditions because the seismic and igneous seepage fluxes are much higher. Therefore, under bounding seepage fluxes resulting from a seismic or igneous initiating event, an insufficient amount of fissile material could accumulate in the near-field to pose a criticality concern. It can be concluded that under nominal repository conditions, an insufficient amount of fissile material can accumulate in the near-field location to pose a criticality concern.

Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869], Section 7.1) the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.1.14.18.0A

FEP NAME:

In-Package Criticality Resulting from a Seismic Event (Intact Configuration)

FEP DESCRIPTION:

The waste package internal structures and the waste form remain intact either during or after a seismic disruptive event. If there is a breach (or are breaches) in the waste package that allow(s) water to either accumulate or flow through the waste package, then criticality could occur in-situ.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality for the seismic scenario assuming an intact configuration. It is possible for in-package criticality to be analyzed as either an intact or degraded configuration. After a seismic event, the in-package, intact configuration is designed to remain subcritical, even under unanticipated fully flooded conditions; therefore, only degraded configurations are relevant for the assessment of criticality in the in-package location. Although configurations not conforming to design specifications are possible, these are evaluated in the degraded configuration class (SNL 2008 [DIRS 173869], Section 6.4). Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability. The in-package degraded configuration resulting from a seismic event is discussed in excluded FEP 2.1.14.19.0A (In-package Criticality Resulting from a Seismic Event (Degraded Configuration)).

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869], Section 7.1), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.1.14.19.0A

FEP NAME:

In-Package Criticality Resulting from a Seismic Event (Degraded Configurations)

FEP DESCRIPTION:

Either during or as a result of a seismic disruptive event, the waste package internal structures and the waste form may degrade. If a critical configuration develops, criticality could occur in-situ. Potential in-situ critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figures 3.2a and 3.2b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality for the seismic scenario. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. Vibratory ground motion (included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components)), faulting (included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components)), seismic-induced drift collapse in the lithophysal units (included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components)), and seismic-induced rockfall (excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components)) are potential initiating events that could cause waste package or drip shield damage or drip shield failure leading to subsequent waste package failure from localized corrosion. Such failures may allow the influx of water (either advective or diffusive) into the waste package, which, in turn, has the potential to initiate processes leading to configurations with potential for criticality.

Note that excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) has been screened from performance assessment on the basis of low consequence, which is not directly applicable to criticality potential evaluations. That FEP indicates that seismic-induced damage to the waste packages and its internals from rock block impacts in nonlithophysal units is screened out from the TSPA model on the basis of low probability. However, FEP 1.2.03.02.0B screens out tearing or rupture of the drip shield plates from large block impacts because of low consequence, which is not directly applicable to criticality potential evaluations. Drip shield failure could result in an advective flow path to the waste package OCB creating an environment for subsequent localized corrosion processes (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)) that could breach the waste package OCB. Therefore, this must be considered as an initiating event that can lead to a potentially critical configuration.

All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact

configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, or fissile materials) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Seismic events that can cause significant displacement (> 0.1 cm) along fault lines that do intersect the drifts have a low probability of occurrence (i.e., mean annual exceedance frequencies of less than 10^{-6} per year) (SNL 2007 [DIRS 176828], Table 6-61). Damage to the drip shield causing loss of function is not expected to result from seismic faulting until sufficient displacement occurs to make contact between the drip shield and the drift. For seismic events with an annual exceedance frequency greater than 1.2×10^{-7} per year (i.e., less-severe earthquakes), no waste package damage is expected to occur due to faulting (DTN: MO0705FAULTABS.000 [DIRS 183150], file: *Fault Displacement Abstraction for Criticality.xls*, worksheet: "Tables by WP Type"). For seismic events with an annual exceedance frequency less than 1.2×10^{-7} per year (i.e., more severe earthquakes), waste package failure from seismically induced faulting is potentially initiated.

Under significant vibratory ground motions, impacts may occur between adjacent waste packages, between a waste package and its emplacement pallet, and between waste packages and the surrounding drip shield. Stress corrosion cracking from high residual stress is expected to be the cause of waste package damage from impact processes under vibratory ground motion (SNL 2007 [DIRS 178851], Section 8.2). Regions where the residual stress from mechanical damage exceeds the tensile failure criterion are expected to be severely cold-worked and, hence, potentially subject to enhanced SCC. However, if cracking were to occur as a result of specific environmental conditions coincident with the mechanical deformation, cracks would take time to develop after the shaking event.

The accumulation of rubble from multiple seismic events and the dynamic motion during a seismic event may generate damaged areas on the drip shield. The drip shields may accumulate damage from rockfall induced by vibratory ground motion from repository closure until the drip shield plates eventually rupture (SNL 2007 [DIRS 176828], Section 6.8). In the nonlithophysal

host rock, blocks released by seismic motion can impact the drip shield, and partial drift collapse may occur, but complete collapse is very unlikely. Rock block impacts may result in damaged areas on the drip shield plates and, in more extreme cases, may cause tearing or rupture of the plates (SNL 2007 [DIRS 176828], Section 6.10).

Waste packages may be contacted by limited amounts of water from condensation or slow leakage through damaged drip shields. However, flow of such condensation or leakage will be insignificant (excluded FEPs 2.1.08.14.0A (Condensation on the Underside of the Drip Shield) and 2.1.03.10.0B (Advection of Liquids and Solids through Cracks in the Drip Shield)). For failed drip shields, waste packages may be contacted directly by seepage from the host rock, which can induce localized corrosion (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)).

As stated in Section 1 of *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), an evaluation of the criticality FEP scenarios from *Configuration Generator Model* (BSC 2004 [DIRS 172494], Section 7) for configurations with potential for criticality has identified two dominant sequences of events that must occur for a criticality event to be credible, and which are common to each of the in-package scenario classes. The two independent events are: (1) improper manufacturing, resulting in the absence and/or loss of efficacy of the neutron absorber material, and (2) for PWR SNF, improper loading of fuel assemblies. These independent events, coupled with the probability of an initiating event that could result in breaching the waste package are evaluated in *Screening Analysis of Criticality Features, Event, and Processes for License Application* (SNL 2008 [DIRS 173869]), and provide an upper bound estimate for the probability of achieving a configuration with potential for criticality. An upper bound is provided because, for independent event (1), absorber material misload–the probability of criticality is conservatively set to the maximum value (i.e., 1.0) within the sequence of events that make up the scenario. For independent event (2), waste form misload–the calculated probability of a criticality from a waste form misload is based on a bounding design basis configuration that maximizes reactivity potential, whereas the actual scenario class limiting configuration would be a less reactive configuration than the design basis configuration, thus having a lower increase in reactivity from a waste form misload.

Certain DOE SNF waste forms have sufficient quantities of fissile material to support unmoderated (fast) criticality if the fissile material is concentrated beyond its design concentration in the waste form and the neutron absorber materials are removed. While concentration of the fissile material beyond its nominal design concentration could result from degradation of the waste form by either water infiltration or a disruptive event, removal of the neutron absorber materials from a DOE SNF waste package would require a breach of the waste package and a removal mechanism. Degradation in the presence of water would result in a moderated system. Likewise, there is no known mechanism that could reconfigure non-degraded fissile material into a compact configuration with unmoderated criticality potential. The most plausible neutron absorber material removal mechanism is through water infiltration resulting in degradation of the waste package internal components, dissolving of the neutron absorber material in the water, and flushing of the material from the waste package. This mechanism is not expected to result in a critical configuration since the corrosion rate of the neutron absorber material is very low. In addition, the gadolinium absorber in the DOE SNF canisters forms

phosphate or carbonate corrosion products (SNL 2007 [DIRS 181165], Section 6.3.16), which have very low solubility.

Since this FEP considers degraded internal configurations, the cladding is considered breached within a damaged or failed waste package and the interior of the fuel rods are assumed to be exposed to the repository environment allowing the fissile material to convert to the mineral schoepite (UO_3:$2H_2O$) (SNL 2008 [DIRS 173869], Section 6.3.2). The criticality potential of the in-package degraded configuration scenario is negligible provided that waste packages are fabricated and loaded according to design specifications as sensitivity studies have shown that the PWR SNF waste form in various degraded configurations such as saturated porous schoepite does not result in a more reactive configuration than the design basis configuration (SNL 2007 [DIRS 181373], Table A-12; SNL 2008 [DIRS 182788], Section 6.2.5). Although configurations not conforming to design specifications are applicable to intact and degraded scenarios, configurations with potential for criticality require sufficient water for moderation.

The criticality potential of a seismic event that damages the waste package OCB and/or the drip shield is dependent upon the probability of a seismic event breaching a waste package in combination with other conditions, notably absorber misload and, for PWR SNF, loading curve violation probabilities. The probability for the occurrence of configurations with potential for criticality is evaluated from a number of independent sets of sequences of events where all of the events in any specific sequence must happen for that configuration to occur. Since the events in any one sequence can also be considered as independent entities, the probability of the sequence is the product of the probability of each individual event. The expected probability of having a particular sequence occur in exactly k waste packages in the repository is a binomial process described by the binomial probability distribution, $P_B(k; p, N)$, with probability "p" for occurrence in a waste package and "$q = 1 - p$" for non-occurrence. The probability of having the sequence occur in at least "$k + 1$" waste packages is given by:

$$P(\text{at least } k+1 \text{ waste packages}) = 1 - \sum_{l=0 \text{ to } k} P_B(l; p, N) \qquad \text{(Eq. 2.1.14.19.0A-1)}$$

where

k = number of items affected (e.g., waste packages, drip shields)

p = probability for occurrence of the event

N = number of possible items involved.

For large N and small "p" where $N \times p \cong \lambda$, the binomial distribution converges to the Poisson distribution (P_p) with a mean of $\lambda = N \times p$. Then, Equation 2.1.14.15.0A-1 can be rewritten as:

$$P(\textit{at least } 1 \textit{ waste packages}) = 1 - P_P(0; N \times p) = 1 - \frac{\lambda^k \times \exp(-\lambda)}{k!}$$

(Eq. 2.1.14.19.0A-2)

The criterion for screening criticality scenarios from consideration in the repository as having a low probability for the occurrence of a criticality event sequence for any waste package in the

repository (which can be stated as the probability of having at least one such sequence occur) and is given by Equation 2.1.14.19.0A-2 with $k = 0$. For the case where $k = 0$ and λ is small, Equation 2.1.14.19.0A-2 can be approximated by λ. Then, the probability of at least one waste package configuration with criticality potential occurring in the repository is given by λ $(= N \times p)$.

Events in the various seismic vibratory scenarios requiring probability values for the calculation are listed as follows:

1. Probability of a seismic vibratory ground motion event
2. Probability of waste package OCB damage from effects of the ground motion
3. Probability of improper absorber material in a commercial SNF or DOE SNF canister
4. Probability of a loading curve violation for a 21-PWR TAD canister
5. Probability of drip shield failure.

Probability of Seismic vibratory ground motion event—For seismic events causing waste package-pallet impacts that can damage a commercial SNF waste package at the 90% residual stress level, the probability of damage is zero at a PGV value of 2.44 m/s (exceedance frequency of 4.518×10^{-7} per year). At a PGV value of 4.07 (exceedance frequency of 1×10^{-8} per year), the probability of impact damage is 0.118 (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *Kinematic Damage Abstraction 23-mm Intact.xls*, sworksheet: "Probability of Damage"). Seismic events with the range of annual exceedance frequencies that can damage a TAD waste package are represented in the column labeled "PGV Value" in Table 2.1.14.19.0A-1. The probability of a seismic event is a random event in time following a Poisson distribution (SNL 2007 [DIRS 176828], Section 5.2), which increases linearly in log-time. Thus, the probabilities that one or more of these basic events occurs (i.e., one minus the probability that none occurs) is determined with Equation 2.1.14.19.0A-2 and the information provided in Table 2.1.14.19.0A-1.

Table 2.1.14.19.0A-1. Probability of Seismic Vibratory Ground Motion Events Causing Damage to TAD Canister-Bearing Waste Packages

PGV Value (m/s)	λ_1 (events/year)	λ_2 (events/year)	t_1 (years)	t_2 (years)	Probability
< 2.44	4.52×10^{-7}	NA	NA	NA	NA
2.44 - 4.07	1.0×10^{-8}	4.52×10^{-7}	10,000	0	4.41×10^{-3}

Source: DTN: MO0705CRITPROB.000 [DIRS 184958], file: *Fault Displacement Abstraction for Criticality Updated DTN 10-25-07.xls*, worksheet: "Tables by WP Type," rows 253 to 258.

Seismic events causing waste package-pallet impacts that can damage a codisposal waste package are shown in Table 2.1.14.19.0A-2. The range of the seismic events is shown in the column labeled "PGV Value" with the associated annual exceedance frequencies in columns 2 and 3.

Table 2.1.14.19.0A-2. Probability of Seismic Vibratory Ground Motion Events Causing Damage to Codisposal Waste Packages

PGV Value (m/s)	λ_1 (Events/year)	λ_2 (Events/year)	t_1 (years)	t_2 (years)	Probability
< 0.364	1.27×10^{-4}	NA	NA	NA	NA
0.364 to 0.4	9.30×10^{-5}	1.27×10^{-4}	10,000	0	2.87×10^{-1}
0.4 to 1.05	9.96×10^{-6}	9.30×10^{-5}	10,000	0	5.64×10^{-1}
1.05 to 2.44	4.52×10^{-7}	9.96×10^{-6}	10,000	0	9.07×10^{-2}
2.44 to 4.07	1.0×10^{-8}	4.52×10^{-7}	10,000	0	4.41×10^{-3}

Source: DTN: MO0705CRITPROB.000 [DIRS 184958], file: *Fault Displacement Abstraction for Criticality Updated DTN 10-25-07.xls*, worksheet: "Tables by WP Type," rows 250 to 256.

Probability of waste package OCB damage from effects of the ground motion—If a seismic vibratory ground motion event occurs, the estimated probability of damage to a TAD canister-bearing waste package from impacts is given as 0.118 (SNL 2007 [DIRS 176828], Section 6.5.1.2) at the 90% RST level at the 4.07 m/s PGV range, resulting in a probability of damage for a TAD canister-bearing waste package given by $4.41 \times 10^{-3} \times (0.0 + 0.118) \times 0.5 = 2.6 \times 10^{-4}$. The probability of damage at the 100% RST level is zero. Since the probability of damage (i.e., 0.118) is a point estimate evaluated at discrete PGV levels, the probability over the frequency range is assigned the average value. The 90% RST level data is used for conservatism for the initiating event probability values.

Similarly, the estimated probability of damage to a codisposal waste package from impacts is given in Table 2.1.14.19.0A-3 at the 90% RST level for PGV values between 0.4 and 4.07 m/s inclusively and at 100% RST level for PGV values between 2.44 and 4.07 m/s inclusively.

Table 2.1.14.19.0A-3. Probability of Damage for Intact Codisposal Waste Package

PGV Level (m/s)	Residual Stress Threshold as Percentage of Yield Strength		
	90%	100%	105%
0.364	0	0	0
0.4	0.029	0	0
1.05	0.559	0	0
2.44	0.941	0.147	0
4.07	1	0.412	0

Source: DTN: MO0703PASDSTST.001 [DIRS 183148], file: *CDSP Kinematic Damage Abstraction 23-mm Intact.xls*, worksheet: "Probability of Damage - New."

Combining the information from Tables 2.1.14.19.0A-2 and 2.1.14.19.0A-3 results in a probability of damage to a codisposal waste package at the 90% and 100% RST levels, respectively, of $(0.29 \times (0.0 + 0.03) + 0.56 \times (0.03 + 0.56) + 0.091 \times (0.56 + 0.94) + 0.0044 \times$

$(0.94 + 1.0)) \times 0.5 = 0.24$ and $(0.091 \times (0.0 + 0.147) + 0.0044 \times (0.147 + 0.412)) \times 0.5 = 7.9 \times 10^{-3}$. The estimated probability of damage from impacts for a codisposal waste package is zero for the 105% RST level. The 90% RST level data is used for conservatism for the initiating event probability values.

Probability of improper absorber material in a CSNF or DOE SNF canister—These types of events (e.g., incorrect material installed during fabrication, absorber content of plates outside specified range) can only occur during fabrication and/or loading of a canister due to process or procedural errors. Errors in fabrication and operational processes are primarily due to human factors that are common to the various processes. Surrogate fabrication and operational processes with associated human factor errors have been evaluated in *Analysis of Mechanisms for Early Waste Package/Drip Shield Failure* (SNL 2007 [DIRS 178765]), and results are used for such initiating events such as improper performance of the neutron absorber plates represented as a material selection error in the waste package component fabrication processes (SNL 2007 [DIRS 178765], Section 6.3.2). The mean value of the probability distribution for a fabrication failure is 1.25×10^{-7} per canister (DTN: MO0705EARLYEND.000 [DIRS 180946], file: *Table 1.doc*, Table 1).

Probability of Loading Curve Violation—An analysis of commercial SNF misload probabilities was documented in *Commercial Spent Nuclear Fuels Waste Package Misload Analysis* (BSC 2003 [DIRS 166316]). Results from this analysis establish that the probability of a loading curve violation in a 21-PWR waste package is 1.18×10^{-5} (BSC 2003 [DIRS 166316], Table 41). The TAD canister specifications require the canisters for PWR SNF to contain 21 assemblies similar to the 21-PWR waste package (SNL 2007 [DIRS 179394], Section 4.1.1.2). The cited analysis is used as a surrogate for misloading waste forms in a TAD canister since the misloading of an assembly into a TAD canister requires the same improper selection of an assembly with characteristics (burnup and enrichment) in the unacceptable range of the loading curve. Thus, the probability of a loading curve violation for TAD canisters is expected to be similar in magnitude to the 21-PWR waste package value. However, neighboring assemblies that have low reactivity values may provide partial compensation for the excess reactivity from the incorrectly loaded assembly. Given that a misloading curve violation occurs, the likelihood of the misloaded configuration having potential for criticality has been shown to be 0.014 from results of a probabilistic calculation of that potential (SNL 2008 [DIRS 182788], Section 7). The probability of a potentially critical configuration resulting from an assembly misload of a 21-PWR TAD canister is $0.014 \times 1.18 \times 10^{-5} = 1.65 \times 10^{-7}$ per TAD canister.

The probability of misloading assemblies in the 44-BWR TAD canister is insignificant since the entire expected BWR inventory for the repository is in the acceptable region of the loading curve map (SNL 2008 [DIRS 182788], Section 6.1.1.1.3). Misloading of waste forms in DOE SNF canisters is considered very improbable because the shape and size of the defense HLW glass canisters and the various DOE SNF canisters differ significantly and can be readily distinguished by visual inspection. Thus, the waste form misload probability for DOE SNF waste packages is considered to be sufficiently low such that, if quantified, would not significantly increase the overall probability of criticality in the repository.

Probability of drip shield failure—Significant rockfall onto and around the drip shields resulting in drip shield rupture is unlikely to occur (probability of 1.8×10^{-4} for PWR SNF repository

wide for 10,000 years in the lithophysal unit) (DTN: MO0712PBANLNWP.000 [DIRS 184664]). The likelihood of such damage in the lithophysal and nonlithophysal zones is discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Sections 6.8.2.2 and 6.10.2). The probability of the waste package OCB failing during the 10,000-year period following repository closure, given conditions for localized corrosion (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)), has been evaluated for both geologic units in DTNs: MO0712PANLNNWP.000 [DIRS 184480] and MO0712PBANLNWP.000 [DIRS 184664]. The combined probabilities associated with the events that would be necessary for criticality to be possible are presented in Table 2.1.14.19.0A-4. These probabilities are based on the TSPA localized corrosion model combined with seismic information for rockfall and drip shield fragility curves in conjunction with the probability of absorber misload and assembly misload for the 21-PWR TAD waste package.

Table 2.1.14.19.0A-4. Probability of Potential Criticality from Waste Package OCB Failure from Localized Corrosion due to Drip Shield Rupture from Rockfall Loading

Criticality Event Sequence	Probability
PWR TAD Canister Loading Curve Violation	5.9×10^{-10}
PWR TAD Canister Absorber Misload	4.4×10^{-10}
BWR TAD Canister Absorber Misload	2.8×10^{-10}
DOE SNF Canister Absorber Misload	2.8×10^{-10}

Source: SNL 2008 [DIRS 173869], Table 6.4-7.

Criticality following a seismic breach—Evaluating the event sequences resulting from breaches that are not fault induced or localized corrosion induced for commercial SNF and DOE SNF using the number of 21-PWR TAD canisters as 4,568, the number of 44-BWR TAD canisters as 2,915, and DOE SNF canisters that require neutron absorber plates (DOE1, DOE2, and DOE7 groups) as 1,223 (SNL 2008 [DIRS 173869], Section 6.4.2) and setting the number of drip shields equal to the number of waste packages gives:

21-PWR TAD canister loading curve violation:

$$2.6 \times 10^{-4} \times \{1-P_B\,(0;\,(1.65 \times 10^{-7}),\,4568)\} = 2.0 \times 10^{-7}$$

21-PWR TAD canister absorber misload:

$$2.6 \times 10^{-4} \times \{1-P_B\,(0;\,(1.25 \times 10^{-7}),\,4568)\} = 1.5 \times 10^{-7}$$

44-BWR TAD canister absorber misload:

$$2.6 \times 10^{-4} \times \{1-P_B\,(0;\,(1.25 \times 10^{-7}),\,2915)\} = 9.5 \times 10^{-8}$$

DOE SNF canister absorber misload (DOE1, DOE2, and DOE7):

$$0.24\,\{1-P_B\,(0;\,(1.25 \times 10^{-7}),\,1223)\} = 3.7 \times 10^{-5}$$

Thus, a conservative estimate for the probability of achieving a configuration with criticality potential in the repository resulting from seismic vibratory induced impact damage, assuming a damage threshold at the 90% RST level, with subsequent SCC breaching of the waste package

OCB for commercial SNF and DOE SNF, based on summing this set of events, including the DOE1, DOE2, and DOE7 contributions, is 3.7×10^{-5} for 10,000 years. In actuality, the number of DOE waste packages that have sufficient criticality potential to require absorber plate criticality control is much less than 1,223 packages. Therefore, an example estimate using only the DOE2 contribution (89 waste packages), is 3.1×10^{-6} for 10,000 years. These results have been developed on a very conservative basis (e.g., use of damage probabilities at the 90% RST level and a maximum of five intervals to represent the seismic hazard curve). The probabilities evaluated from complete event sequences are expected to be significantly lower than from using a truncated sequence of events to estimate the probability of achieving a configuration with potential for criticality. For example, using a maximum of 35 intervals in the hazard curve for estimating the probability of impact damage to codisposal waste packages reduced the estimated probability of vibratory impact damage to the codisposal waste packages by approximately 20% (DTN: MO0705CRITPROB.000 [DIRS 184958], file: *CSNF TAD & CDSP WP Impact damage.xls*).

Seismic Faulting

Results from analyses of waste package damage due to fault displacement during a seismic event are documented in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.11.7) and FEP. The information for the criticality analysis is consistent with the methodology for the damage abstraction for fault displacement in the TSPA, but represents a finer level of detail. The finer level of detail is based on the damage abstraction for the TSPA being based on two waste package groups: the TAD canister group and the codisposal group. While this grouping is consistent with the representation of waste package groups in the TSPA, criticality studies require a more detailed analysis of waste package failures by individual waste package type. The calculations for the criticality analysis are given in *Fault Displacement Abstraction for Criticality.xls* derived from DTN: MO0705FAULTABS.000 [DIRS 183150]) updated to the waste package inventory from *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869], Table 4.1-2).

Events considered in the seismic faulting scenario requiring probability values for the calculation are listed as follows:

1. Probability of a seismic faulting event over an exceedance range where sufficient displacement can shear waste packages

2. Number of failed waste packages for a seismic faulting event

3. Probability of improper absorber material in a TAD or DOE SNF canister

4. Probability of a loading curve violation for a 21-PWR TAD canister.

Fractional lengths of the various waste package types in the inventory, which are used to determine the expected number of waste package failures from faulting, are listed in Table 2.1.14.19.0A-5. Table 2.1.14.19.0A-6 provides the expected number of waste packages by type that are emplaced on each fault. Tables 2.1.14.19.0A-7 and 2.1.14.19.0A-8 show the result of combining the exceedance frequencies that cause failure and the number of packages

emplaced on faults in Table 2.1.14.19.0A-6 to determine the cumulative number of waste packages expected to fail by type as a function of annual exceedance frequency.

Table 2.1.14.19.0A-5. Fractional Length per Waste Package Variant

Waste Package Type	Nominal Quantity	Total Length of Waste Package Type (mm)	Fraction of Waste Packages (% of Total Length)
CSNF TAD Canister	7,483	4.378×10^7	74.7
CDSP Short	1,600	5.196×10^6	10.1
CDSP Long	1,474	7.818×10^6	13.3
CDSP MCO	210	1.109×10^6	1.9

1.0×10^{-8} to 1.3×10^{-8}	21.6	28.5		

Source: DTN: MO0705CRITPROB.000 [DIRS 184958], file: *Fault Displacement Abstraction for Criticality Updated DTN 10-25-07.xls*, worksheet: "Tables by WP Type," rows 189 to 198.

For seismic events with an annual exceedance frequency greater than 1.2×10^{-7} per year (i.e., less severe earthquakes), no waste package damage is expected to occur due to faulting as shown in Tables 2.1.14.19.0A-7 and 2.1.14.19.0A-8. For seismic events with an annual exceedance frequency less than 1.2×10^{-7} per year (i.e., more severe earthquakes), waste package failure from seismically induced faulting is initiated. The number of failed waste packages increases with increasing seismic energy (decreasing annual exceedance frequency) to a maximum number that depends on waste package variant as shown in Tables 7 and 8. The annual exceedance frequency range for the commercial SNF TAD canister and codisposal waste packages is subdivided into three or four ranges for this analysis, depending on the waste package variant as shown in the column labeled "Exceedance Frequency Range" in Tables 2.1.14.19.0A-7 and 2.1.14.19.0A-8 for each waste package variant. The probabilities of these basic events are determined with Equation 2.1.14.19.0A-1 and the information provided in Table 2.1.14.19.0A-9.

Table 2.1.14.19.0A-9. Probabilities of Seismic Faulting Events with Waste Package Failure Capability

PGV Value (m/s)	λ_1 (events/year)	λ_2 (events/year)	t_1 (years)	t_2 (years)	Probability
Commercial SNF TAD Waste Package Variant					
4.07 to 3.77	1.0×10^{-8}	2.7×10^{-8}	10,000	0	1.7×10^{-4}
3.77 to 3.41	2.7×10^{-8}	7.0×10^{-8}	10,000	0	4.3×10^{-4}
3.41 to 3.34	7.0×10^{-8}	8.2×10^{-8}	10,000	0	1.2×10^{-4}
Codisposal Waste Package Variant					
4.07 to 4.00	1.0×10^{-8}	1.3×10^{-8}	10,000	0	3.0×10^{-5}
4.00 to 3.62	1.3×10^{-8}	4.1×10^{-8}	10,000	0	2.8×10^{-4}
3.62 to 3.21	4.1×10^{-8}	1.1×10^{-7}	10,000	0	6.9×10^{-4}
3.21 to 3.18	1.1×10^{-7}	1.2×10^{-7}	10,000	0	1.0×10^{-4}

Source: DTN: MO0705CRITPROB.000 [DIRS 184958], file: *Fault Displacement Abstraction for Criticality Updated DTN 10-25-07.xls*, worksheet: "Tables by WP Type," rows 203 to 209.

The mean probability of a seismic faulting event is a point value derived from the probability of a seismic event with faulting as given in Table 2.1.14.19.0A-9 multiplied by the incremental number of waste packages with criticality potential being impacted within each frequency range given in Tables 2.1.14.19.0A-7 and 2.1.14.19.0A-8.

The probabilities of the remaining events in this scenario were discussed above and resulted in the following: The probability of installing improper absorber plate material in a TAD canister is 1.25×10^{-7} per canister, and the probability of a potentially critical configuration resulting from an assembly misload of a 21-PWR TAD canister is 1.65×10^{-7} per TAD canister.

Evaluating the event sequences for commercial SNF and DOE SNF using the fractions of 21-PWR TAD canisters (4,568/7,483), 44-BWR TAD canisters (2,915/7,483), and DOE SNF canisters that require neutron absorber plates (DOE1, DOE2, and DOE7 groups) (1,223/3,074) (SNL 2008 [DIRS 173869], Section 6.4.3) gives:

PWR TAD canister loading curve violation:

$1.2 \times 10^{-4} \times (1-P_B (0; 1.65 \times 10^{-7}, (19.4 \times 4568/7483)) + 4.3 \times 10^{-4} \times (1-P_B (0; 1.65 \times 10^{-7}, (27.6 -19.4) \times 4568/7483)) +1.7 \times 10^{-4} \times (1-P_B (0; 1.65 \times 10^{-7}, (32.1 - 27.6) \times 4568/7483)) = 6.3 \times 10^{-10}$

PWR TAD canister absorber misload:

$1.2 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (19.4 \times 4568/7483)) + 4.3 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (27.6 -19.4) \times 4568/7483)) +1.7 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (32.1 - 27.6) \times 4568/7483)) = 4.8 \times 10^{-10}$

44-BWR TAD canister absorber misload:

$1.2 \times 10^{-4} \times (1\ P_B (0; 1.25 \times 10^{-7}, (19.4 \times 2915/7483)) + 4.3 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (27.6 - 19.4) \times 2915/7483)) +1.7 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (32.1 - 27.6) \times 2915/7483)) = 2.9 \times 10^{-10}$

DOE SNF canister absorber misload (DOE1, DOE2, and DOE7):

$1.0 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (2.6+3.5) \times 1223/3074)) + 6.9 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (3.7-2.6 + 4.9-3.5) \times 1223/3074)) + 2.8 \times 10^{-4} \times (1-P_B (0; 1.25 \times 10^{-7}, (4.3-3.7 + 5.7-4.9) \times 1223/3074)) + 3.0 \times 10^{-5} \times (1-P_B (0; 1.25 \times 10^{-7}, (21.6-4.3 + 28.5-5.7) \times 1223/3074)) = 8.1 \times 10^{-11}$

Thus, a conservative estimate for the probability of achieving a configuration with criticality potential in the repository resulting from a seismic faulting initiating event for commercial SNF and DOE SNF is 1.5×10^{-9} for 10,000 years.

Summary—The events in the short sequences are considered as the principal contributors to the probability of occurrence of configurations having criticality potential following a seismic initiating event. Extending the sequences to include additional events would further decrease the probability for the occurrence of configurations with potential for criticality. Summing the probabilities of potential criticality for the in-package location from the seismic vibratory, drip shield rupture inducing localized corrosion, and fault displacement initiating events results in a

probability of criticality of 3.7×10^{-5} over 10,000 years. This is less than 1 chance in 10,000 (1×10^{-4}) of occurrence within 10,000 years of disposal. Accordingly, FEP 2.1.14.19.0A (In-Package Criticality Resulting from a Seismic Event (Degraded Configurations) is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869], Section 7.1), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.1.14.20.0A

FEP NAME:

Near-Field Criticality Resulting from a Seismic Event

FEP DESCRIPTION:

Either during or as a result of a seismic disruptive event, near-field criticality could occur if fissile material-bearing solution from the waste package is transported into the drift and the fissile material is precipitated into a critical configuration. Potential near-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3a).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the near-field location for the seismic scenario, where *near-field* is defined as the region inside the drift external to the waste package. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Near-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the near-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated. It then follows that the probability of near-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the near-field environment.

If a waste package is breached, water and solutes might enter and leave the waste package by several mechanisms, including diffusion, condensation of vapor, and advection of liquid water. Leakage through a crack-damaged drip shield is an insignificant source for liquid water penetration through cracks in the underlying waste package especially when compared to the threshold flow rate (0.1 kg/yr) used in TSPA to define whether seepage occurs (excluded FEP 2.1.03.10.0 (Advection of Liquids and Solids through Cracks in the Waste Package)). Therefore, the predominant mechanism for water inflow and outflow through a breached waste package is through diffusive transport unless the drip shield has failed. *Geochemistry Model Validation Report: Material Degradation and Release Model* (SNL 2007 [DIRS 181165], Section 6.2) indicated that the quantity of material released by diffusion would be small due to the tortuosity of the path, and therefore the diffusion-only scenario is not considered a viable method for material transport. Thus, advective flow of water is necessary for transporting fissile materials from the waste package to the near-field in any appreciable quantities to be considered for criticality.

Vibratory ground motion (included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components)), faulting (included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components)), seismic induced drift collapse in the lithophysal units (included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components)), and seismic induced rockfall (excluded FEP 1.2.03.02.0B (Seismic Induced Rockfall Damages EBS Components)) are potential initiating events that are capable of creating advective flow paths into the waste package. Such failures may allow the influx of water (either advective or diffusive) into the waste package, which, in turn, has the potential to initiate processes leading to degradation and transport of the fissile material to the near-field location.

Note that excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) has been screened from performance assessment on the basis of low consequence, which is not directly applicable to criticality potential evaluations. FEP 1.2.03.02.0B indicates that seismic-induced damage to the waste packages and its internals from rock block impacts in nonlithophysal units is screened out from the TSPA model on the basis of low probability. However, FEP 1.2.03.02.0B screens out tearing or rupture of the drip shield plates from large

block impacts because of low consequence, which is not directly applicable to criticality potential evaluations. Drip shield failure could result in an advective flow path to the waste package OCB, creating an environment for subsequent localized corrosion processes (included FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)) that could breach the waste package OCB.

The probability of drip shield and waste package failure from a fault event varies with the magnitude of the earthquake but ranges from 1.2×10^{-4} to 4.3×10^{-4} for the commercial SNF waste packages and from 3.0×10^{-5} to 6.9×10^{-4} for the codisposal waste packages (SNL 2008 [DIRS 173869], Table 6.4-7).

There are several hundred distinct types of DOE SNF, and it is not practical to attempt to determine the impact of each individual type on repository performance. These fuels come from a wide range of reactor types, such as light- and heavy-water-moderated reactors, graphite-moderated reactors, and breeder reactors, with various cladding materials and enrichments, varying from depleted uranium to over 93% enriched ^{235}U. Many of these reactors, now decommissioned, had unique design features, such as core configuration, fuel element and assembly geometry, moderator and coolant materials, operational characteristics, and neutron spatial and spectral properties (DOE 2004 [DIRS 171271]).

Therefore, to facilitate DOE SNF waste form evaluations, the DOE SNF inventory was first reduced to 34 DOE SNF groups based on fuel matrix, cladding, cladding condition, and enrichment. These parameters are the fuel characteristics that were determined to have major impacts on the release of radionuclides from the DOE SNF and contributed to nuclear criticality scenarios (DOE 2000 [DIRS 118968], Section 5). Separate groups were further refined for the purposes of criticality, design basis events, and TSPA based on key parameters such as fuel matrix, cladding, and fuel condition, as well as fissile species and enrichment, and reactor and fuel design (DOE 2000 [DIRS 118968], Section 5.1). For criticality, nine DOE SNF criticality groups have been identified and are listed in *General Description of Database Information Version 5.0.1* (DOE 2007 [DIRS 182577], Table 6).

Within each of the nine DOE SNF criticality groups, a single fuel design was selected as being representative of the remaining fuel within each group. The term representative means that all fuels would perform similarly regarding chemical interactions within the waste package and basket, and that canister loading limits from the representative fuel (ranges of key parameters important to criticality such as linear fissile loading and total fissile mass) are established, which other fuels within the group can be shown to not exceed. Waste forms within a single criticality group that have configurations or key criticality parameters outside the range of applicability of the representative fuel will require supplemental analysis and/or additional reactivity control mechanisms.

Evaluations for naval fuel are conducted by the Naval Nuclear Propulsion Program. A miscellaneous waste form category, which has a variety of fuel matrix properties originating from various post-irradiation examinations and other testing are not included in the criticality evaluations for the fuel groups as they will need to be evaluated on a case-by-case basis. Thus, the disposal criticality analysis methodology (YMP 2003 [DIRS 165505]) can be applied to nine DOE SNF representative fuel groups for criticality evaluations.

The minimum fissile mass necessary for criticality external to the waste packages is discussed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], Section 8.1.4[a]), where it was concluded that insufficient fissile material can collect over 10,000 years to achieve a critical mass for the seismic scenario, where a critical mass is defined as one where k_{eff} (effective neutron multiplication factor) exceeds the critical limit for the material. Note that the material degradation of the internals and subsequent accumulation in the near-field based on the seismic scenario are bounding for localized corrosion because the seismic seepage flux is based on the entire waste package footprint area collecting seeps, whereas localized corrosion seeps would only be a fraction of the total area with a reduced seepage flux. In addition, these values are predicated on having an initiating event (i.e., seismic fault displacement rupturing the drip shield and waste package), which is an unlikely event (1.2×10^{-8} per year). The critical mass limits were evaluated for commercial SNF and DOE SNF waste forms using bounding parameters with regard to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would most likely need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]).

Model abstractions were performed for commercial SNF and three DOE SNF waste forms in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]) (i.e., N Reactor (DOE3), Three-Mile Island (DOE9), and FFTF (DOE1)) (SNL 2008 [DIRS 173869], Section 4.1.15), which make up approximately 90% of the metric tons of heavy metal in the DOE SNF inventory expected to be stored in the repository. In addition to these waste forms making up ~90% of the inventory by mass, they were selected because they provide degradation and accumulation characteristics of uranium-metal (N Reactor), mixed-oxide (FFTF), and damaged uranium dioxide (Three-Mile Island) waste forms that may be applicable to other representative DOE waste forms. Some of the other DOE SNF waste forms, such as Shippingport light-water breeder reactor (LWBR) (DOE5) and Ft. St. Vrain (DOE6), are not expected to be a concern for external criticality due to the corrosion resistance of the waste form (SNL 2007 [DIRS 181395], Section 6.9.3[a]).

Ft. St. Vrain fuels (DOE6) have an integral silicon carbide (SiC) protective layer that not only retains the fission products, but also protects the uranium and thorium dicarbide (ThC_2) from oxidation and hydrolysis (DOE 2003 [DIRS 166027], p. 48). Comparative analysis has indicated that the Ft. St. Vrain fuel has the lowest degradation rate of all DOE SNF and should behave significantly better in terms of fissile material dissolution, transport, and accumulation. In some residual quantities (< 250 grams per block), ^{233}U bred into the ThC_2 fertile particles. A canister loaded with five Ft. St. Vrain blocks contains sufficient quantities of ^{233}U to have criticality potential in solution; however, a mechanism to separate the uranium from within the SiC-coated fertile particles, and then a mechanism to accumulate in a concentrated fissile mass in a favorable geometry, is not credible.

For Shippingport LWBR fuel (DOE5), studies have indicated that both air and water oxidation of uranium and thorium oxide fuel pellets [$(Th, U)O_2$] proceed more slowly than in pure uranium oxide (UO_2), and decrease with decreasing UO_2 content in the $(Th, U)O_2$ (DOE 2003 [DIRS 166027], p. 33). Tests have shown that the thorium oxide pellets in the Shippingport LWBR fuel have excellent corrosion resistance with an estimated solubility of 10^{-14} mol/L at 25°C and pH > 5 (DOE 2003 [DIRS 166027], p. 32). With the less-reactive degradation rate, a

mechanism to separate the uranium, transporting, and accumulation into a favorable geometry is also not credible.

Table 2.1.14.20.0A-1 shows the ranges of minimum critical mass required to accumulate in the invert to achieve a critical limit of k_{eff} (effective neutron multiplication factor) equal to 0.96. Also shown is the calculated accumulation or mass released from the waste package for the waste forms evaluated for external criticality. For each of the waste forms evaluated, the results indicate that an insufficient amount of fissile material accumulates to pose a criticality concern.

Table 2.1.14.20.0A-1. Summary of Seismic Scenario External Criticality Results

Scenario	Waste Package Type	Calculated Accumulation or Mass Released from Waste Package (Uranium mass, unless otherwise noted (kg))	Mass of Uranium or Plutonium (for FFTF) Required to Achieve Critical Limit of k_{eff} = 0.96 in the Invert (kg)
Seismic	DOE3 (N Reactor)	Not calc[a]	266,000
	DOE9 (TMI II Fuel)	Not calc[a]	350
	Commercial SNF	90.3	126
	DOE1 (FFTF) (Plutonium mass)	0	1.66

[a] "Not calc" means that this scenario is bounded by another scenario. In most cases, this means that if commercial SNF waste is very subcritical, then Three-Mile Island and N Reactor had to be also.

Source: SNL 2007 [DIRS 181395], Table 6.9-1[a].

DOE fuel groups in DOE2, DOE4, DOE7, and DOE8 representing UZrHx (TRIGA), high enriched uranium oxide (Shippingport PWR), aluminum-based (ATR), and U-Zr/U-Mo alloy (Fermi), respectively (SNL 2008 [DIRS 173869], Table 4.1-2), have not been analyzed in detail for external fissile mass transport and accumulation as the other waste forms have. However, considering the processes that must occur to allow advective seepage into a DOE SNF canister without substantial drainage to allow degradation of the internal components and waste form, along with the other conservative modeling parameters that have been used to create a process to facilitate fissile material transport to the external environment, and the bounding modeling parameters respective to maximizing criticality potential, these waste forms are not expected to result in an increase in the total probability of criticality in the near-field location.

Some of the conservative modeling parameters are provided as follows:

- The material degradation and release model (SNL 2007 [DIRS 181165]) uses constant corrosion rates for the SNF; however, laboratory experiments on the surface structure of commercial SNF during dissolution have shown that UO_2 dissolution is accompanied by the formation of a protective layer of secondary phases that retards further corrosion (SNL 2007 [DIRS 181165], Section 6.6.2). Therefore, the release of uranium from the fuel would be slower and therefore less would be released.

- Experimental and field data indicate that actinides would be adsorbed on or incorporated into alteration products that form in the waste package (SNL 2007 [DIRS 181165], Section 6.6.3). This solid solution formation and adsorption would tend to lower

actinide concentrations below those predicted by EQ6 and would delay release from the waste package.

- The material degradation and release model (SNL 2007 [DIRS 181165]) considers the cladding and DOE SNF canister as breached upon emplacement in the repository, and unzipping immediately upon waste package breach, whereas a more likely scenario would be that the failure would take place over many years. This would also delay the release of actinides.

- Many conservative modeling approximations are used to simplify the critical mass calculations presented in Table 2.1.14.20.0A-1. For the commercial SNF and low-enriched DOE fuels analyzed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]), the conservatisms are appropriate, because the results show that a criticality is very unlikely. However, for the higher enriched DOE fuels, less conservative (increased detail) modeling parameters of the criticality potential are expected to generate similar conclusions.

Summary – The critical mass limits were evaluated for several waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would most likely need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]). Model abstractions were performed for commercial SNF and three DOE SNF waste forms and resulted in insufficient fissile material accumulation in the near-field location to pose a criticality concern. Therefore, based on the analyzed waste forms representing the majority (>95% of the total metric tons) of the waste for disposal in the repository, and considering the conservative modeling parameters discussed above that would be further developed for other DOE representative fuel groups, in conjunction with the order of magnitude of the probability of a seismic faulting event causing waste package failure, the probability of near-field criticality is considered insignificant. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.1.14.21.0A

FEP NAME:

In-Package Criticality Resulting from Rockfall (Intact Configuration)

FEP DESCRIPTION:

The waste package internal structures and the waste form remain intact either during or after a rockfall event. If there is a breach (or are breaches) in the waste package that allow(s) water to either accumulate or flow through the waste package, then criticality could occur in-situ.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality resulting from a rockfall event. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the waste package. Excluded FEP 2.1.07.01.0A (Rockfall) indicates that rockfall related to non-seismic processes such as drift degradation induced by in situ gravitational and excavation-induced stresses as well as thermally induced stresses do not generate rock block sizes sufficient to tear or rupture the drip shield plates. Drip shield damage from rockfall induced by thermal loading is found to be minor since the block sizes for such rockfall are small with a mean mass of less than 0.2 MT (BSC 2004 [DIRS 166107], p. 6-102). In addition, drift degradation (i.e., considering thermal and time-dependent effects on drift collapse, but excluding seismic effects) results in only partial collapse of the emplacement drifts at 20,000 years (see excluded FEP 2.1.07.02.0A (Drift Collapse)). The conclusion for the nominal scenario is that negligible drift degradation will occur over the initial 10,000-year postclosure period (BSC 2004 [DIRS 166107], Section 8.1 and Appendix S). Therefore, rockfall does not result in waste package outer barrier breaching. Without a waste package breach, there is no potential for in-package criticality.

Summary—Since the drip shield continues to function through rockfall events as described above, the waste package will be protected from advective water flow paths during the postclosure period, for as long as the drip shield remains intact. The probability of the occurrence of configurations with criticality potential for the in-package location resulting from rockfall is insignificant since no damage to the waste package OCBs is expected from the non-seismically initiated rockfall events. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability. This result is applicable for all waste forms and waste package variants.

FEP: 2.1.14.22.0A

FEP NAME:

In-Package Criticality Resulting from Rockfall (Degraded Configurations)

FEP DESCRIPTION:

Either during or as a result of a rockfall event, the waste package internal structures and the waste form may degrade. If a critical configuration develops, criticality could occur in situ. Potential in situ critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figures 3.2a and 3.2b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality resulting from a rockfall event. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the waste package. Excluded FEP 2.1.07.01.0A (Rockfall) indicates that rockfall related to nonseismic processes such as drift degradation induced by in situ gravitational and excavation-induced stresses as well as thermally induced stresses do not generate rock block sizes sufficient to tear or rupture the drip shield plates. Drip shield damage from rockfall induced by thermal loading is found to be minor as the block sizes for such rockfall are small with a mean mass of less than 0.2 MT (BSC 2004 [DIRS 166107], p. 6-102). In addition, drift degradation (i.e., considering thermal and time-dependent effects on drift collapse, but excluding seismic effects) results in only partial collapse of the emplacement drifts at 20,000 years (see excluded FEP 2.1.07.02.0A (Drift Collapse)). The conclusion for the nominal scenario is that negligible drift degradation will occur over the initial 10,000-year postclosure period (BSC 2004 [DIRS 166107], Section 8.1 and Appendix S). Therefore, rockfall does not result in waste package outer barrier breaching. Without a waste package breach, there is no potential for in-package criticality.

FEP: 2.1.14.23.0A

FEP NAME:

Near-Field Criticality Resulting from Rockfall

FEP DESCRIPTION:

Either during or as a result of a rockfall event, near-field criticality could occur if fissile material-bearing solution from the waste package is transported into the drift and the fissile material is precipitated into a critical configuration. Potential near-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3a).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the near-field location resulting from rockfall, where *near-field* is defined as the region inside the drift external to the waste package. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Near-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the near-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in a favorable geometry. It then follows that the probability of near-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the near-field environment.

Excluded FEP 2.1.07.01.0A (Rockfall) indicates that rockfall related to nonseismic processes such as drift degradation induced by in situ gravitational and excavation-induced stresses as well as thermally induced stresses don't generate rock block sizes sufficient to tear or rupture the drip shield plates. Drip shield damage from rockfall induced by thermal loading is found to be minor since the block sizes for such rockfall are small with a mean mass of less than 0.2 metric tons (BSC 2004 [DIRS 166107], p. 6-102). In addition, drift degradation (i.e., considering thermal and time-dependent effects on drift collapse, but excluding seismic effects) results in only partial collapse of the emplacement drifts at 20,000 years (see excluded FEP 2.1.07.02.0A (Drift Collapse)). The conclusion for the nominal scenario is that negligible drift degradation will occur over the initial 10,000-year postclosure period (BSC 2004 [DIRS 166107], Section 8.1 and Appendix S).

A waste package must be breached in order to transport fissile material out. If a waste package is breached, water and solutes might enter and leave the waste package by several mechanisms, including diffusion, condensation of vapor, and advection of liquid water. Therefore, rockfall does not result in waste package outer barrier breaching. Without a waste package breach, there is no potential for external criticality.

Summary - Since the drip shield continues to function through rockfall events as described above, there is no advective flow of water to the waste package for as long as the drip shield remains intact. Therefore, there is no means to transport fissile material to the near field by precluding the introduction of water to the waste package, which is necessary to degrade the internals and transport material into the near-field location. The probability of the occurrence of configurations with criticality potential for the near-field location resulting from rockfall is insignificant since no damage to the waste package OCBs is expected from the non-seismically initiated rockfall events. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability. This result is applicable for all waste forms and waste package variants.

FEP: 2.1.14.24.0A

FEP NAME:

In-Package Criticality Resulting from an Igneous Event (Intact Configuration)

FEP DESCRIPTION:

The waste package internal structures and the waste form remain intact either during or after an igneous disruptive event. If there is a breach (or are breaches) in the waste package that allow(s) water to either accumulate or flow through the waste package, then criticality could occur in situ.

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality for the igneous scenario. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) describes an event where an igneous basaltic dike (magma-filled crack) intersects one or more repository drifts, followed by the intrusion of effusive (liquid) magma flow or pyroclastic flow (clots of melt in a stream of gas) into the drifts. The temperature of the waste package, the canister internals, and the SNF will heat up to near-magma temperatures in days to weeks (SNL 2007 [DIRS 177430], Figure 6-94) exceeding 700°C for one to nineteen months, depending on the temperature of the

magma and the decay heat generated by the waste (SNL 2007 [DIRS 177430], Section 6.4.6). At these high waste package temperatures, the fuel and the materials surrounding the fuel (i.e., cladding and structural materials) may be affected. Iron-zirconium and nickel-zirconium liquid eutectics are expected to form (starting at approximately 948°C (ASM International 1996 [DIRS 181641], iron-zirconium and nickel-zirconium phase diagrams)) but are not expected to provide any mechanisms causing appreciable removal of the neutron-absorber materials from their general locale in relation to the waste form since the eutectic is expected to contain both the absorber and waste form materials. In addition, thermal creep of the internal components resulting in internal slumping is also expected. In summary, it is expected that an igneous intrusion would sufficiently compromise the integrity of the waste packages, drip shields, and cladding in affected emplacement drifts to make them ineffective (i.e., a total loss of function in isolating waste packages and waste forms from seepage water when it returns after drifts have cooled), which is also indicated in *Dike/Drift Interactions* (SNL 2007 [DIRS 177430], Section 6.4.8.3). The damage is expected to be ubiquitous. Thus, it is improbable that a bathtub configuration (forming a closed-bottom container necessary for pooling) can be maintained or even created in a post-igneous intrusion environment.

During an igneous disruptive event, water, silica, and carbon are the only potential moderating materials for internal and external configurations. Carbon is not present within the magma composition, and the amount of silicon necessary to act as a moderator combined with its relatively low moderating effectiveness is insufficient to support criticality for low enriched systems. The physical and chemical environment around the waste package and waste form materials in contact with active magma will include abundant steam and other potentially corrosive or reactive volatiles (SNL 2007 [DIRS 177430], Section 6.4.8.3) where the estimated water content of potential magmas at Yucca Mountain ranges from 1.0 to 5.0 wt % with a uniform probability (DTN: LA0612DK831811.001 [DIRS 179987], file: *LA0612DK831811_001.xls*, worksheet: "EPAR_TPO-13Jan07"). As stated previously, temperatures could be in the range of $700 < T\ (°C) < 1{,}200$ for several months. The vapor pressures can be on the order of 7 MPa, giving a vapor density approximately double the density at atmospheric pressure. Thus, the water density during the igneous event will be too low to moderate the neutrons sufficiently to result in a criticality event for low enriched systems. In addition, the waste package internals are designed to preclude criticality when fully flooded with full density water. This fact, coupled with the fact that as fuel temperatures increase, the resonance absorption increases, which causes low enriched systems to decrease in reactivity, indicates that a criticality event during the igneous event is very improbable (i.e., physical conditions necessary are not present to support criticality). Therefore, the probability of sufficient moderating material to support criticality during an igneous event is considered to be sufficiently low such that, if quantified, would not significantly increase the overall probability of criticality in the repository.

The technical basis for inclusion of igneous intrusion into the repository in the TSPA is founded on the results of the probabilistic volcanic hazard analysis CRWMS M&O 1996 [DIRS 100116]) described in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1), which indicates that the computed mean annual frequency of intersection of the repository footprint by a dike is 1.7×10^{-8}. The computed 5th

and 95th percentiles of the uncertainty distribution for frequency of intersection are 7.4×10^{-10} and 5.5×10^{-8}, respectively.

This FEP is for the in-package location with intact configuration, which considers events such as canister and waste package OCB fabrication errors, neutron absorber misloads, and waste form misloads for configurations without degradation to evaluate those events for criticality potential. Each of these probabilities is less than 1 and some much less than 1 as identified in excluded FEP 2.1.14.15.0A (In-package Criticality (Intact Configuration)). Waste packages impacted by an igneous event are not expected to retain an intact internal configuration. In the unlikely event that it does, the intact configuration is designed to remain subcritical when fully flooded (SNL 2008 [DIRS 182788], Section 7; Radulescu et al. 2004 [DIRS 165482]; BSC 2004 [DIRS 168935], Section 6; BSC 2004 [DIRS 171926], Section 6). In addition, all packages shipped for disposal will have been required to meet the transportation requirements of 10 CFR 71.55 [DIRS 181967] in order to be shipped, which requires a demonstration that the fully flooded configuration remains subcritical. Although configurations not conforming to design specifications are applicable to both intact and degraded scenarios, these nonconformances would be based on probabilites associated with human reliability failures that occur during preclosure activities, making them independent of the postclosure period.

Considering that the igneous intrusive initiating event has a mean annual frequency of 1.7×10^{-8} (or a probability of 1.7×10^{-4} over 10,000 years), and the reasonable assurance implied by compliance with other NRC regulations and quality assurance programs (e.g., 10 CFR Parts 71 [DIRS 181967] and 72 [DIRS 181968], and 10 CFR Part 63 [DIRS 180319]), additional probability values associated with not meeting the design specifications because of human reliability failures would all be much less than 1 and result in a monotonically decreasing value of the overall probability for the igneous event sequence. Therefore, the resultant probability of criticality in the in-package location with intact configuration resulting from a disruptive igneous event is considered to be sufficiently low (below 1 chance in 10,000 (10^{-4}) of occurrence within 10,000 years of disposal) such that, if evaluated, would not change the conclusion, based on low probability, that a criticality event in the repository can be screened from further consideration in analyses for all waste forms. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 2.1.14.25.0A

FEP NAME:

In-Package Criticality Resulting from an Igneous Event (Degraded Configurations)

FEP DESCRIPTION:

Either during or as a result of an igneous disruptive event, the waste package internal structures and the waste form may degrade. If a critical configuration develops, criticality could occur in situ. Potential in situ critical configurations are defined in Disposal Criticality Analysis Methodology Topical Report (YMP 2003 [DIRS 165505], Figures 3.2a and 3.2b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for in-package criticality for the igneous scenario. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935], Section 6), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926], Section 6).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) describes an event where an igneous basaltic dike (magma-filled crack) intersects one or more repository drifts, followed by the intrusion of effusive (liquid) magma flow or pyroclastic flow (clots of melt in a stream of gas) into the drifts. The temperature of the waste package, the canister internals, and the SNF will heat up to near-magma temperatures in days to weeks (SNL 2007 [DIRS 177430],

Figure 6-94), exceeding 700°C for one to nineteen months, depending on the temperature of the magma and the decay heat generated by the waste (SNL 2007 [DIRS 177430], Section 6.4.6). At these high waste package temperatures, the fuel and the materials surrounding the fuel (i.e., cladding and structural materials) may be affected. Iron-zirconium and nickel-zirconium liquid eutectics are expected to form (starting at approximately 948°C (ASM International 1996 [DIRS 181641], iron-zirconium and nickel-zirconium phase diagrams)) but are not expected to provide any mechanisms causing appreciable removal of the neutron-absorber materials from their general locale in relation to the waste form since the eutectic is expected to contain both the absorber and waste form materials. In addition, thermal creep of the internal components resulting in internal slumping is also expected. In summary, it is expected that an igneous intrusion would sufficiently compromise the integrity of the waste packages, drip shields, and cladding in affected emplacement drifts to make them ineffective (i.e., a total loss of function in isolating waste packages and waste forms from seepage water when it returns after drifts have cooled), which is also indicated in *Dike/Drift Interactions* (SNL 2007 [DIRS 177430], Section 6.4.8.3). The damage is expected to be ubiquitous. Thus, it is improbable that a bathtub configuration (forming a closed-bottom container necessary for pooling) can be maintained or even created in a post-igneous intrusion environment.

During an igneous disruptive event, water, silica, and carbon are the only potential moderating materials for internal and external configurations. Carbon is not present within the magma composition, and the amount of silicon necessary to act as a moderator combined with its relatively low moderating effectiveness is insufficient to support criticality for low enriched systems. The physical and chemical environment around the waste package and waste form materials in contact with active magma will include abundant steam and other potentially corrosive or reactive volatiles (SNL 2007 [DIRS 177430], Section 6.4.8.3) where the estimated water content of potential magmas at Yucca Mountain ranges from 1.0 wt % to 5.0 wt % with a uniform probability (DTN: LA0612DK831811.001 [DIRS 179987], file: *LA0612DK831811_001.xls*, worksheet: "EPAR_TPO-13Jan07"). As stated previously, temperatures could be in the range of $700 < T\ (°C) < 1{,}200$ for several months. The vapor pressures can be on the order of 7 MPa, giving a vapor density approximately double the density at atmospheric pressure. Thus, the water density during the igneous event will be too low to moderate the neutrons sufficiently to result in a criticality event for low enriched systems. In addition, the waste package internals are designed to preclude criticality when fully flooded with full density water. This fact, coupled with the fact that as fuel temperatures increase, the resonance absorption increases, which causes low enriched systems to decrease in reactivity, indicates that a criticality event during the igneous event is very improbable (i.e., physical conditions necessary are not present to support criticality). Therefore, the probability of sufficient moderating material to support criticality during an igneous event has been considered to be sufficiently low such that, if quantified, would not significantly increase the overall probability of criticality in the repository.

The technical basis for inclusion of igneous intrusion into the repository in the TSPA is founded on the results of the probabilistic volcanic hazard analysis (CRWMS M&O 1996 [DIRS 100116]) described in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1), which indicates that the computed mean annual frequency of intersection of the repository footprint by a dike is 1.7×10^{-8}. The computed 5th

and 95th percentiles of the uncertainty distribution for frequency of intersection are 7.4×10^{-10} and 5.5×10^{-8}, respectively.

In addition to the igneous disruptive event itself, additional events that must be considered, for which the probability is less than or equal to one but not necessarily quantifiable, that are necessary for a configuration to have criticality potential in the igneous disruptive scenario are as follows:

- Immediate or delayed waste package damage: The combined effects of plastic deformation, an enhanced corrosive environment, phase transformation, and ordering reactions (e.g., atomic dislocations or slippage), causing embrittlement and increased susceptibility to localized corrosion suggest that the waste packages will fail rather rapidly with respect to the time scale of interest (10,000 years).

- Separation of fissionable material from the neutron absorber material or lack of absorber material: During the igneous intrusive event and immediately following, temperatures will be elevated for a sufficiently long period to induce thermal creep and reconfiguration of the internal components. However, there is no expectation that most of the components or materials in CSNF waste packages will relocate from their locations relative to each other. This is reasonable given that intrusion temperatures do not exceed the melting temperatures of the majority of the waste package (SNL 2007 [DIRS 177430], Section 6.4.8.3) or waste form component materials (melting temperature of UO_2 is approximately 2,600°C (Todreas and Kazimi 1990 [DIRS 107735]), p. 306)), with the exception of the eutectics that are self limiting.

The specific geometry and composition of the numerous intermediate configurations are dependent on the environmental conditions and cannot all be defined individually for analysis. Considering the increased variability in the potential geometric reconfigurations, effects on material performance, and neutron spectrum changes resulting in varied neutron absorber effectiveness, the explicit detailed evaluations would be of limited value considering the high degree of uncertainty associated with any given scenario that may be evaluated. Therefore, the impact of an intrusive igneous event on waste packages and various SNF types has been evaluated for configurations with criticality potential (i.e., presence of fissile material, neutron moderator, lack of neutron absorbers) by considering a representative configuration in lieu of attempting to evaluate a range of specific environmental parameters and configurations, along with an estimate of their probability of occurrence, that could generate a large number of possible event sequences and outcomes. The single representative configuration is considered representative of ones having criticality potential following an initiating intrusive igneous event and provides a basis for demonstrating the additional events and processes that would be required to result in criticality following an intrusive igneous event. A detailed criticality assessment of configurations for the commercial SNF and various DOE SNF waste forms has been performed (SNL 2007 [DIRS 181373]; BSC 2006 [DIRS 181335]), with all configurations shown to be subcritical provided the SNF canisters were fabricated and loaded according to specifications. Although configurations not conforming to design specifications are applicable to both intact and degraded scenarios, these nonconformances would be based on probabilities associated with human reliability failures that occur during preclosure activities, making them independent of the postclosure period.

An evaluation documented in *DOE SNF Material Interaction Potentials during an Intrusive Igneous Event at Yucca Mountain* (Smith and Loo 2007 [DIRS 183392], Section 11) concluded that there was potential for some reconfigurations in most of the nine criticality fuel groups if immersed in magma. Results from the evaluation indicated that there is no obvious mechanism that can lead to liquefaction and reconfiguration of the mixed oxide waste form group. Other waste forms, particularly aluminum based SNF and uranium metal SNF, are expected to exhibit some geometry changes. However, results of criticality analyses for all of the representative DOE SNF waste forms in waste packages affected by an igneous intrusion showed that, for the range of reconfigurations considered, none exceeded the critical limit for the particular waste form (BSC 2006 [DIRS 181335], Section 7.10) provided the SNF canisters were fabricated and loaded according to specifications.

Several of the DOE SNF fuel types incorporate neutron poison that is necessary for criticality control for certain degraded scenarios. The poison is provided by basket material made of a nickel-gadolinium alloy and/or gadolinium-bearing shot composed of iron or aluminum. Temperatures during an igneous intrusive event scenario and immediately following will be sufficiently high such that the DOE aluminum fuels and gadolinium-containing aluminum shot used with certain DOE fuels for criticality control are expected to melt. Thus, these configurations are susceptible to fuel and absorber material reconfiguration by melting and collecting towards the bottom of the DOE SNF canister. Basket structure slumping due to the high temperature environment from the surrounding magma or from the formation of a mass either by melting or eutectic formation is not expected to lead to configurations where the fissile material is concentrated away from the bulk of the neutron absorber in the canisters. Melting or eutectic formation or slumping will always provide some mixing between the fissile materials and the neutron absorber.

Additionally, the commercial SNF fissionable material is not expected to separate significantly from the neutron absorber material in the commercial SNF waste packages. Sensitization of stainless steel and borated stainless steel can occur during heating and cooling, such as would occur from magmatic intrusion. In principle, heating of the stainless steel to magmatic temperatures might cause sensitization and a reduction in corrosion resistance. During sensitization, the chemical composition in the vicinity of the grain boundaries can be altered by the precipitation of chromium-containing carbides, which depletes chromium at the edges of the adjacent alloy grains (typically austenite) and increases potential for intergranular corrosion, since the chromium-depleted regions fail to produce a chromium-oxide passivating layer. Subsequent slow cooling at 500°C to 750°C may desensitize the steel, as chromium diffuses back into the depleted zones. However, the situation at lower temperatures is less clear, as the solubility of the carbide phase decreases. Fox and McCright (1983 [DIRS 159344]) argue that heating in the repository for years, at temperatures of 350°C and below, may cause desensitization, especially in Stainless Steel Type 304 alloys. Stainless Steel Type 304B does not suffer sensitization in the same way that Stainless Steel Type 304L is affected. The metal borides are actually boro-carbides of the form $(Cr,Fe)_2(B,C)$ or $(Cr,Fe)_{23}(B,C)_6$ and effectively soak up most excess carbon. The borides precipitate at rather high temperatures and are stable down to fairly low temperatures, so there is no formation of chromium carbide. For heat-treated Stainless Steel Type 304B, Moreno et al. (2004 [DIRS 179295]) conclude:

> …it is not possible to talk about a common sensitized state as no carbides are found at the grain boundaries.

Regardless of the sensitization effects on the corrosion resistance of the neutron absorber material, most of the boron is expected to remain between the assemblies.

Certain DOE SNF waste forms have sufficient quantities of fissile material to support unmoderated (fast) criticality if the fissile material is concentrated beyond its design concentration in the waste form and the neutron absorber materials are removed. While concentration of the fissile material beyond its nominal design concentration could result from degradation of the waste form by either water infiltration or a disruptive event, removal of the neutron absorber materials from a DOE SNF waste package would require a breach of the waste package and a removal mechanism. Degradation in the presence of water would result in a moderated system. Likewise, there is no known mechanism that could reconfigure nondegraded fissile material into a compact configuration with unmoderated criticality potential. The most likely neutron absorber material removal mechanism is through water infiltration resulting in degradation of the waste package internal components, dissolving of the neutron absorber material in the water, and flushing of the material from the waste package. This mechanism is not expected to result in a critical configuration since the corrosion rate of the neutron absorber material is very low. In addition, the gadolinium absorber in the DOE SNF canisters forms phosphate or carbonate corrosion products (SNL 2007 [DIRS 181165], Section 6.3.16), which have very low solubility.

Considering that the igneous intrusive initiating event has a mean annual frequency of 1.7×10^{-8} (or a probability of 1.7×10^{-4} over 10,000 years), and the reasonable assurance implied by compliance with other NRC regulations and quality assurance programs (e.g., 10 CFR Parts 71 [DIRS 181967] and 72 [DIRS 181968] and 10 CFR Part 63 [DIRS 180319]), additional probability values associated with not meeting the design specifications because of human reliability failures would all be much less than one and result in a monotonically decreasing value of the overall probability for the igneous event sequence (an example of these probabilities is identified in excluded FEP 2.1.14.15.0A (In-package Criticality (Intact Configuration)). Therefore, the resultant probability of criticality in the in-package location with degraded configurations resulting from a disruptive igneous event is considered to be sufficiently low (below 1 chance in 10,000 (10^{-4}) of occurrence within 10,000 years of disposal) such that, if evaluated, would not change the conclusion, based on low probability, that a criticality event in the repository can be screened from further consideration in analyses for all waste forms. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

FEP: 2.1.14.26.0A

FEP NAME:

Near-Field Criticality Resulting from an Igneous Event

FEP DESCRIPTION:

Either during or as a result of an igneous disruptive event, near-field criticality could occur if fissile material-bearing solution from the waste package is transported into the drift and the fissile material is precipitated into a critical configuration. Potential near-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3a).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the near-field location for the igneous scenario, where *near-field* is defined as the region inside the drift external to the waste package. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than one are not quantified, but rather are conservatively set to one.

Near-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the near-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in favorable geometry. It then follows that the probability of near-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form

- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the near-field environment.

Included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) is an event where an igneous basaltic dike (magma-filled crack) intersects one or more repository drifts, followed by the intrusion of effusive (liquid) magma flow or pyroclastic flow (clots of melt in a stream of gas) into the drifts. The temperature of the waste package, the canister internals, and the SNF will heat up to near-magma temperatures in days to weeks (SNL 2007 [DIRS 177430], Figure 6-94), exceeding 700°C for one to nineteen months, depending on the temperature of the magma and the radioactive decay heat generated by the waste (SNL 2007 [DIRS 177430], Section 6.4.6). At these high waste package temperatures, the fuel and the materials surrounding the fuel (i.e., cladding and structural materials) may be affected. Iron-zirconium and nickel-zirconium liquid eutectics will form (starting at approximately 948°C (ASM International 1996 [DIRS 181641], iron-zirconium and nickel-zirconium phase diagrams)), but are not expected to provide any mechanisms causing appreciable removal of the neutron-absorber materials from their general locale in relation to the waste form since the eutectic melt is expected to contain both the absorber and waste form materials. In addition, thermal creep of the internal components resulting in internal slumping is also expected. In summary, it is expected that an igneous intrusion would sufficiently compromise the integrity of the waste packages, drip shields, and cladding in affected emplacement drifts to make them ineffective (i.e., a total loss of function in isolating waste packages and waste forms from seepage water when it returns after drifts have cooled).

The technical basis for inclusion of igneous intrusion into the repository in the TSPA is founded on the results of the PVHA (CRWMS M&O 1996 [DIRS 100116]) described in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1), which indicates that the computed mean annual frequency of intersection of the repository footprint by a dike is 1.7×10^{-8}. The computed 5th and 95th percentiles of the uncertainty distribution for frequency of intersection are 7.4×10^{-10} and 5.5×10^{-8}, respectively.

An igneous intrusion is not expected to increase the criticality potential for the near-field scenario and is expected to reduce the near-field potential since the drift will be filled with magma. In addition, the temperatures in the invert fill supporting the pallets and waste packages will approach or exceed the glass transition temperature for the crushed tuff. This is expected to result in formation of tuff vitrophyre up to 3 m from the contact surface (SNL 2007 [DIRS 174260], Section F.2.2), which would have a significantly reduced void fraction within the invert for fissile material accumulation.

There are several hundred distinct types of DOE SNF. These fuels come from a wide range of reactor types, such as light- and heavy-water-moderated reactors, graphite-moderated reactors, and breeder reactors, with various cladding materials and enrichments, varying from depleted uranium to over 93% enriched ^{235}U. Many of these reactors, now decommissioned, had unique design features, such as core configuration, fuel element and assembly geometry, moderator and coolant materials, operational characteristics, and neutron spatial and spectral properties (DOE 2004 [DIRS 171271]).

Therefore, to facilitate DOE SNF waste form evaluations, the DOE SNF inventory was first reduced to 34 DOE SNF groups based on fuel matrix, cladding, cladding condition, and enrichment. These parameters are the fuel characteristics that were determined to have major impacts on the release of radionuclides from the DOE SNF and contributed to nuclear criticality scenarios (DOE 2000 [DIRS 118968], Section 5). Separate groups were further refined for the purposes of criticality, design basis events, and TSPA based on key parameters such as fuel matrix, cladding, and fuel condition, as well as fissile species and enrichment, and reactor and fuel design (DOE 2000 [DIRS 118968], Section 5.1). For criticality, nine DOE SNF criticality groups have been identified and are listed in *General Description of Database Information Version 5.0.1* (DOE 2007 [DIRS 182577], Table 6).

Within each of the nine DOE SNF criticality groups, a single fuel design was selected as being representative of the remaining fuel within each group. The term representative means that all fuels would perform similarly regarding chemical interactions within the waste package and basket, and that canister loading limits from the representative fuel (ranges of key parameters important to criticality such as linear fissile loading and total fissile mass) are established, which other fuels within the group can be shown to not exceed. Waste forms within a single criticality group that have configurations or key criticality parameters outside the range of applicability of the representative fuel will require supplemental analysis and/or additional reactivity control mechanisms.

Evaluations for naval fuel are conducted by the Naval Nuclear Propulsion Program. A miscellaneous waste form category that has a variety of fuel matrix properties originating from various post-irradiation examinations and other testing is not included in the criticality evaluations for the fuel groups as they will need to be evaluated on a case-by-case basis. Thus, the disposal criticality analysis methodology (YMP 2003 [DIRS 165505]) can be applied to nine DOE SNF representative fuel groups for criticality evaluations.

The minimum fissile mass necessary for criticality external to the waste packages is discussed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], Section 8.1.4[a]), where it was concluded that insufficient fissile material can collect over 10,000 years to achieve a critical mass for the igneous scenario, in which a critical mass is defined as one where k_{eff} (effective neutron multiplication factor) exceeds the critical limit for the material. The critical mass limits were evaluated for commercial SNF and DOE SNF waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]).

Model abstractions were performed for commercial SNF and three DOE SNF waste forms in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]) (i.e., N Reactor (DOE3), TMI (DOE9), and FFTF (DOE1)) (SNL 2008 [DIRS 173869], Section 4.1.15), which make up a ~90% of the metric tons of heavy metal in the DOE SNF inventory expected to be stored in the repository. In addition to these waste forms making up ~90% of the inventory by mass, they were selected because they provide degradation and accumulation characteristics of uranium-metal (N Reactor), mixed-oxide (FFTF), and damaged uranium dioxide (TMI) waste forms which may be applicable to other representative DOE waste forms. Some of the other DOE SNF waste forms, such as Shippingport light-water

breeder reactor (LWBR) (DOE5) and Ft. St. Vrain (DOE6), are not expected to be a concern for external criticality due to the corrosion resistance of the waste form (SNL 2007 [DIRS 181395], Section 6.9.3[a]).

Ft. St. Vrain fuels (DOE6) have an integral silicon carbide (SiC) protective layer that not only retains the fission products but also protects the uranium and thorium dicarbide (ThC_2) from oxidation and hydrolysis (DOE 2003 [DIRS 166027], p. 48). Comparative analysis has indicated that the Ft. St. Vrain fuel has the lowest degradation rate of all DOE SNF and should behave significantly better in terms of fissile material dissolution, transport, and accumulation. In some residual quantities (<250 grams per block), ^{233}U bred into the ThC_2 fertile particles. A canister loaded with five Ft. St. Vrain blocks contains sufficient quantities of ^{233}U to have criticality potential in solution; however, a mechanism to separate the uranium from within the SiC-coated fertile particles, and then a mechanism to accumulate in a concentrated fissile mass in a favorable geometry, is not credible.

For Shippingport LWBR fuel (DOE5), a number of studies have indicated both air and water oxidation of uranium and thorium oxide fuel pellets [$(Th, U)O_2$] proceed more slowly than in pure uranium oxide (UO_2), and decrease with decreasing UO_2 content in the $(Th, U)O_2$ (DOE 2003 [DIRS 166027], p. 33). Tests have shown that the thorium oxide pellets in the Shippingport LWBR fuel have excellent corrosion resistance, with an estimated solubility of 10^{-14} mol/L at 25°C and pH > 5 (DOE 2003 [DIRS 166027], p. 32). With the less-reactive degradation rate, a mechanism to separate the uranium, transporting, and accumulation into a favorable geometry is also not credible.

Table 2.1.14.26.0A-1 shows the ranges of minimum critical mass required to accumulate in the invert to achieve a critical limit of k_{eff} (effective neutron multiplication factor) equal to 0.96. Also shown is the calculated accumulation or mass released from the waste package for the waste forms evaluated for external criticality. For each of the waste forms evaluated, the results indicate that an insufficient amount of fissile material accumulates to pose a criticality concern.

Table 2.1.14.26.0A-1. Summary of Igneous Scenario External Criticality Results

Scenario	Waste Package Type	Calculated Accumulation or Mass Released from Waste Package (uranium mass, unless otherwise noted (kg))	Mass of Uranium or Plutonium (for FFTF) Required to Achieve Critical Limit of k_{eff} = 0.96 in the Invert (kg)
Igneous	DOE3 (N Reactor)	0.109	Infinite[a]
	DOE9 (TMI II Fuel)	30.7	538
	Commercial SNF	74.8	159
	DOE1 (FFTF) (Plutonium mass)	6.34×10^{-3}	1.66

Source: SNL 2007 [DIRS 181395], Table 6.9-1[a].

[a] "Infinite" means that an infinite amount of fissile waste released in this model will not produce an arrangement that can reach the critical limit.

DOE fuel groups in DOE2, DOE4, DOE7, and DOE8 representing UZrHx (TRIGA), high enriched uranium oxide (Shippingport PWR), aluminum-based (ATR), and U-Zr/U-Mo alloy (Fermi), respectively (SNL 2008 [DIRS 173869], Table 4.1-2), have not been analyzed in detail

for external fissile mass transport and accumulation as the other waste forms have. However, considering the processes that must occur to allow advective seepage into a DOE SNF canister without substantial drainage to allow degradation of the internal components and waste form, along with the other conservative modeling parameters that have been used to create a process to facilitate fissile material transport to the external environment, and the bounding modeling parameters respective to maximizing criticality potential, these waste forms are not expected to result in an increase in the total probability of criticality in the near-field location.

Some of the conservative modeling parameters are provided as follows:

- The material degradation and release model (SNL 2007 [DIRS 181165]) uses constant corrosion rates for the SNF; however, laboratory experiments on the surface structure of commercial SNF during dissolution have shown that UO_2 dissolution is accompanied by the formation of a protective layer of secondary phases that retards further corrosion (SNL 2007 [DIRS 181165], Section 6.6.2). Therefore, the release of uranium from the fuel would be slower and therefore less would be released.

- Experimental and field data indicate that actinides would be adsorbed on or incorporated into alteration products that form in the waste package (SNL 2007 [DIRS 181165], Section 6.6.3). This solid solution formation and adsorption would tend to lower actinide concentrations below those predicted by EQ6 and would delay release from the waste package.

- The material degradation and release model (SNL 2007 [DIRS 181165]) considers that the cladding and DOE SNF canister as breached upon emplacement in the repository, and unzipping immediately upon waste package breach, whereas the expected scenario would be that the failure would take place over many years. This would also delay the release of actinides.

- Many conservative modeling approximations are used to simplify the critical mass calculations presented in Table 2.1.14.26.0A-1. For the commercial SNF and low-enriched DOE fuels analyzed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]), the conservatisms are appropriate, because the results show that a criticality is very unlikely. However, for the higher enriched DOE fuels, less conservative modeling parameters of the criticality potential are expected to generate similar conclusions.

Summary—The critical mass limits were evaluated for several waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would need to be greater than what was identified in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], Section 8.1.4[a]). Model abstractions were performed for commercial SNF and three DOE SNF waste forms and resulted in insufficient fissile material accumulation in the near-field location to pose a criticality concern. Therefore, based on the analyzed waste forms representing the majority (>95% of the total metric tons) of the waste for disposal in the repository, and considering the conservative modeling parameters discussed above that would be further developed for other DOE representative fuel groups, in conjunction with the probablity of

the igneous intrusive initiating event, the probability of near-field criticality is considered insignificant.

Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.2.01.01.0A

FEP NAME:

Mechanical Effects of Excavation and Construction in the Near-Field

FEP DESCRIPTION:

Excavation will produce some disturbance of the rocks surrounding the drifts due to stress relief. Stresses associated directly with excavation (e.g., boring and blasting operations) may also cause some changes in rock properties. Properties that may be affected include rock strength, fracture spacing and block size, and hydrologic properties such as permeability.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This disposition discusses two aspects of this FEP. The first aspect relates to changes in geomechanical properties caused by the mechanical effects of excavation and construction in the near-field rock. These have been shown to have a negligible effect on rock geomechanical properties. The second aspect relates to changes affecting hydrological properties, which have been included in the TSPA and are discussed in the following paragraphs.

The excavation-induced fracturing of the tunnel periphery is confined to a depth of influence of only a few centimeters. The depth of mechanically induced damage is therefore less than 1% of the tunnel diameter except where natural fractures are abundant and damage effects can penetrate up to 50 cm (Craig 2001 [DIRS 171411], p. 16). This is consistent with observations documented in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Figure 7-25), which show that excavation-induced fracturing in the Exploratory Studies Facility (ESF) ranges from zero in good quality lithophysal rock to a maximum penetration of about 60 cm (2 ft) in poor quality lithophysal rock. In either case, no significant impacts on rock mass mechanical properties are expected to result from mechanical damage associated with excavation-related impacts (see excluded FEP 1.1.02.00.0B (Mechanical Effects of Excavation and Construction in EBS)). Likewise, no significant impacts on near-field rock mechanical properties are expected.

Fracture spacing data have been collected within the tunnel and analyzed in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.1) to determine a range of block sizes. Excavation-induced changes associated with these block sizes have been accounted for in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Sections 6.3 and 6.4), and are discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) and included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components).

Mechanical effects of excavation on hydrologic properties and seepage are taken into account in the air injection tests and seepage tests conducted in the ESF (BSC 2004 [DIRS 170004]). Since the testing boreholes are located within the excavation-disturbed zone in the vicinity of ESF niches, the data derived from these tests implicitly reflect mechanical effects of excavation. The

measured post-excavation air permeability data are consistent with geomechanical model results (SNL 2007 [DIRS 181244], Section 6.3.3.1).

Based on the data from air injection and seepage tests, seepage-relevant parameters have been developed in *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.3, 6.5.2, and 6.6) and were then used for seepage predictions in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Sections 6.3.2 and 6.4). Results from these calibration and prediction efforts are included in the seepage abstraction through the use of the measured post-excavation air-permeability data (SNL 2007 [DIRS 181244], Section 6.6.3 and Table 6.6-3) and the calibrated capillary-strength data determined from seepage tests (SNL 2007 [DIRS 181244], Section 6.6.2 and Table 6.6-1). Statistics of these parameters, excavation-disturbed permeability and calibrated capillary strength, provide the basis for the probability distributions that are given in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.7.1). These probability distributions are used in the TSPA to calculate seepage from seepage lookup tables, using the methodology defined in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.7.1). Simulations conducted with the thermal seepage model also incorporate the effects of excavation on seepage-relevant parameters (BSC 2005 [DIRS 172232], Section 6.2.2.1.4). Thus, the impact of excavation around a large opening (niche or drift) is included in the TSPA calculation of drift seepage. The impact of excavation on hydrologic properties near emplacement drifts is not considered in mountain-scale models, such as the UZ flow model or the UZ transport model, where these local changes are not relevant.

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.2.01.01.0B

FEP NAME:

Chemical Effects of Excavation and Construction in the Near-Field

FEP DESCRIPTION:

Excavation may result in chemical changes to the incoming groundwater and to the rock in the excavation disturbed zone.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

FEP 2.2.01.01.0B concerns the chemical effects of excavation and construction in the host rock environment immediately surrounding the waste emplacement drifts. This FEP is focused on seepage water changes and near-field rock changes. Related excluded FEP 1.1.02.00.0A (Chemical Effects of Excavation and Construction in the EBS) is focused on the possible changes in the EBS. Excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) addresses the effect of cementitious material in the turnout intersections, exhaust air (ventilation) turnouts, and access ramps. Requirements have been established to identify, analyze, and control the use of any introduced or committed materials (including water) that could adversely impact postclosure performance, thus limiting undesired effects from excavation and construction. The application of these controls is described in *Total System Performance Assessment Data Input Package for Requirements Analysis for Engineered Barrier System In-Drift Configuration* (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03). During construction of the emplacement drifts, and operation and closure of the repository, administrative controls will be imposed to prevent impact on waste isolation from materials used, lost, or left in the repository. These controls will be supported by technical evaluation. All tracers, fluids, and materials that may be used during construction, operation, and closure will be controlled. Various aspects of committed materials are discussed in excluded FEP 1.1.02.03.0A (Undesirable Materials Left).

The following constraints will be imposed on the administrative control of tracers, fluids, and materials; construction materials; and committed materials (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 02-03):

(A) All material not technically evaluated and determined acceptable prior to the permanent closure of the repository will be removed from subsurface facilities prior to permanent closure.

(B) Committed materials that are proposed to remain in the underground repository following the permanent closure period will be technically evaluated and determined acceptable prior to use.

(C) Administrative controls will include accounting and inspection, as appropriate, to confirm that controls on the approved TFM quantities and compositions are met.

Changes are expected in the rock fracture properties from excavation disturbance, stress relief around the opening, and ground support. However, these changes will not affect water chemistry; the effects of ground support on water chemistry are discussed later. Excavation will introduce water (for dust control), but it is not expected to have any significant effect on water chemistry. This is based on the controls on water use that limit the volumes of water that are lost during underground excavation as described in *Determination of Importance Evaluation for the Subsurface Exploratory Studies Facility* (BSC 2005 [DIRS 175089], Section 13.2.16). Furthermore, any water that remains local to the emplacement drifts and penetrates the unsaturated zone through fractures will have a dilute composition similar to that of nearby groundwater. Any salt solid forming as a result of evaporation would be present in relatively small quantities, even with additional dissolved solids from potential mixing of construction water with salt-bearing dust from the tunnel. *Drift-Scale THC Seepage Model* (SNL 2007 [DIRS 177404]) illustrates that upon rewetting, redissolution of salts has a minor effect on waters seeping into the drift. Therefore, even with the possible formation of salt solids as a result of evaporation, the effects on water chemistry are minimal upon rewetting. Salt-bearing dust could be generated by construction activities, and its potential effect on corrosion is discussed in excluded FEPs 2.1.09.28.0A (Geochemical Interactions and Evolution in the UZ), and 2.1.09.28.0B (Localized Corrosion on Drip Shield Surfaces due to Deliquescence). Included FEP 2.2.01.01.0A (Mechanical Effects of Excavation and Construction in the Near-field) describes the excavation-induced effects on rock properties and seepage in the near-field environment.

The principal ground supports in the emplacement drifts are expected to be Stainless Steel Type 316L rock bolts and steel sheets, while low-alloy Carbon Steel Type A588 comprises most of the invert structure (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-15). Sensitivity analyses of the effects of ground support and invert steels on aqueous chemistry are documented in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.8). The P&CE report utilizes four initial water types that are provided by the NFC model to represent the range of water chemistries in the TSw (SNL 2007 [DIRS 177412], Sections 6.3.2 and 6.6). The steel sensitivity analyses considered the interaction of the two most chemically distinct of these starting waters ("Group 1" and "Group 3"), with and without alkali feldspar added (SNL 2007 [DIRS 177412], Section 6.8.2). Corrosion rates for Stainless Steel Type 316L and Carbon Steel Type A588 (approximated by Carbon Steel Type A516) were taken from *Aqueous Corrosion Rates for Waste Package Materials* (BSC 2004 [DIRS 169982]). Solubility limiting phases for Stainless Steel Type 316L corrosion products included goethite (FeOOH), Ni-ferrite ($NiFe_2O_4$), Ni-chromite ($NiCr_2O_4$), Ni-carbonate ($NiCO_3$), and nontronite clays. Solubility limiting phases for Carbon Steel Type A588 corrosion include goethite (FeOOH) and MnO_2. The effect of dissolving Stainless Steel Type 316L and Carbon Steel Type A588 into "Group 1" and "Group 3" waters was found to be negligible (SNL 2007 [DIRS 177412], Section 6.8.4.1 and Tables 6.8-3 to 6.8-6). Simulations aimed at characterizing the impact of invert steel corrosion on water chemistry were conducted using 100 g Carbon Steel Type A588 (1.77 moles per liter) and five times this amount for bounding calculations. Even with such large quantities of low-alloy steels, there were only negligible changes in water chemistries (SNL 2007 [DIRS 177412], Section 6.8.4.2, Tables 6.8-3 and 6.8-4). In general,

these conclusions indicate that if there is no limit to the oxygen supply, the result of adding more steel to the water is simply the formation of more corrosion product precipitates. The results of these simulations demonstrate that there is no impact on seepage water chemistry, as described in Section 6.8.3 of *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412]).

Chemical changes to the minerals in the EDZ rock as a result of excavation and construction are not expected to be significant given the little change expected in the aqueous water chemistry at the EDZ. Any construction water that penetrates the EDZ to flow through unsaturated zone fractures is not expected to cause any significant geochemical interactions involving mineral phase changes in the unsaturated zone host rock. See excluded FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ) for additional discussion of this point.

Based on the previous discussion, omission of FEP 2.2.01.01.0B (Chemical Effects of Excavation and Construction in the Near-Field) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.01.02.0A

FEP NAME:

Thermally-Induced Stress Changes in the Near-Field

FEP DESCRIPTION:

Changes in host rock properties may result from thermal effects or other factors related to emplacement of the waste. Properties that may be affected include rock strength, fracture spacing and block size, and hydrologic properties such as permeability and sorption.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses the thermal-mechanical effects on drift seepage and thermal effects on rock strength, fracture spacing, and block size. The effects of thermal-mechanical stresses as a result of radioactive heating of the rock by the emplaced wastes may change the characteristics (e.g., permeability of the fractures) (see excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository) for details) and the faults (see excluded FEP 2.2.10.04.0B (Thermo-mechanical Stresses Alter Characteristics of Faults Near Repository)). Furthermore, fracturing of the rocks above and below the repository might occur to affect vertical permeability and infiltration in the unsaturated zone (see excluded FEP 2.2.10.05.0A (Thermo-mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository) for details). In addition, thermal effects on sorption, solubility, and precipitation/dissolution may be changed, and these are evaluated in excluded FEP 2.2.10.06.0A (Thermo-chemical Alteration in the UZ).

Thermal effects on rockfall in waste emplacement drifts are evaluated as part of *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.2). The analyses documented in that report (BSC 2004 [DIRS 166107]) use rockfall models that explicitly include rock strength, fracture spacing, and block size, as well as the potential impact of thermally induced stress changes in the rock mass. The effects of thermally induced stress changes are documented in *Drift Degradation Analysis* for nonlithophysal rock and for lithophysal rock (BSC 2004 [DIRS 166107], Sections 6.3.1.3 and 6.4.2.3, respectively). These effects are part of *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 8.1) and are incorporated into the rockfall calculations. Rockfall in the absence of seismic events (see excluded FEP 2.1.07.01.0A (Rockfall)) and seismic-induced rockfall (see excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components)) have been excluded with regard to effects on the EBS. However, the effects of seismic-induced drift collapse on the EBS are included in TSPA (see included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components)).

Thermal effects on rock strength are discussed in *Subsurface Geotechnical Parameters Report* (BSC 2007 [DIRS 178693], Figure 6-32), which shows that the temperature has little effect on rock strength. Variations in rock strength resulting from temperature are much smaller than the

natural variations found between samples at ambient conditions. Because of the high degree of fracturing in the lithophysal units, the rock mass will break into relatively small block sizes controlled by the spacing of natural fractures (BSC 2004 [DIRS 166107], Section 6.4.1.1). The character of fracturing in the nonlithophysal rock leads to discontinuous fractures. Although these discontinuities could lead to rock breakage under stress (BSC 2004 [DIRS 166107], Section 6.3.1), model results indicate that heating will not induce stress levels inside the blocks that are sufficient to cause damage (BSC 2004 [DIRS 166107], Section 6.3.1.3). Therefore, there are no thermal effects on fracture spacing or rock block size.

The Drift Scale Test is a large-scale, long-term thermal test designed to investigate coupled thermal-mechanical-hydrological-chemical behavior in a fractured, welded tuff rock mass (CRWMS M&O 1998 [DIRS 111115]). Simulations of the displacement response in the Drift Scale Test, based on elastic THM processes, were found to be in agreement with measurements. The dominant mode for stress-induced permeability change for THM processes was found to be elastic fracture opening or closing caused by changes in stress normal to the fractures (BSC 2004 [DIRS 169864], Section 8.2). The results of the drift-scale THM model show that thermal stress is not expected to induce failure at an emplacement drift located in the Tptpmn unit. For an emplacement drift located in the Tptpll unit, a limited yielding at the sidewalls of the drift is expected during excavation, but only for a drift located in low-quality lithophysal rock (BSC 2004 [DIRS 169864], Section 8.1). Low quality lithophysal rock is expected to be less than 10% of the waste emplacement areas (BSC 2004 [DIRS 166107], Figure S-50). Furthermore, the analysis indicates that the effects of stress-induced changes on hydrological properties and the flow field are small, particularly for the Tptpll, which occupies approximately 80% of repository emplacement area in the current design (BSC 2004 [DIRS 169864], Section 8.1; SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). Furthermore, the changes in permeability around drifts from THM effects are either insignificant or result in decreases in the vertical permeability and increases in the horizontal permeability (BSC 2004 [DIRS 169864], Sections 6.5.5, 6.6.1, and 6.7.2)

The effects of thermally induced stress changes around the emplacement drifts on drift seepage were evaluated in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.4). The drift-scale THM model was applied to assess the magnitude and distribution of stress-induced changes in hydrologic properties due to repository heating (SNL 2007 [DIRS 181244], Section 6.4.4). The report concludes that when comparing the fully coupled THM simulations with TH simulations, where the stress-induced property changes are neglected, the flow field differences are small to moderate. The changes in permeability resulting from THM effects appeared to give rise to less water reaching the drift crown (SNL 2007 [DIRS 181244], Figure 6.4-32). However, the identified impact on drift seepage was small and lies within the uncertainty of the seepage abstraction model (SNL 2007 [DIRS 181244], Figure 6.4-33 and Section 6.7.2). It was concluded in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.7) that these anisotropic THM property changes would increase the likelihood of flow being diverted around the drift, and thus would reduce the potential for seepage. Based upon these analyses, it is concluded that thermally induced stresses have a minimal impact on the hydrologic performance of the emplacement drift, and the impacts that it does have reduce the seepage of water into the drift.

Based on the previous discussion, omission of FEP 2.2.01.02.0A (Thermally-Induced Stress Changes in the Near Field) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.01.02.0B

FEP NAME:

Chemical Changes in the Near-Field from Backfill

FEP DESCRIPTION:

Changes in host rock properties may result from chemical effects of backfill. Properties that may be affected include permeability and sorption.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Backfill is not part of the design for the waste emplacement regions of the repository. Specifically, engineered backfill shall not be present in the space between the drip shield and the drift wall (SNL 2007 [DIRS 179354], Table 4-4, Parameter Number 05-04). Closure of shafts and ramps shall include backfill of the opening (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01); however, because backfill in shafts and ramps will not be in close proximity to the waste emplacement region, permeability and sorption and other host rock properties will have a negligible impact on long-term performance.

Based on the previous discussion, omission of FEP 2.2.01.02.0B (Chemical Changes in the Near-Field from Backfill) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.3331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.01.03.0A

FEP NAME:

Changes in Fluid Saturations in the Excavation Disturbed Zone

FEP DESCRIPTION:

Fluid flow in the region near the repository may be affected by the presence of the excavation, waste, and EBS. Some dry-out will occur during excavation and operations.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP screening justification focuses on dryout caused by preclosure ventilation during excavation and operations. Other causes of changes in fluid saturations in the excavation disturbed zone are discussed elsewhere. The effects of the engineered barrier system (rock bolt holes) on fluid flow have been excluded in FEP 1.1.01.01.0B (Influx through Holes Drilled in Drift Wall or Crown). The mechanical effects of drift excavation on fluid flow are included as described in FEP 2.2.01.01.0A (Mechanical Effects of Excavation and Construction in the Near-Field). The effects of waste heat on fluid flow have been included in FEPs 2.2.10.10.0A (Two-Phase Buoyant Flow/Heat Pipes) and 2.2.10.12.0A (Geosphere Dry-Out due to Waste Heat).

Preclosure ventilation of the waste emplacement drifts will result in dryout of the surrounding rock. However, this dryout is not significant for the long-term evolution of flow and transport near emplacement drifts because thermal dryout and rewetting during and after the thermal period, respectively, will overlay nearly all the earlier effects of ventilation dryout. Dryout has been observed in the Exploratory Studies Facility (ESF) and Enhanced Characterization of the Repository Block (ECRB) tunnels during site characterization (BSC 2004 [DIRS 170004], Sections 6.10.1.2 and 6.10.2.1).

In general, the observed dryout region in the ESF and ECRB ranges from 1 to 3 m into the drift walls (BSC 2004 [DIRS 170004], Section 6.10.1.2.1). The zone of dryout is qualitatively identified as the zone where matrix saturation and/or water potential are noticeably reduced by dryout relative to natural fluctuations in these quantities. Observations of dryout in the ECRB at station 15+00 show an approximately 1.5 m zone of dryout (BSC 2004 [DIRS 170004], Figure 6-109(a)). These measurements were taken on July 29, 2000, approximately two years after completion of the ECRB tunnel excavation (BSC 2004 [DIRS 170004], Section 6.10.1.2.3). The preclosure subsurface ventilation period is planned to be a minimum of 50 years (SNL 2007 [DIRS 179466], Table 4-2). The rate of dryout is maximized in areas of low natural percolation flux. In the absence of natural percolation flux and negligible gas-phase advective transport, the rate of dryout is dependent on vapor diffusion and capillary imbibition to move water from regions of higher water saturation in the rock to the tunnel atmosphere. Capillary imbibition may be approximated as a diffusive process (Marshall and Holmes 1979 [DIRS 102532], Section 5.1).

A characteristic of diffusive mass transfer processes is that the cumulative mass transfer is proportional to the square root of time (Crank 1975 [DIRS 122990], Section 3.3; Marshall and Holmes 1979 [DIRS 102532], Section 5.1). Given the cylindrical geometry, this scaling is strictly correct only for a boundary condition at the drift center rather than the drift wall. In this case, the use of the square-root scaling may be considered a one-dimensional approximation to radial diffusion. Using the square-root scaling and the observation of a 1.5 m dryout zone after two years of ventilation, the estimated dryout zone after 50 years of preclosure ventilation is 7.5 m beyond the drift wall. Natural percolation flux will have a more pronounced effect slowing the expansion of the dryout zone as the size of the dryout zone increases. Therefore, natural percolation will cause the dryout zone to be smaller than 7.5 m as computed from the square-root scaling.

The majority of waste emplacement will be in the Tptpll geological unit, with a smaller amount in the Tptpmn and other units (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). A comparison of dryout in fractures around waste emplacement drifts in the Tptpmn and Tptpll geological units (BSC 2005 [DIRS 172232], Figures 6.2.2.1.7(a) and 6.2.3.1-3(a)) suggests that the dryout resulting from waste heat is similar in these two units. Furthermore, the size of the dryout in both units is expected to be greater than the size of the dryout zone resulting from the combined effects of ventilation and natural percolation. Therefore, thermal dryout effects will encompass a larger region than that affected by preclosure ventilation dryout. The small enhancement in dryout resulting from preclosure ventilation would lead to minor increases in the time to re-wet the rock around waste emplacement drifts and would not lead to an underestimate of seepage. Because the dryout zone and drift seepage in the postclosure period are not significantly affected by preclosure ventilation, the effects on radionuclide releases to the accessible environment or radiological exposures to the reasonably maximally exposed individual are also negligible.

Based on this analysis, preclosure ventilation dryout is not significant to the modeling studies investigating the potential for seepage during the thermal period (BSC 2005 [DIRS 172232], Section 6.2.1.3.3). Preclosure ventilation is even less important for ambient seepage at later stages when the near-field rock has cooled and resaturated. For the same reason, the effect of ventilation dryout on EBS radionuclide transport is insignificant.

Based on the previous discussion, omission of FEP 2.2.01.03.0A (Changes in Fluid Saturations in the Excavation Disturbed Zone) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

INPUTS:

FEP: 2.2.01.04.0A

FEP NAME:

Radionuclide Solubility in the Excavation Disturbed Zone

FEP DESCRIPTION:

Radionuclide solubility limits in the excavation-disturbed zone may differ from those in the EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is excluded because the effects of potentially lower radionuclide solubility limits in the EDZ compared to those in the drifts will not have significant effect on radionuclide transport. If solubility limits are higher in the EDZ than in the emplacement drifts, then radionuclides entering the EDZ will remain in solution and there will be no retardation effect on radionuclide transport.

The EDZ is the zone around the drift where native materials have been disturbed from their natural conditions by excavation activities, resulting in chemical and/or hydrological alterations. The impact of this FEP may be qualitatively evaluated through a comparison of the different ranges of chemical environments estimated for the engineered barrier system, compared with the EDZ and unsaturated zone in general. The modeled pH of waters inside the drift ranges from approximately 5 to more than 11 (SNL 2007 [DIRS 177412], Figures 6.13-5 through 6.13-8). The evolution of water chemistry in the unsaturated zone, however, is not so broad because of the buffering effect of native rocks. For example, at the sides and crown of the drift, the pH ranges from roughly 7 to 10 (SNL 2007 [DIRS 177404], Figures 6.5-16, 6.6-1, 6.6-5, 6.6-7, 6.6-9, and 6.6-14). Given the much larger range of pH inside the drift, caused by the engineered materials, equilibrium solution concentrations for radionuclides inside the drift could be significantly larger than equilibrium solution concentrations in the unsaturated zone, including the EDZ. Excluded FEP 2.2.01.05.0A (Radionuclide Transport in the Excavation Disturbed Zone**)** provides additional information on this subject. If radionuclide solubility limits are lower in the EDZ than in the emplacement drifts, dissolved radionuclides could precipitate in the EDZ. This would occur only if the radionuclide concentrations entering the EDZ were higher than the solubility limits in the EDZ. However, contaminated water entering the EDZ is expected to be diluted by uncontaminated water and radionuclides will stay dissolved, even if the radionuclide concentration in the incoming water (before dilution) exceeds the solubility limit in the EDZ. Therefore, the effects of potentially lower radionuclide solubility limits in the EDZ compared to those in the drifts will not have a significant effect on radionuclide transport.

If solubility limits are higher in the EDZ than in the emplacement drifts, then radionuclides entering the EDZ will remain in solution and the difference in solubility limits between the EBS and the EDZ will not affect radionuclide transport.

Solubility limits, which depend on the solution chemistry, pH, and temperature, could also affect the formation of certain kinds of true colloids, such as polymeric forms of plutonium oxide (SNL 2007 [DIRS 177423], Section 6.3.1). However, only small quantities of true colloids have been observed to form in experiments on waste form degradation (SNL 2007 [DIRS 177423], Sections 6.3.1). Furthermore, these colloids are expected to dissolve into the aqueous phase with very little migration and provide radionuclides to be sorbed onto pseudocolloids (SNL 2007 [DIRS 177423], Section 6.3.1), the formation of which is not affected by solubility limits. Therefore, radionuclide solubility limits in the EDZ will not affect colloid-facilitated transport.

Based on the previous discussion, omission of FEP 2.2.01.04.0A (Radionuclide Solubility in the Excavation Disturbed Zone) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.01.05.0A

FEP NAME:

Radionuclide Transport in the Excavation Disturbed Zone

FEP DESCRIPTION:

Radionuclide transport through the excavation disturbed zone may differ from transport in the EBS and the undisturbed host rock. Transport processes such as dissolution and precipitation, sorption, and colloid filtration should be considered.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The EDZ, which is the area immediately surrounding the waste emplacement drifts, may be characterized by larger apertures due to the mechanical effect of excavation and reduced apertures due to chemical alteration due to excavation. One aspect of this FEP refers to the effects of altered fracture properties in the EDZ immediately surrounding the waste emplacement drifts on radionuclide transport. The effects of changes in fracture aperture on radionuclide transport were investigated at the mountain scale (excluded FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures)). The results of this analysis indicate that radionuclide transport behavior is relatively insensitive to changes in fracture aperture by as much as a factor of ten. Investigations on the effects of stress relief on fracture permeability in the EDZ have found that the vertical permeability beneath the drift is affected over a very narrow zone, on the order of one to two meters for changes in permeability of more than a factor of two (BSC 2004 [DIRS 169864], Sections 6.5.1 and 6.6.1).

An important factor affecting radionuclide transport immediately below the waste emplacement drift is the partitioning of radionuclides exiting the drift between rock fractures and matrix. Aperture affects this partitioning through its influence on fracture water content, which affects diffusive mass flux at the interface (SNL 2007 [DIRS 177407], Equations 6.5.1.2-7 and 6.5.2.5-5). Large reductions in fracture aperture will lead to large reductions in fracture porosity and water content. However, reducing fracture water content increases the partitioning of radionuclides from the waste emplacement drift to the rock matrix, which can only result in reduced rates of radionuclide transport. Increases in fracture aperture are limited in terms of their effect on fracture water content because of limitations on the increase in fracture porosity and the trend for residual saturation to decrease with an increase in aperture or permeability (Dombrowski and Brownell 1954 [DIRS 163222], Figure 7). The potential increases and decreases in fracture aperture are within the range of uncertainty already considered within the current UZ transport model (SNL 2007 [DIRS 170806]). Due to limited information regarding functional dependencies between fracture aperture and residual saturation, residual saturation is not treated in the model as a function of fracture aperture. Given the limited potential range for increases in fracture aperture (i.e., porosity), the effects of the EDZ on fracture water content, and hence on fracture aperture, may be discounted.

The effects of precipitation of aqueous radionuclides on transport in the EDZ also are excluded based on low consequence (see excluded FEP 2.2.01.04.0A (Radionuclide Solubility in the Excavation Disturbed Zone)). The precipitation of radionuclides as a solid immobile phase slows the progress of radionuclide transport in the aqueous phase. Because of the relatively short transport distance in the EDZ and the slow release of radionuclide from the waste emplacement drifts, any remobilization of precipitated radionuclides in the EDZ will have negligible effects on the dose to the RMEI and the environment.

Thermal effects on sorption are evaluated in excluded FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the unsaturated zone (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)), where increased temperatures are found to slightly increase sorption, which means more retardation in the EDZ. Compositional variations found in *Drift-Scale THC* (SNL 2007 [DIRS 177404], Figures 6.5-13, 6.5-13, 6.5-16, 6.5-17, 6.5-18, 6.5-21, and 6.5-23) lie within the range of compositional variations expected in the unsaturated zone and are accounted for in terms of radionuclide sorption (SNL 2007 [DIRS 177396], Appendix A, Section A4).

The behavior of different colloids in the emplacement drifts and the near-field are discussed in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.3.1). Colloidal filtration in the EBS is excluded from the TSPA (excluded FEP 2.1.09.20.0A (Filtration of Colloids in EBS)). Once colloids have been transported into the EDZ from the EBS (included FEP 2.1.09.19.0B (Advection of Colloids in EBS) and included FEP 2.1.09.24.0A (Diffusion of colloids in EBS)), they become subject to advection and dispersion. See included FEP 2.2.08.10.0B (Colloidal Transport in the UZ), which treats radionuclide transport in the unsaturated zone via movement of colloids.

Therefore, the effects of altered fracture properties, precipitation, and other processes that might retard radionuclide transport in the EDZ are excluded from the TSPA.

Based on the previous discussion, omission of FEP 2.2.01.05.0A (Radionuclide Transport in the Excavation Disturbed Zone) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.03.01.0A

FEP NAME:

Stratigraphy

FEP DESCRIPTION:

Stratigraphic information is necessary information for the performance assessment. This information should include identification of the relevant rock units, soils and alluvium, and their thickness, lateral extents, and relationships to each other. Major discontinuities should be identified.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP is similar to included FEP 2.2.03.02.0A (Rock Properties of Host Rock and Other Units). For the sake of clarity, the unsaturated zone stratigraphy is discussed first and the saturated zone stratigraphy is discussed second.

The bases for the unsaturated zone and saturated zone stratigraphic models are different. The unsaturated zone uses the geologic framework model, GFM2000 (BSC 2004 [DIRS 170029]; DTN: MO0012MWDGFM02.002 [DIRS 153777]), and the saturated zone uses the hydrogeologic framework model, HFM, which has been documented in *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007[DIRS 174109]). These different models for stratigraphy are used as a result of the different domains treated by the unsaturated zone and saturated zone models. The UZ model encompasses rock above the water table over a region around the repository that is roughly 5 km × 9 km (SNL 2007 [DIRS 184614], Figure 6.1-1). The unsaturated zone model depth is roughly 600 m (SNL 2007 [DIRS 184614], Figure 6.2-1). The saturated zone model encompasses rock below the water table over an area that is roughly 30 km × 45 km (SNL 2007 [DIRS 177391], Figure 6-1) and approximately 6 km deep (SNL 2007 [DIRS 177391], Table 6-4).

Unsaturated Zone Stratigraphy

Unsaturated zone stratigraphy is incorporated in the output from reports that develop different data sets for drifts in the Topopah Spring Tuff lower lithophysal zone (Tptpll) and Topopah Spring Tuff middle nonlithophysal zone (Tptpmn). This includes *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]) and *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Sections 6.3.2 through 6.3.4). Stratigraphy is also incorporated in *Analysis of Hydrologic Properties Data* (BSC 2004 [DIRS 170038]). Stratigraphy is incorporated in *Simulation of Net Infiltration for Present-Day and Future Climates* (SNL 2008 [DIRS 182145], Section 6.5.2.5[a]), because different strata are exposed at the soil-bedrock interface at different locations.

This FEP is included in the UZ flow model (SNL 2007 [DIRS 184614], Sections 6.1.1 and 6.1.2) by use of the grids developed with the information contained in *Geologic Framework Model (GFM2000)* (BSC 2004 [DIRS 170029]) and DTN: MO0012MWDGFM02.002 [DIRS 153777]. The stratigraphic unit and layers are developed into a model grid in *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855]). Because the assignment of hydrologic properties is associated with the grid used for the UZ flow model, the stratigraphy information is embedded in the TSPA through the flow fields. Aspects that affect hydrogeologic properties for flow are further discussed in *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855], Section 6). See also included FEP 2.2.03.02.0A (Rock Properties of Host Rock and Other Units).

The uncertainty in stratigraphic contact locations is not significant in comparisons with other uncertainties affecting unsaturated zone flow (SNL 2007 [DIRS 184614], Section 6.10), and its subsequent effects on radionuclide transport, drift seepage, and drift-scale coupled processes (see included FEP 2.2.07.02.0A (Unsaturated Groundwater Flow in the Geosphere)). Therefore, this uncertainty is not propagated into TSPA.

This FEP is also included for radionuclide transport in the unsaturated zone through the use of flow fields generated by the UZ flow model (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) and used by FEHM in TSPA multirealization runs (SNL 2008 [DIRS 184748], Section 6.5.1[b]).

Ambient seepage as a result of incomplete flow diversion around drifts is a local process simulated by the drift-scale seepage process model (SNL 2007 [DIRS 181244], Section 6.4). The stratigraphy of the repository host rock is included in the drift seepage models (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). The UZ flow model, which provides the percolation flux distributions used for seepage calculations, accounts for the effects of various geological units and major faults on the flow boundary condition for drift seepage (SNL 2007 [DIRS 184614], Sections 6.1.1 and 6.1.2). This is because the overall distribution of percolation flux at the repository horizon is influenced by stratigraphic layering and by major discontinuities. For example, the PTn unit overlying the Topopah Spring welded tuff units can divert a fraction of percolating water to intercepting faults and fault zones, thereby changing the spatial distribution of fluxes (SNL 2007 [DIRS 184614], Section 6.6.2.3), which could affect water–rock interaction and seepage water chemistry.

The drift-scale process models addressing thermal-hydrologic, THM, and THC processes (SNL 2007 [DIRS 181244], Sections 6.4.3.1, 6.4.4.1, and 6.4.4.2) also represent the stratigraphy in the unsaturated zone at Yucca Mountain in an explicit manner. This is needed because the thermal perturbation of the unsaturated rock extends far into the overlying and underlying geological units. Thus, the stratigraphy information is inherently embedded in the respective model results from the UZ flow and transport model and the thermal-hydrologic, THM, and THC drift-scale models. Finally, because the thermal perturbation affects the geologic units overlying and underlying the emplacement drifts, the THC seepage model includes the Yucca Mountain stratigraphy (SNL 2007 [DIRS 177404], Sections 4.1.2 and 6.5.1), using stratigraphic information from DTN: LB03023DKMGRID.001 [DIRS 162354] and mineralogical information from DTNs: LA9908JC831321.001 [DIRS 113495], LA9912SL831151.001

[DIRS 146447], LA9912SL831151.002 [DIRS 146449], and LA0009SL831151.001 [DIRS 153485].

The seepage water chemistry abstraction model includes the effects of stratigraphy within the TSw (SNL 2007 [DIRS 177412], Section 6.3.2.4.4), through the porosities and thicknesses of the stratigraphic units. The percolation flux values used in the model are based on fluxes at the PTn/TSw boundary predicted by the UZ flow model, given in DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332], which represent each climate state. The approach used is a plug flow model that has a transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4).

Saturated Zone Stratigraphy

The stratigraphic (i.e., hydrologic) nature of the saturated zone rocks as it affects flow and transport is incorporated into the TSPA SZ site-scale flow and transport models (SNL 2007 [DIRS 177391]; SNL 2008 [DIRS 184806]). The primary hydrogeologic subdivisions are based on and coincide with (1) common permeability and porosity characteristics (on a regional scale) of the rock and (2) whether the rock's primary mode of origin is volcanic, clastic, sedimentary (carbonates), or alluvial in nature (SNL 2007 [DIRS 177391], Section 6.3.1.2). The hydrogeologic subdivisions employed for the TSPA are a synthesis of the hydrogeologic framework model, documented in *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Sections 4.1.1, 4.1.4, 6.1, and 6.3), and the calibrated SZ site-scale flow model as documented in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Sections 6.3.1.2, 6.4.3.1, 6.4.3.3, and 6.4.3.10).

Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model (SNL 2007 [DIRS 174109]]) documents HFM2006 (DTN: MO0610MWDHFM06.002 [DIRS 179352]). HFM2006 is used in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]) to supply the spatial location of hydrogeologic units for the site-scale model. The 23 hydrogeologic units from HFM2006 (SNL 2007 [DIRS 174109]) are incorporated in the site-scale flow model (SNL 2007 [DIRS 177391], Section 6.5.1.3) via permeability zones. Additional permeability zones reflecting other features such as the altered permeability zone to the north, the regional horizontal anisotropy, and numerous faults are used to represent important structural or conceptual features. Ten additional zones representing faults and Lower Fortymile Wash alluvium were established to represent important structural or conceptual (large hydraulic gradient) features. The additional features reflect the degree of fracturing, faulting, fault orientation, and mineralogical alteration of glassy materials to zeolites and clay minerals. The site-scale saturated zone flow model is incorporated in the site-scale SZ transport model documented in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806]). The site-scale SZ transport model is used in SZ flow and transport model abstraction documented in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]). The SZ flow and transport model abstraction provides breakthrough curves and a one-dimensional transport model.

In all, there are 23 hydrogeologic units employed in the formulation of the SZ flow model (SNL 2007 [DIRS 177391], Section 6.4.3.1), and the SZ flow and transport abstraction (SNL 2008 [DIRS 183750], Section 6.5.2[b]). These same units are modeled in the SZ transport model (SNL 2008 [DIRS 184806]), as a result of the transport model being constructed from the SZ flow model. The uncertainty in transport parameters specific to stratigraphy, such as the effective diffusion coefficient, matrix porosity, and bulk density are described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2.6, 6.5.2.18, and 6.5.2.19).

In the hydrogeologic units where flow and transport are expected to take place, the alluvium units, Crater Flat Group, upper volcanic aquifer, and the upper volcanic confining units (SNL 2007 [DIRS 177391], Section 6.5.2.3), variability in transport properties between the major hydrogeologic units is implemented using a range of sampled parameters assigned to each unit for a particular realization (SNL 2008 [DIRS 183750], Section 6.5.2[b]). The primary stratigraphic uncertainty that has a significant effect on SZ flow and transport is the location of the contact between volcanic rocks and the alluvium (SNL 2008 [DIRS 183750], Section 6.5.2.2[a]). This is the only stratigraphic uncertainty propagated into TSPA for SZ flow and transport. Uncertainty in the contact between volcanic rocks and alluvium at the water table is addressed by a probability distribution function that represents the extent of the northwestern boundary of the alluvium uncertainty zone (SNL 2008 [DIRS 183750], Section 6.5.2.2[a]). For the fractured volcanic units, uncertainty in the spacing between intervals conducting significant quantities of groundwater flow is assessed in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014]).

How the physical properties of stratigraphic units are modeled is discussed in included FEP 2.2.03.02.0A (Rock Properties of Host Rock and Other Units). Further discussions of the various aspects of stratigraphy affecting flow and transport in the saturated zone are found in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2[b], 6.5.2.1[b], 6.5.2.2[a], 6.5.2.3[a], 6.5.2.6, 6.5.2.18, and 6.5.2.19), and *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Section 6.3).

FEP: 2.2.03.02.0A

FEP NAME:

Rock Properties of Host Rock and Other Units

FEP DESCRIPTION:

Physical properties such as porosity and permeability of the relevant rock units, soils, and alluvium are necessary for the performance assessment. Possible heterogeneities in these properties should be considered. Questions concerning events and processes that may cause these physical properties to change over time are considered in other FEPs.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP is similar to included FEP 2.2.03.01.0A (Stratigraphy). For the sake of clarity, the unsaturated zone is discussed first and the saturated zone second. This FEP is implemented in TSPA by way of the infiltration model, the drift seepage abstraction, the EBS physical and chemical environment abstraction (via THM and THC seepage models), the unsaturated zone flow models and submodels, the unsaturated zone particle tracking transport abstraction, and the saturated zone flow and transport model abstraction.

Rock properties used are defined for each of the stratigraphic units/layers classified in *Geological Framework Model (GFM2000)* (BSC 2004 [DIRS 170029]; DTN: MO0012MWDGFM02.002 [DIRS 153777]), which are further developed into a model grid in *Development of Numerical Grids for Unsaturated Zone Flow and Transport Modeling* (BSC 2004 [DIRS 169855]). However, rock properties are not developed in the grid development report. For the unsaturated zone flow model, rock properties and their distributions are modeled in terms of the sequence of hydrogeologic units and discrete faults (SNL 2007 [DIRS 184614], Sections 6.1.1 and 6.1.5). Therefore, rock properties are embedded in the TSPA through the output flow fields, with site-scale layering and faults taken into account. Rock properties used as input for *Unsaturated Zone Flow Models and Submodels* (SNL 2007 [DIRS 184614]) are developed in *Analysis of Hydrologic Properties Data* (BSC 2004 [DIRS 170038], Section 6) and *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3). Effects of rock property heterogeneity within a hydrogeologic unit on site-scale water flow processes are also evaluated and found to be insignificant (BSC 2004 [DIRS 170035], Section 6.3.4), which supports the use of the approach to represent subsurface heterogeneities (in the site-scale unsaturated zone model) by assigning uniform rock properties in a given unit.

Unsaturated Zone Rock Properties

The bedrock properties at the soil–rock interface, their spatial heterogeneities, and their uncertainties are employed in developing net-infiltration maps reported in *Simulation of Net*

Infiltration for Present-Day and Potential Future Climates (SNL 2008 [DIRS 182145], Section 6.5.2.6). For a given climate state, infiltration uncertainty is represented through four discrete infiltration scenarios, which are sampled in the TSPA model according to flow weighting factors (SNL 2007 [DIRS 184614], Section 6.8). These weighting factors are determined by the goodness of matches between simulated and observed chloride and temperature data in the unsaturated zone. The chloride and temperature data are used because they are relatively sensitive to the percolation flux in the unsaturated zone. The simulations used to determine these weighting factors are performed with the site-scale unsaturated zone flow model that, as previously discussed, includes rock properties and their heterogeneity.

The key rock-property data used in the three-dimensional unsaturated zone flow model and its submodel development include the following (SNL 2007 [DIRS 184614], Table 4.1-1):

- Fracture properties (frequency, permeability, van Genuchten α and *m* parameters, porosity, and interface area per unit volume rock) for each unsaturated zone model layer
- Matrix properties (porosity, permeability, and the van Genuchten α and *m* parameters) for each unsaturated zone model layer
- Thermal and transport properties (grain density, wet and dry thermal conductivity, grain specific heat, and tortuosity coefficients) for each unsaturated zone model layer
- Fault properties (fracture parameters) for each major hydrogeologic unit as defined by Table 6.1-1 of *Unsaturated Zone Flow Models and Submodels* (SNL 2007 [DIRS 184614]). Note that matrix properties in faults are the same as the adjacent matrix blocks of nonfault zones.

The calibrated parameter sets also include an estimate for each model layer of the active-fracture parameter, γ, that accounts for the reduction in interaction between matrix and fracture flow resulting from flow fingering and channelization (Liu et al. 1998 [DIRS 105729]). Uncertainty in the input data and parameters are addressed in Section 6.10 of *Unsaturated Zone Flow Models and Submodels* (SNL 2007 [DIRS 184614]). Specific input data sets and associated data tracking numbers (DTNs) are listed in Table 4.1-1 of *Unsaturated Zone Flow Models and Submodels* (SNL 2007 [DIRS 184614]).

Rock properties of host rock and other units are included and used in the simulations of radionuclide transport through the unsaturated zone. *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Sections 6.5.3[b] and 6.5.7[b]; SNL 2008 [DIRS 184748], Addendum Section 4.1) documents the matrix porosity, rock density, fracture porosity, fracture spacing, and aperture data (DTNs: LB0205REVUZPRP.001 [DIRS 159525], LB0207REVUZPRP.001 [DIRS 159526], and LB0207REVUZPRP.002 [DIRS 159672]) and their uses in the particle tracking model. The generated distributions of fracture porosity and fracture frequency are given in DTN: LA0407BR831371.001 [DIRS 170806], and are used by the TSPA model in multirealization runs to determine aperature values as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Sections 6.5.3[b], 6.5.5[b], and 6.5.7[b]).

All the seepage process models that feed into seepage abstraction represent the physical properties of the unsaturated host rock and their heterogeneity (SNL 2007 [DIRS 181244], Section 6.4). Percolation flux distributions provided by *Unsaturated Zone Flow Models and Submodels* (SNL 2007 [DIRS 184614]) are used in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.6.5.1; SNL 2007 [DIRS 181244], Section 6.4[a]), which accounts for rock properties and their variation on a larger scale (e.g., stemming from stratigraphy effects). Small-scale heterogeneity is accounted for by a stochastic continuum representation of fracture permeability. Thus, heterogeneity on this scale is embedded in the model output from the seepage calibration model (BSC 2004 [DIRS 171764], Section 6.5.2), the seepage model for performance assessment (BSC 2004 [DIRS 167652], Sections 6.3.2 through 6.3.4), and the thermal-hydrological seepage model (BSC 2005 [DIRS 172232]) provided respectively in DTNs: LB0407AMRU0120.001 [DIRS 173280], LB0706UZSEEP05.001 [DIRS 181445], and LB0301DSCPTHSM.002 [DIRS 163689]. The intermediate-scale spatial variability and uncertainty of seepage-relevant rock properties are accounted for by appropriate probability distributions that were developed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.6.1 and 6.6.2; SNL 2007 [DIRS 181244], Section 6.3[a]).

Potential alterations of these properties, as a result of THM or THC processes, have been assessed using drift-scale process models (SNL 2007 [DIRS 181244], Sections 6.4.4.1 and 6.4.4.2). It was demonstrated that these potential alterations can be neglected in the TSPA model, because the expected changes would lead to less seepage (SNL 2007 [DIRS 181244], Section 6.5.1.4; see excluded FEP 2.1.09.12.0A (Rind (Chemically Altered Zone) Forms in the Near-Field) and excluded FEP 2.2.10.04.0A (Thermo-mechanical Stesses Alter Characteristics of Fractures Near Repository)). The THC seepage model represents the physical properties of the unsaturated rock (SNL 2007 [DIRS 177404], Section 6.4.7 and Table 6.4-2). Simulated chemical concentrations through time are presented in DTNs: LB0705DSTHC001.001 [DIRS 181217] and LB0705DSTHC001.002 [DIRS 180854]. These data are used to feed and/or provide the technical basis for *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412]), which generates lookup tables used in the TSPA model.

Small-scale fracture permeability heterogeneity was also investigated and determined not to significantly affect seepage water chemistry (SNL 2007 [DIRS 177404], Section 6.3). The THC seepage model includes rock properties from DTNs: LB0205REVUZPRP.001 [DIRS 159525] and LB0610UZDSCP30.002 [DIRS 179180]). Potential alterations of fracture permeability values as a result of THC processes are accounted for by the modeling of coupled THC processes, and result in reducing fracture permeability (SNL 2007 [DIRS 177404], Section 6.5.5.3).

Saturated Zone Rock Properties

Considering the saturated zone, geologic features and heterogeneous hydrostratigraphic units are included in *Saturated Zone Flow and Transport Abstraction Model* (SNL 2008 [DIRS 183750], Section 6.5[a]) as cells with specific hydrologic parameter values in a configuration based on the hydrogeologic framework used in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.4.3.1). Available geologic information on rock properties that affect saturated zone flow and transport in the Yucca Mountain region is used to determine the 23 hydrostratigraphic units modeled in the site-scale saturated zone flow domain (SNL 2007

[DIRS 177391], Table 6-5). The supporting geologic information is updated in *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Sections 6.2, 6.3, and 6.4).

Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model (SNL 2007 [DIRS 174109], Sections 6.2 to 6.4) documents HFM2006 (DTN: MO0610MWDHFM06.002 [DIRS 179352]). The TSPA disposition of this FEP is supported by *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Sections 6.2 to 6.4).

In *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.6), base-case permeability and flow fields are generated. There are numerous broad and distinct zones in this model, categorized as "features," that affect or potentially affect flow. Many of these are directly or indirectly associated with faults, including zones of mineralogical alteration along faults and contact zones between offset units (SNL 2007 [DIRS 177391], Section 6.4.3.7, Table 6-7). The zones are categorized depending upon how their rock properties, most notably porosity and permeability, affect flow and transport. The rock properties in these zones can be specified to act as either barriers or conduits (or simultaneously as barriers in one direction and conduits in another direction (i.e., horizontal or vertical anisotropy)) to saturated zone flow (SNL 2007 [DIRS 177391], Section 6.4.3.7, Table 6-7). In all, 12 zones associated with 10 features plus a boundary separating a northern region of lower permeability from a southern region of higher permeability (attributed to geologic alteration associated with the Claim Canyon caldera north of Yucca Mountain and helping to account for the large hydraulic gradient north of Yucca Mountain) are built into the saturated zone site-scale flow model (SNL 2007 [DIRS 177391], Section 6.4.3.7). One feature, the Fortymile Wash fault, has two spatially separated zones in the model. The specified base-case flow properties and the effects of each feature/zone on flow are listed in Table 6-7 of *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.4.3.7). Additional discussion of the features/zones is provided in included FEP 2.2.07.13.0A (Water-conducting Features in the Saturated Zone).

The saturated zone transport abstraction model and the saturated zone one-dimensional transport model (both described in SNL 2008 [DIRS 183750], Sections 6.3, 6.5[a], and 6.6) take the flow and transport model and indirectly account for additional uncertainty and heterogeneity in rock permeability through the stochastically sampled groundwater specific discharge multiplier parameter (SNL 2008 [DIRS 183750], Section 6.5.2.1[a]). Additional uncertainty and spatial variability in rock properties in the SZ transport abstraction model are accounted for in the flow and transport abstraction model by specifying uncertainty distributions for the following stochastically sampled parameters: (1) horizontal flow anisotropy in the volcanics; (2) effective porosity in the alluvium units 11 and 26; (3) flowing interval spacing in the volcanics; (4) flowing interval porosity; (5) sorption coefficients (K_d) for the sorbing radionuclides modeled in both the alluvium and volcanic units; and (6) longitudinal dispersivity. The above parameters are described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5.2[b]). Uncertainty in the flowing interval spacing parameter is assessed in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014], Sections 6.4 and 6.5). The basis for anisotropy in permeability in the volcanic units and assessment of groundwater specific discharge in the alluvium are discussed in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Sections 6.2.6 and 6.5.5). Other parameters that are

stochastically varied to account for uncertainty in rock parameters include the location of the transition boundary from volcanic units to alluvium, and volcanic and alluvium porosities and bulk densities, which are discussed in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5.2[b]). The impacts of rock properties on the uncertainty of sorption coefficients are discussed in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Sections 6.3 and 6.4 and Appendix A). Impacts of rock properties on effective diffusion coefficients of radionuclides are discussed in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5.2.6).

The uncertainty in the location of the alluvium-volcanic contact boundary is accounted for through a probabilistically sampled parameter (SNL 2008 [DIRS 183750], Section 6.5.2.2[a]), which defines the northwestern boundary of the alluvial (valley-fill aquifer) uncertainty zone. This parameter determines whether nodes within the zone of uncertainty in the saturated zone flow and transport model(s) are assigned alluvium or volcanic rock properties.

FEP: 2.2.06.01.0A

FEP NAME:

Seismic Activity Changes Porosity and Permeability of Rock

FEP DESCRIPTION:

Seismic activity (fault displacement or vibratory ground motion) has a potential to change rock stresses and result in strains that affect flow properties in rock outside the excavation-disturbed zone. It could result in strains that alter the permeability in the rock matrix. These effects may decrease the transport times for potentially released radionuclides.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Plate tectonic activity has imparted crustal extension stresses within the Basin and Range Province (which includes the Yucca Mountain region) during the past 12 million years. The height of this activity occurred between 10 and 12 million years ago, with estimated extension rates ranging between 10 and 30 mm per year (National Research Council 1992 [DIRS 105162], Chapter 2). During this period, major faults and fractures were created in the vicinity of Yucca Mountain. Approximately 5 million years ago, regional extension rates declined to 5 to 10 mm per year. At present, extension rates are still in a declining state (National Research Council 1992 [DIRS 105162], Chapter 2).

Regional extension imparts local extensional, compressional, and/or shear stresses on the crust, depending on location, depth, and the juxtaposition of parent rock units and existing faults and fractures. Release of stress results in seismic activity that creates faults (rupture), and causes fault displacement, vibratory motion, and/or spatial redistribution of stresses not associated with specific faults. Vibratory motion and spatial redistribution of stress in the rock matrix can alter the hydrologic properties of the parent rock by (1) causing a change in pore pressure, or (2) causing dilation, compression, or breakage of granular structures in the rock, leading to corresponding changes in permeability.

Pore pressure changes associated with seismic events are addressed in detail under excluded FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity) and are based on the results of an investigation conducted by the National Research Council (1992 [DIRS 105162], Chapter 5) that evaluated water table fluctuations for a predicted seismic event. It was concluded that a future seismic event would not alter the rock hydrologic properties on a regional scale.

Damage of the rock matrix material due to seismic loading would manifest itself in the form of inter-lithophysal tensile fractures that coalesce to form observable shear fractures with offset. The exposed lithophysal rocks in the ESF and the ECRB Cross-Drift show no fracturing of this type. Observed fracturing is consistent with typical cooling-fracture-related history (BSC 2005

[DIRS 170137], Sections 6 and 6.3). These findings indicate that the matrix material is largely unaffected by redistribution of strain introduced by seismic activity.

Given the relatively high strength of the matrix material and the extensive fracture network in the rock mass, the strain introduced by seismic activity would be expected to be accommodated by deformation of, and slip along, existing faults and fractures. The effects of seismic activity on the properties of faults and fractures are discussed under excluded FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults) and excluded FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures). However, localized changes in hydrologic properties could occur adjacent to existing faults and fractures due to the creation of brecciation and gouge zones and possibly due to the creation of new fractures (outside of the brecciated zone). This disturbed rock zone, labeled herein as a "zone of alteration," is correlated with the amount of fault offset (Sweetkind et al. 1997 [DIRS 177047]). Faults with 1 to 5 m of cumulative offset have a zone of increased fracturing of only 1 to 2 m; faults with tens of meters of offset can have a zone of fracturing up to tens of meters wide (Sweetkind et al. 1997 [DIRS 177047], pp. 68 to 72). The hydrologic properties in the zone of alteration reflect the cumulative response of a dynamic seismic past, demonstrative of rapid extension rates in existence 10 to 12 million years ago and, to a lesser extent, the lower extension rates occurring today. In light of the cumulative nature of seismic stresses at Yucca Mountain over more than 10 million years, any changes in hydrologic properties resulting from seismic activity over the 10,000-year postclosure period are expected to be negligible.

The effects of a future seismic event on the hydrologic properties of the host rock are evaluated here based on the findings of the expert elicitation analysis documented in the PSHA report (CRWMS M&O 1998 [DIRS 103731], Sections 4 and 8). The PSHA group assessed the mean displacement for intact host rock in the vicinity of the repository to be less than 0.1 cm for a 10^{-8} annual-exceedance probability (DTN: MO0401MWDRPSHA.000 [DIRS 185014], file: *s7d.frac_mean*; CRWMS M&O 1998 [DIRS 103731], Section 8.2.1). Consequently, the rock matrix is largely unaffected by strain redistribution caused by seismic activity and no significant new faults or fractures are likely to form in the Yucca Mountain vicinity within the next 10,000 years. The small seismic displacement for intact rock, less than 0.1 cm, for an annual-exceedance probability of 10^{-8} corresponds to the level of displacement that occurred as a result of thermal stress in the Drift Scale Test, as measured in multiple-point borehole extensometers (BSC 2004 [DIRS 169864], Figure 7.4.2-2). The simulations of the displacement response in the Drift Scale Test, based on elastic thermal-hydrological-mechanical processes, were found to be in agreement with measurements. The dominant mode for stress-induced permeability change for THM processes was found to be elastic fracture opening or closing caused by changes in stress normal to the fractures, as opposed to changes in matrix permeability (BSC 2004 [DIRS 169864], Section 8.2). For similar displacements and stresses (as found in the Drift Scale Test) associated with seismic motion, the same conclusions apply to both the unsaturated zone and saturated zone. Therefore, the small seismic displacements in the intact rock matrix will have a negligible effect on rock-matrix hydrologic properties and may be excluded on the basis of low consequence.

In summary, any changes to hydrologic processes as a result of changes to rock matrix properties caused by seismic activity are expected to be negligible. Based on the previous discussion, omission of FEP 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock)

will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.06.02.0A

FEP NAME:

Seismic Activity Changes Porosity and Permeability of Faults

FEP DESCRIPTION:

Seismic activity (fault displacement or vibratory ground motion) has a potential to produce jointed-rock motion and change stress and strains that alter the permeability along faults. This could result in reactivation of pre-existing faults or generation of significant new faults, which could significantly change the flow and transport paths, alter or short-circuit the flow paths and flow distributions close to the repository, and/or create new pathways through the repository. These effects may decrease the transport times for potentially released radionuclides.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Fault displacements and concomitant formation or alteration of fractures can have a marked effect on hydrologic properties of the saturated and unsaturated zones. This FEP describes the processes by which seismic activity can alter the porosity and permeability of faults. The general topic of seismic hazard at Yucca Mountain has been investigated in detail in *Probabilistic Seismic Hazard Analyses for Fault Displacement and Vibratory Ground Motion at Yucca Mountain, Nevada* (CRWMS 1998 [DIRS 103731]), also known as the PSHA. Bates and Jackson (1987 [DIRS 164050], p. 257]) describe faults as a type of fracture, and as such, much of the discussion in excluded FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures) is also of considerable relevance here, as is the discussion contained in excluded FEP 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock). Direct hydrologic responses to seismic activity (such as transient changes in the water table) are discussed in excluded FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity). The seismic history of the Basin and Range Province is outlined in excluded FEP 1.2.01.01.0A (Tectonic Activity-Large Scale).

Movements produced by a fault displacement will result in changes in the rock stress in the vicinity of the fault (BSC 2004 [DIRS 169734], Section 4.3.4.1). The change in rock stress will decrease with distance from any given fault where movement occurs (BSC 2004 [DIRS 169734], Section 4.3.1). However, the magnitude of the changes in rock stress as a function of distance from the fault depends on the specific details of the fault displacement (e.g., magnitude of fault motion, direction of fault movement, extent of the fault that participates in the movement) and the mechanical properties of the surrounding rock (e.g., fracture spacing, fracture stiffness, geomechanical properties of the rock matrix). Given some change in rock stress, the fractured rock mass will respond to the change in stress through deformation, or strain, in the rock. This has the potential to alter hydrologic properties (BSC 2004 [DIRS 169864], Section 6.2.3).

Potential for the Development of New Faults—An aspect of faulting that could be important to repository performance is the formation of new faults. Expert elicitation, documented in the PSHA report (CRWMS M&O 1998 [DIRS 103731], Section 4), provides information that can be used to assess the effects of a seismic event on fault formation. As part of the PSHA, six teams of experts evaluated the available data to assess the fault displacement potential for nine sites that represent the range of fault conditions in the Yucca Mountain vicinity (CRWMS M&O 1998 [DIRS 103731], Figure 4-9). The teams also characterized the uncertainty in their assessment by defining alternative models and approaches and assigning weights. For each combination of alternatives, results for each site were provided as the annual frequency with which given levels of fault displacement would be exceeded. Uncertainty in the results was characterized by calculating the mean hazard and various percentile values. Results for each team were then combined using equal weights to determine the integrated fault displacement hazard (CRWMS M&O 1998 [DIRS 103731], Sections 4 and 8). The PSHA group assessed the mean displacement in the intact rock for the area between the Solitario Canyon and the Ghost Dance faults to be less than 0.1 cm for a 10^{-8} annual-exceedance probability. The development of new faults and fractures (which would have the potential to create new flow paths or significantly change the existing flow paths and flow directions) is inferred from the PSHA to be relatively inconsequential and is therefore of low consequence.

The major faults in the vicinity of the repository are the Solitario Canyon and Bow Ridge faults, which have been examined in terms of the probability distribution for fault displacement in the PSHA report (CRWMS M&O 1998 [DIRS 103731], Section 4). Extrapolating the PSHA results out to the annual exceedance probability of 10^{-8} results in a 13-m approximate mean displacement for the Solitario Canyon fault and a 6-m approximate mean displacement for the Bow Ridge fault (DTN: MO0401MWDRPSHA.000 [DIRS 185014], files: *s1.frac_mean* and *s2.frac_mean*; CRWMS M&O 1998 [DIRS 103731], Figures 8-2 and 8-3).

Current Solitario Canyon fault hydrologic properties reflect the cumulative effects of an active tectonic and seismic past that have resulted in a 260 m cumulative fault displacement where it intersects the ECRB Cross-Drift (Mongano et al. 1999 [DIRS 149850], pp. 48 to 65). An approximately 13-m displacement of the Solitario Canyon fault (and other faults) will release local stresses accumulated along the fault plane but will not alter the large and globally extensive stresses in effect over the past 10 to 12 million years incurred in the parent rock and embedded faults within the Yucca Mountain region (National Research Council 1992 [DIRS 105162], Chapter 5). The height of this activity occurred between 10 and 12 million years ago, with estimated extension rates ranging between 10 and 30 mm per year (National Research Council 1992 [DIRS 105162], Chapter 2). During this period, major faults and fractures were created in the vicinity of Yucca Mountain. Approximately 5 million years ago, regional extension rates declined to 5 to 10 mm per year. At present, extension rates are still in a declining state (National Research Council 1992 [DIRS 105162], Chapter 2) and are associated with a decline in seismic activity. It is these areally extensive stresses imposed on the fault that determine the hydrologic properties of the fault, such as permeability and porosity. The logical conclusion is that any changes in Solitario Canyon fault's hydrologic properties will be small, given an approximate 13-m displacement, as will any changes in hydrologic properties of other, smaller faults, which exhibit less extensive displacements. The Solitario Canyon fault will continue to serve as a groundwater divide between the Yucca Mountain and the Crater Flat regions (SNL 2007 [DIRS 177391], Section 6.3.2.3).

Changes in Fault Hydrologic Properties Due to Formation of Gouge/Brecciation Zones—Fault displacement can cause deformation and breakage of the parent rock, leading to the formation of gouge and brecciated zones in the vicinity of the fault. This is discussed in greater detail in excluded FEP 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock). The presence of gouge and brecciated zones only in close proximity to fault planes suggests that much of the strain introduced by seismic activity will be mechanically dissipated within or near the fault planes. The disturbed rock zone is correlated with the amount of fault offset. For instance, in the Solitario Canyon fault zone in the ECRB Cross-Drift, the total displacement is approximately 260 m, but the gouge and brecciated zones are limited to less than 20 m from the main fault trace (Mongano et al. 1999 [DIRS 149850], pp. 59 to 65). Other faults display less extensive fault offsets, so the corresponding gouge/brecciation zones are not expected to exceed that observed for the Solitario Canyon fault zone. Therefore, changes in hydrologic properties as a result of fault displacement are also expected to center within the fault zones.

Evaluation of Changes in Fault Zone Hydrologic Properties in the UZ—The effects of a given fault displacement on unsaturated zone hydrologic properties could be evaluated using process-level calculations for the effects of the induced stress and strain on fracture geometry. However, this direct approach was not used to specifically evaluate seismic effects because of the large uncertainty in the specification of the seismic event and complexity of translating seismic motion along faults into imposed stresses. An alternative bounding approach that employed two sensitivity studies was used to assess the potential effects of fault displacement on changes in fracture apertures and consequently on fracture hydrologic properties (Appendix I). Two bounding cases were considered. The first case considered changes in fracture aperture over the entire model domain (including faults). The second case, which considers change in fracture properties within the faults only, is directly applicable to this FEP. The results of the second sensitivity study have shown that fracture aperture changes confined to fault zones resulted in virtually no effect on transport behavior in the unsaturated zone (Appendix I, Section I3.3.1). Changes in fault properties would also have little effect on flow above the repository because faults carry about 1% of the flow in this region of the unsaturated zone (SNL 2007 [DIRS 184614], Tables 6.6-1 and 6.6-2). Fault permeabilities are high relative to the predicted flux. Changes in fault properties, other than a very substantial reduction in fault permeability, would not be expected to affect this flow percentage. This is because the percentage of flow in the faults above the repository is related to the fault area at the ground surface available for direct infiltration into faults and lateral flow processes in the unsaturated zone. A substantial reduction in fault permeability would result in flow redirection into more permeable zones near faults and would not have a signifcant effect on water arrival at the repository. A similar conclusion can be reached concerning transient flow between the ground surface and the repository. Any change in transient flow would be limited to the small fraction of flow that moves through faults.

This result is also supported by the parameter sensitivity study for unsaturated zone flow (BSC 2005 [DIRS 174116]) and corresponding effects on radionuclide transport (SNL 2008 [DIRS 184748], Section 6.6.3[b]). For this sensitivity, fracture permeability is varied by one standard deviation, which for the faults is a factor of 14. The sensitivity was conducted for both an increase and decrease in permeability by this factor, with changes to fracture permeability occurring globally over the entire model domain (BSC 2005 [DIRS 174116], Tables 6.2-1 and 6.2-4). The sensitivity calculation is not restricted to faults, but varies all fracture permeabilities

within the unsaturated zone model domain (note that the standard deviations for fracture permeability vary by hydrogeologic unit). The resulting flow fields were analyzed for effects on radionuclide transport. The transport results show that global variations in fracture permeability have only a small effect on transport relative to other uncertainties included in the TSPA (SNL 2008 [DIRS 184748], Section 6.6.3[b]). The effects of fracture permeability in these sensitivities are expected to be overestimated because the effects of changes in capillary strength, which are negatively correlated with permeability (SNL 2007 [DIRS 181244], Section 6.5.1.1), would tend to offset changes in permeability. This is because increased fracture permeability leads to greater flow in fractures, but the associated reduction in capillary strength (represented by an increase in the fracture α), leads to a reduction in fracture flow through enhanced matrix imbibition. This effect may be seen in the response to unsaturated zone flow distributions between fractures, matrix, and faults with changes in fracture α (BSC 2005 [DIRS 174116], Table 6.4-1(c)) and by the effects of changes in fracture α on radionuclide transport (SNL 2008 [DIRS 184748], Figures 6-25[b] and 6-26[b]).

The effects of changes in hydrologic properties of fractures on seepage into repository drifts are reported in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.5.1.1 and 6.8.2). Changes in fracture permeability and capillary strength above a drift as a result of seismic activity are expected to lead to either negligible changes in drift seepage or reduced seepage into drifts (BSC 2004 [DIRS 169864], Section 6.8.4; SNL 2007 [DIRS 181244], Section 6.4.4.1.2). This is a result of the fact that apertures above a drift tend to increase as a result of such a disturbance, and the resulting increase in permeability that permits greater drainage of water around the drift has more influence on seepage than the reduction in capillary strength. The effects of seismic activity on seepage into drifts is addressed in included FEP 1.2.03.02.0D (Seismic-Induced Drift Collapse Alters In-Drift Thermohydrology).

Evaluation of Changes in Fault Zone Hydrologic Properties in the Saturated Zone—As discussed in excluded FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity), the primary response of regional water levels to seismic events is a transient change (increase or decline) in the water table. The SZ flow and transport model abstraction (SNL 2008 [DIRS 183750], Section 6.5.2.3[a]) uses the flowing interval concept. The flowing interval concept, based on site data, indicates that only some of the fractures within the saturated zone contribute to the flow. Additionally, the saturated zone abstraction produces radionuclide breakthrough curves that implicitly include fracture zones (faults) by considering the horizontal anisotropy in permeability located in the fractured volcanic units downgradient of the repository (SNL 2008 [DIRS 183750], Section 6.5.2.10). The saturated zone abstraction does not explicitly address changes to fracture properties due to changes in stress (SNL 2008 [DIRS 183750], Section 6.5.2). However, the abstraction model includes a wide range of uncertatinty in the groundwater specific discharge multiplier (0.03 to 10), flowing interval spacing (1 m to 417 m), horizontal permeability anisotropy ratio (0.05 to 20), and fracture porosity of the volcanic units (10^{-5} to 0.1) (SNL 2008 [DIRS 183750], Table 6-8). These are factors that could potentially be affected by changes in fracture properties as a result of seismically-induced stress changes. The breadth of the uncertainty included in the model is expected to bound any changes that may result from seismic activity. A sensitivity study considers the effects of the addition of a high-permeability feature to the model (SNL 2008 [DIRS 183750], Section 6.9.3[a]). The feature added to the model is a 6-km long, 100-m wide, 30-m thick high-permeability zone oriented north-south along the transport pathway south of Yucca Mountain. The north-south

orientation is consistent with the approximate strike of major faults in this area (SNL 2008 [DIRS 183750], Section 6.9.3[a]). The permeability assigned to the feature is more than two orders of magnitude larger than the most permeable faults in the base model (SNL 2008 [DIRS 183750], Section 6.9.3[a]; SNL 2007 [DIRS 177391], Table 6-9). The resulting changes in SZ transport behavior was not significant in comparison to the range of transport results representing uncertainties included in the saturated zone abstraction model (SNL 2008 [DIRS 183750], Section 6.9.3[a] and Figure 6-18[a]). Therefore, changes in the hydrologic properties of faults in the saturated zone are of low consequence. Relevant aspects of modeling SZ flow and transport are discussed further in excluded FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures).

In summary, changes in the porosity and permeability of faults as a result of future seismic events will not significantly alter groundwater flow and radionuclide transport in the region of the Yucca Mountain Repository based on the following conclusions:

1. Current fault porosities and permeabilities reflect the effects of a seismically active past within the Yucca Mountain region. Past seismic activity is reflective of major plate extension and caldera formation phases in the Basin and Range Province, which includes the Yucca Mountain region. Seismic activity within the Yucca Mountain region is currently occurring at a reduced level relative to the period of most active extension 10 to 12 million years ago. Consequently, future seismic events are expected to have a relatively low impact on existing fault hydrologic properties.

2. Future seismic events are expected to rupture existing faults, rather than develop new faults.

3. Changes to fault properties (which implicitly affect the fault's hydrologic properties) will tend to occur in a relatively narrow zone, and be on the order of a few meters to, at most, tens of meters wide along the length of the fault. This is of low significance to the mountain-scale flow and transport properties.

4. Changes in fault permeability due to variation in the hydrologic properties of fractures contained within faults result in a negligible effect on radionuclide transport behavior in the unsaturated zone. In addition, the expected increase in fracture permeability and reduction in capillary strength associated with fracture dilation cause by seismic activity either leads to small or reduced seepage into drifts.

5. The uncertainty in the effective hydrologic properties incorporated in the SZ flow and transport model, coupled with uncertainty in specific discharge, overwhelms the changes that would be caused by small movements along existing faults.

Based on the previous discussion, omission of FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.06.02.0B

FEP NAME:

Seismic Activity Changes Porosity and Permeability of Fractures

FEP DESCRIPTION:

Seismic activity (fault displacement or vibratory ground motion) has a potential to change stress and strains that alter the permeability along fractures. This could result in reactivation of pre-existing fractures or generation of new fractures, which could significantly change the flow and transport paths, alter or short-circuit the flow paths and flow distributions close to the repository, and/or create new pathways through the repository. These effects may decrease the transport times for potentially released radionuclides.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Fractures involve a range from small cracks with no displacement, up to and including features with considerable displacement that are typically called faults. The potential for changes in the porosity and permeability of faults due to seismic activity is discussed more specifically in excluded FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults). Features considered within this FEP are typically smaller, with little or no displacement, but may be strongly associated with regions of faulting. The spatial relationship between faults and other fracture features is discussed in excluded FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults).

Future seismic activity could redistribute strain within the system. Movements produced by a fault displacement will result in changes in the rock stress in the vicinity of the fault. However, the magnitude of the changes in rock stress as a function of distance from the fault depends on the specific details of the fault displacement (e.g., magnitude of fault motion, direction of fault movement, extent of the fault that participates in the movement) and the mechanical properties of the surrounding rock (e.g., fracture spacing, fracture stiffness, geomechanical properties of the rock matrix). Given some change in rock stress, the fractured rock mass will respond to the change in stress through deformation, or strain, in the rock. This induced strain can affect the geometry of fractures in the rock.

This FEP describes the processes by which seismic activity can alter the porosity and permeability of fractures. The potential for formation of new fractures and reactivation of existing fractures is first considered, followed by a consideration of the effects of seismic activity on the hydrologic properties of existing fractures.

Potential for Fracture Reactivation or the Development of New Fractures—Redistribution of strain could open new fractures and close some existing fractures, as discussed by Gauthier et al. (1996 [DIRS 100447], p. 163). Much of this redistribution would be expected to occur within the

fault zones. Although an analysis of fractures was not the primary purpose of the study, the PSHA (CRWMS M&O 1998 [DIRS 103731], p. 8-7) examines the probability of movement along existing fractures and the development of new fractures. The results lead to the conclusion that the development of new fractures, given current geologic conditions and the existing stress field, is not expected and would be of low consequence.

The PSHA (CRWMS M&O 1998 [DIRS 103731], Section 8.2.1, Points 7 and 8 in Table 8-1) examined displacements at specific points along faults, including hypothetical points representing existing small faults, shears, and fractures. The PSHA indicates that for a 10^{-8} annual-exceedance probability, the mean displacement in the intact rock will be less than 0.1 cm (DTN: MO0401MWDRPSHA.000 [DIRS 185014], file: *s7d.frac_mean*; CRWMS M&O 1998 [DIRS 103731], p. 8-7, Point 7d in Table 8-1). Given the current network of small to large displacement fractures with varying apertures and other characteristics, the development of a few more very small displacement (less than 0.1 cm) fractures in presently intact rock will not noticeably affect groundwater flow or radionuclide transport. Therefore, based on the PSHA, the development of new fractures due to seismic activity (and associated fault displacement) is inconsequential, particularly given the existing extensive fracture network. The PSHA also indicates that fractures within the repository area having no measured displacements can be expected to experience on the order of 0.1 to 1 cm of displacement (reactivation) at the 10^{-8} annual-exceedance probability (DTN: MO0401MWDRPSHA.000 [DIRS 185014], files: *s7c.frac_mean* and *s8c.frac_mean*; CRWMS M&O 1998 [DIRS 103731], Figures 8-10 and 8-13 for points 7c and 8c). Thus, the results from the PSHA indicate that movement along existing fractures is expected to be the predominant effect of seismic activity on fractures rather than the development of new fractures.

The small seismic displacement for intact rock, less than 0.1 cm for an annual-exceedance probability of 10^{-8}, corresponds to the level of displacement that occurred as a result of thermal stress in the Drift Scale Test, as measured in multiple-point borehole extensometers (BSC 2004 [DIRS 169864], Figure 7.4.2-2). The simulations of the displacement response in the Drift Scale Test, based on elastic THM processes, were found to be in agreement with measurements. The dominant mode for stress-induced permeability change for THM processes was found to be elastic fracture opening or closing caused by changes in stress normal to the fractures, as opposed to changes in matrix permeability (BSC 2004 [DIRS 169864], Section 8.2). For similar displacements and stresses (as found in the DST) associated with seismic motion, the same conclusions apply to both the unsaturated zone and saturated zone. Therefore, the small seismic displacements in the intact rock matrix will have a negligible effect on rock-matrix hydrologic properties and may be excluded on the basis of low consequence.

Field observations indicate that the rock at Yucca Mountain is highly fractured and that existing fractures and joints have been subject to reactivation (BSC 2004 [DIRS 166107], Section 6.3). Evidence for reactivation of joints includes the presence of thin brecciated zones along cooling joints and observable slip lineations along joint surfaces (Sweetkind et al. 1996 [DIRS 106957]). Cooling joints, formed originally as tensional openings, have only normal displacement, not shear. However, thin selvages of tectonic breccia are locally present along the trace of cooling joints, indicating later slip. Formation of brecciated/gouge zones is discussed in excluded FEPs 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock) and 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults). Based on these

field observations, the fracture network appears to act as a significant preexisting weakness in the rock mass that can accommodate extensional strain through distributed slip along many reactivated joints. Coupled with the results of the PSHA for movement in the intact rock, it appears that changes in strain are expected to be accommodated through reactivation of existing fractures, rather than through the initiation of new fractures.

Evaluation of Changes in Fracture Hydrologic Properties for Infiltration as a Result of Reactivation—The reactivation of fractures can result in a change in fracture properties. The effects of changes in fracture system properties due to seismic activity on infiltration are negligible because of the high fracture bedrock permeabilities used in the infiltration model (SNL 2008 [DIRS 182145], Section 6.5.2.6). Sensitivity analyses indicate that futher increase in bedrock permeability would also have a negligible effect on infiltration (SNL 2008 [DIRS 182145], Section 7.1.4). Reduction in bedrock permeabilities could only result in decreased net infiltration, which would have no significant adverse effect on repository performance.

Evaluation of Changes in Fracture Hydrologic Properties in the Unsaturated Zone as a Result of Reactivation—The reactivation of fractures can result in a change in fracture properties. The effects of changes in fracture system properties due to seismic activity on mountain-scale flow and radionuclide transport in the unsaturated zone have been investigated using a sensitivity approach (Appendix I). Changes in fracture hydrologic properties were considered in terms of variation in fracture aperture induced by fault displacement. The effects of fracture aperture changes are examined because several fracture hydrologic properties (permeability, capillary pressure, and porosity) are functions of fracture aperture. The sensitivity study was performed (Appendix I) with the nominal UZ three-dimensional flow model using several approaches that together provided bounding cases for determining whether changes in fractures will significantly impact repository performance. The analysis was performed using a dual-permeability active-fracture flow model and was based on fracture aperture changes that could result from changes in strain conditions or other factors. Given a change in fracture aperture, other fracture hydrologic properties (permeability, capillary pressure, and porosity) were estimated using theoretical models (Appendix I). Calculations were then performed for unsaturated flow and transport using the modified fracture properties and the results were compared to the corresponding base case (Section I3.3). The sensitivity study (Appendix I) included two bounding cases: (1) uniform change in fracture properties throughout the UZ flow model domain and (2) change in fracture properties within the faults only. The first bounding case is particularly applicable to this FEP; the latter case is directly applicable to and is discussed in excluded FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults). The two bounding cases were chosen to bound a range of fracture-aperture changes resulting from fault movement. No direct observations for Yucca Mountain relate stress caused by fault displacement to strain and the resultant changes in fracture aperture (Appendix I).

A potential upper bound for the sensitivity analysis lies in the estimated fracture aperture. A maximum ten-fold increase in fracture aperture was selected as the model's upper-bound value. The justification for this treatment (Appendix I) cites distance-strain relationships derived from models for a 1-m displacement along a strike-slip fault at Yucca Mountain, and for a 1-m displacement on a theoretical normal fault. The changes in fracture apertures for the sensitivity analysis were derived presuming a 10-m fault movement along the Solitario Canyon fault and

multiplying the strains cited in the justification for the 1-m faults. The potential upper bound is mentioned here, primarily because the presumed 10-m displacement, although a mean value, is greater than the probabilistically determined (median and 85th quantile) and observed fault displacements. The results of the PSHA (DTN: MO0401MWDRPSHA.000 [DIRS 185014], files: *s2.frac_mean*; CRWMS M&O 1998 [DIRS 103731], Figure 8-3) indicate that, for the Solitario Canyon fault, there is a large uncertainty range in the potential displacements from 3 m (the median value) to approximately 10 m (the 85th quantilevalue) at the 10^{-8} annual-exceedance probability. By contrast, the maximum measured single-event Quaternary displacement (i.e., during the past 1.6 million years) on the Solitario Canyon fault is only 1.3 m (Ramelli et al. 1996 [DIRS 101106], Table 4.7.3). Therefore, the sensitivity analysis parameterization bounds potential changes in fracture aperture that could result from any fault displacement at Yucca Mountain with an annual exceedance probability greater than 10^{-8}.

The results of geomechanical models used to investigate the amount of strain induced by fault movements in the rock at Yucca Mountain suggest that a factor of 10 change in facture aperture would bound the effects of tensile strain from such a fault movement (Appendix I, Section I3.2.4). Based on the cubic law for fracture permeability, a factor of 10 change in aperture leads to a factor of 1,000 change in permeability. Fracture permeabilities reduced by a factor of 1,000 were found to be inconsistent with the infiltration rates imposed on the model, because the bulk permeability was insufficient to accommodate the flow conditions. So, either reduced infiltration rates or a smaller reduction factor for the aperture would need to be used. Because the reduced apertures lead to reduced transport rates, this sensitivity does not show a potential adverse impact on performance. Therefore, a case with a reduction in aperture of a factor of 0.2 is considered sufficient.

The results of the sensitivity study have shown that fracture aperture changes confined to fault zones resulted in virtually no effect on transport behavior in the unsaturated zone (Appendix I, Section I3.3.1) and that increased fracture aperture applied over the entire unsaturated zone domain results in effects that are no more significant than other uncertainties related to infiltration that are included in the TSPA (Appendix I, Section I4).

This result is also supported by the parameter sensitivity study for unsaturated zone flow (BSC 2005 [DIRS 174116]) and corresponding effects on radionuclide transport (SNL 2008 [DIRS 184748], Section 6.6.3[b]). For this sensitivity, fracture permeability is varied by one standard deviation. The sensitivity was conducted for both an increase and decrease in permeability by this factor, with changes to fracture permeability occurring globally over the entire model domain (BSC 2005 [DIRS 174116], Tables 6.2-1 and 6.2-4). The resulting flow fields were analyzed for effects on radionuclide transport. The transport results show that global variations in fracture permeability have only a small effect on transport relative to other uncertainties (SNL 2008 [DIRS 184748], Section 6.6.3[b]). The effects of fracture permeability in these sensitivities are expected to be overestimated because the effects of changes in capillary strength, which are negatively correlated with permeability (SNL 2007 [DIRS 181244], Section 6.5.1.1), would tend to offset changes in permeability. This is because increased fracture permeability leads to greater flow in fractures, but the associated reduction in capillary strength (represented by an increase in the fracture α), leads to a reduction in fracture flow through enhanced matrix imbibition. This effect may be seen in the response to unsaturated zone flow distributions between fractures, matrix, and faults with changes in fracture α (BSC 2005

[DIRS 174116], Table 6.4-1 (c)) and by the effects of changes in fracture α on radionuclide transport (SNL 2008 [DIRS 184748], Figures 6-25[b] and 6-26[b]).

Evaluation of Changes in Fracture Hydrologic Properties in the Saturated Zone as a Result of Reactivation—The primary response of regional water levels to seismic events, as discussed in excluded FEP 1.2.10.01.0A (Hydrologic Response to Seismic Activity), is a transient change (increase or decline) in the water table. Flow and transport in the saturated zone is dominated by fault orientation and existing fractures, fracture clusters, and fracture spacing, collectively labeled as flowing intervals in the SZ flow and transport model (SNL 2008 [DIRS 183750], Section 6.5.2.4). This model (SNL 2008 [DIRS 183750], Section 6.5.2.4) uses the flowing intervals concept, which is based on site data and indicates that only some of the fractures within the saturated zone contribute to the flow. Additionally, the SZ flow and transport model abstraction produces radionuclide breakthrough curves that implicitly include fracture zones in the nominal case by considering the horizontal anisotropy in permeability located in the fractured volcanic units downgradient of the repository (SNL 2008 [DIRS 183750], Section 6.5.2.10).

The saturated zone model does not explicitly address changes to fracture or fault properties due to changes in stress. Rather, the model evaluates uncertainties assigned to flowing interval properties.

The uncertainty in the effective hydrologic properties incorporated in the SZ flow and transport model (SNL 2008 [DIRS 183750], Table 6-8), which reflects the cumulative changes in hydrologic properties since deposition, coupled with the scale of the model, overwhelms the changes in fracture properties, and their effects on flow paths and transport times, that would be caused by future seismic events. The SZ flow and transport model evaluates uncertainties, such as horizontal anisotropy in permeability, flowing interval spacing, flowing interval porosity in the volcanic units, and longitudinal dispersion (SNL 2008 [DIRS 183750], Table 6-8). Transport times through the saturated zone are sensitive to uncertainty in the specific discharge scaling parameter and flowing interval spacing. The uncertainty incorporated in the horizontal anisotropy (which accounts for the uncertainty in maximum and minimum in situ stresses imposed on fractures and faults) results in transport paths varying by several kilometers (SNL 2008 [DIRS 183750], Figure 6-6). Thus, the scale of the SZ flow and transport model, together with incorporated parameter uncertainties used for the analysis, overwhelms any potential changes in the hydrologic properties of fractures associated with future seismic activity. Therefore, the effects of changes in the hydrologic properties of fractures on groundwater flow and radionuclide transport in the saturated zone are excluded based on low consequence.

Furthermore, existing regional stresses imposed on fracture hydrologic properties reflect the crustal extension stresses in effect today. A fracture's physical properties (orientation, length, connectivity, and clustering) are reflective of a cumulative response to seismic events in existence in the last 10 to 12 million years. A change in regional fracture properties, given predicted seismic activity, will be minimal relative to the multiple seismic events imposed on the region over this period. Therefore, it is inferred that regional fracture hydrologic properties will not be significantly altered from current conditions by future seismic activity. As a result, effects of changes in fracture hydrologic properties, resulting from seismic activity, are excluded based on low consequence.

In summary, the effect of future seismic events on the porosity and permeability of fractures will not significantly alter flow and transport in the region of the Yucca Mountain repository. Reactivation of existing fractures is expected to be the main result of seismic activity rather than the opening of new fractures such that any new fractures formed would have a negligible effect on hydrologic or transport properties. The effects of changing the size of fracture apertures on the hydrologic properties of fractures and hence, on groundwater flow and radionuclide transport in the unsaturated zone, are small in comparison with the uncertainty in unsaturated zone flow and transport related to infiltration that is incorporated in the TSPA. Similarly, the uncertainty in hydrologic properties incorporated in the SZ flow and transport model are large in comparison with any changes in fracture hydrologic properties resulting from seismic activity.

Based on the previous discussion, omission of FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.06.03.0A

FEP NAME:

Seismic Activity Alters Perched Water Zones

FEP DESCRIPTION:

Strain caused by stress changes from tectonic or seismic events could alter the rock permeabilities that allow formation and persistence of perched-water zones.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

A change in stress due to seismic activity has the potential to result in strains that affect groundwater flow and radionuclide transport properties, leading to increased or decreased dose. The question raised by this FEP is whether seismic activity and any associated changes in rock permeabilities could affect the formation and persistence of perched water. Perched water has only been found at Yucca Mountain near the TSw–CHn interface. In particular, the presence of perched water appears to be correlated with the presence of zeolitically altered minerals within the Calico Hills nonwelded unit (CHn) (SNL 2007 [DIRS 184614], Section 6.2.2.2). The presence of perched water appears to be a function of the lithology and local percolation flux. Seismic effects on permeability are discussed in excluded FEPs 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock), 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults), and 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures). Zeolitic alteration is found primarily in the basal vitrophyre of the TSw, CHn, Prow Pass, and Bullfrog units (BSC 2004 [DIRS 170031], Section 6.2.2). The observed relationship of the vitric-zeolitic tuff contact and other stratigraphic contacts of vocanic units indicates that zeolitization occurred prior to uplift and rotation (Broxton et al. 1987 [DIRS 102004], p. 101). The timing of eruptions between 11.3 and 12.5 million years ago constrain the timing of uplift and rotation, leading to the conclusion that zeolitization occurred at least 11.3 million years ago (Broxton et al. 1987 [DIRS 102004], p. 101). This result is consistent with petrofabric constraints on the age of zeolitic alteration (Bish et al. 1984 [DIRS 106336], p. 72). Therefore, any effects of tectonic or seismic processes on the lithologic units associated with perched water should have already occurred. The process of zeolitic alteration occurs when the original volcanic glass dissolves and zeolites precipitate at ambient temperatures in a water-rich environment, and therefore is independent of seismic activity (BSC 2004 [DIRS 169734], Section 3.3.4.6). The fact that perched water occurrence is strongly correlated with zeolitic lithology indicates that the effects of seismic and tectonic processes do not play a significant role in the formation and persistence of perched water.

The concept that normal displacement along west-dipping faults on the east flank of Yucca Mountain could cause perching of water if fault displacement has created permeability contrasts on opposite sides of a fault was discussed by Montazer and Wilson (1984 [DIRS 100161], Figure 14, pp. 47 to 48). Given the declining extension rates and seismic activity described in

excluded FEP 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults), the existing contribution of permeability barriers at faults to perching of water should not be significantly changed by future fault displacement in response to tectonic or seismic events.

Based on the previous discussion, omission of FEP 2.2.06.03.0A (Seismic Activity Alters Perched Water Zones) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.06.04.0A

FEP NAME:

Effects of Subsidence

FEP DESCRIPTION:

Subsidence above the mined underground facility or other openings may affect the properties of the overlying rocks and surface topography. Changes in rock properties, such as enhanced permeability, may alter flow paths from the surface to the repository. Changes in surface topography may alter run-off and infiltration, and may perhaps create impoundments.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Subsidence can occur as a result of underground excavations. Subsidence calculations for Yucca Mountain were done as the first step in the analysis of drift-scale thermal-hydrological-mechanical effects (BSC 2004 [DIRS 169864]). The model domain extends upward to the ground surface (BSC 2004 [DIRS 169864], Tables 4.1-3c and 4.1-3d). The simulation was conducted by first excavating the drift and then implementing a thermal line load into the drift opening (BSC 2004 [DIRS 169864], Sections 6.5.1 and 6.6). Subsidence data at the drift crown and at the ground surface directly above the drift were extracted from model results in DTNs: LB0306DRSCLTHM.001 [DIRS 169733] (files: *Fmn1_0.sav* and *Fll1_0.sav*) and LB0308DRSCLTHM.001 [DIRS 171567] (file: *Fll1c1_001y.sav*), and have been entered in a scientific notebook (Rutqvist 2006 [DIRS 183044], pp. 38 and 39). These results show that the simulated subsidence from excavation of a single drift, without input of heat, is greater at the drift crown than at the ground surface. The maximum subsidence in the absence of drift collapse predicted was 1.4 cm at the drift crown and 0.07 cm at the ground surface, for a drift in Tptpll low-quality rock. In the case of drift collapse, displacements of 8 to 12 cm were found about 12 m above the drift center, showing a trend of decreasing displacements with increasing distance from the drift (BSC 2004 [DIRS 166107], Figures V-1, V-5, and V-7). These calculated subsidence distances would be indistinguishable from natural variations in the ground surface, are far smaller than the absolute elevation uncertainty (7 m) in the model describing infiltration at Yucca Mountain (SNL 2008 [DIRS 182145], Section 6.5.2.1[a]), and are too small to affect run-off or infiltration, or to create impoundments. Based on these considerations, subsidence is expected to have a negligible impact on large-scale groundwater flow in the unsaturated zone, and on surface topography.

Brady and Brown (1985 [DIRS 126811], Figure 16.18) present an empirical correlation for the ratio of the maximum subsidence, S, to the extraction thickness, m (height of the opening), as a function of the width, w, of a rectangular opening and the depth of the opening below the ground surface, d. A circular drift, being smaller, will cause less subsidence than a rectangular opening; that is, the empirical correlation represents an upper bound. For repository drifts, $w = m = 5.5$ m and $d = 300$ m. For this combination of variables, the maximum subsidence is off the chart on

the low side; that is, *S/m* is substantially below the lowest curve presented at a value of 0.05, which corresponds to a value of *S* that is substantially below 27.5 cm.

Corroborative evidence comes from mining experience. In coal mining, subsidence has been found to occur when more than 50% of the coal bed was removed (Keller 1992 [DIRS 146831], p. 142). In the case of Yucca Mountain, the percentage of earth removal is very small. The emplacement drift diameter (5.5 m) is less than 10% of the drift spacing of 81 m between center lines (SNL 2007 [DIRS 179466], Table 4-1, Parameter Numbers 01-10 and 01-13). The effects of changes to fracture characteristics around emplacement drifts caused by stress relief have been found to be small to moderate and to have no adverse effects on seepage (BSC 2004 [DIRS 169864], Section 8.1; BSC 2004 [DIRS 167652], Section 6.6.3). Effects on permeability further from the drift have been shown to decrease (BSC 2004 [DIRS 169864], Figures 6.5.1-1 and 6.6.1-1).

Based on the previous discussion, omission of FEP 2.2.06.04.0A (Effects of Subsidence) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.06.05.0A

FEP NAME:

Salt Creep

FEP DESCRIPTION:

Salt creep may lead to changes in the stress field, compaction of the waste packages, and consolidation of the long-term components of the sealing system.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Salt creep is the continuous deformation of a salt formation as a response to an applied stress such as overburden pressure. Yucca Mountain is located in the southwestern Nevada volcanic field and consists of tilted fault blocks composed of layered sequences of ash flow, ash-fall, carbonates, and bedded tuffs of Miocene age (BSC 2004 [DIRS 170029], Sections 6 and 6.5, and Table 6-2; SNL 2007 [DIRS 174109], Sections 6.3 and 6.4, Table 6-2; BSC 2004 [DIRS 169734], Section 3.3.4; Day et al. 1998 [DIRS 100027]). Salt or evaporite deposits of sufficient volume to result in significant salt creep have not been reported to exist near Yucca Mountain. Any sizable deposit would be evident in well logs or high sodium or chloride measurements in groundwater. Measured sodium levels at the saturated zone site scale flow model range from 30 to 200 mg/L (SNL 2007 [DIRS 177391], Section A6.3.4.9) and measured chloride ranges from 3 to 125 mg/L (SNL 2007 [DIRS 177391], section A6.3.4.2). By comparison, at the Waste Isolation Pilot Plant site in Carlsbad, NM, sodium concentrations in the Rustler/Culebra dolomite (non-sodium) formation range from 54 mg/L to 63,000 mg/L with most wells containing more than 10,000 mg/L (Siegel et al. 1991 [DIRS 183944], Figure 1-8) reflecting dissolution of the underlying Salado (halite) formation and contamination of wells throughout the area. Thus, the presence of any sizable salt formation would be noticed in well logs or high sodium or chloride concentrations in wells.

The repository is not planned to be developed in a salt dome or cavern, and the related process of lithologic flow is therefore not relevant to the geologic setting for Yucca Mountain. Any salt formations in the area would necessarily be either too small or so far away as too not be of significance to flow and transport in the repository area, and there are no rocks in the repository that are sufficiently plastic to creep in a manner similar to salt.

Based on the previous discussion, omission of FEP 2.2.06.05.0A (Salt Creep) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.07.01.0A

FEP NAME:

Locally Saturated Flow at Bedrock/Alluvium Contact

FEP DESCRIPTION:

In arid areas and particularly in areas with shallow soils, infiltration can descend to the alluvium/bedrock interface and then proceed along that interface as a saturated flow system distinct from the surface water flow and distinct from the local water table. This phenomenon usually requires that the permeability of the bedrock be considerably less than that of the overlying soils.

SCREENING DECISION:

Excluded – Low consequence

SCREENING JUSTIFICATION:

The phenomenon of infiltration resulting in a saturated condition at the bedrock–alluvium contact, with water then either infiltrating into fractures or contributing to lateral drainage, is also referred to as interflow. This term refers to the lateral flow of liquid water in the unsaturated zone that can occur during and following precipitation events. This flow is driven by a lateral head gradient component, which is typically the result of a sloping bedrock surface (SNL 2008 [DIRS 182145], Section 5.1[a]).

Interflow is an excluded process on the basis of low consequence for the following reasons. First, most of the infiltration model domain is characterized by relatively low slopes. For example, the median slope for the infiltration model domain is approximately 10 degrees from horizontal and 90% of the domain has a slope less than 25 degrees. The lower the slope, the less the lateral head gradient (SNL 2008 [DIRS 182145], Section 5.1[a]). Second, bulk bedrock saturated hydraulic conductivity values are generally higher than the saturated hydraulic conductivity values in the overlying soil (SNL 2008 [DIRS 182145], Section 6.5.2.6), and therefore once water reaches the soil–bedrock interface, it would tend to enter bedrock instead of flowing laterally along the interface.

Observations also support this justification. For example, if significant interflow were occurring in the area of Yucca Mountain, one would expect that stream flows would continue for several days following large precipitation events, seeps would form at the toes of slopes, and mass wasting would occur when thin soils on steep slopes became saturated. None of these indicators of significant interflow characterize the site. Stream flows observed in the washes draining from Yucca Mountain tend to persist only as long as the significant precipitation events events that cause them (SNL 2008 [DIRS 182145], Section 7.1.3), seeps have only been described for areas tens of kilometers away from Yucca Mountain (BSC 2004 [DIRS 169734], Section 5.2.2.3), and recent mass wasting (debris flows) are rarely documented, such as that documented following a July 1984 storm (BSC 2004 [DIRS 169734], Section 3.4.6.4).

In areas that have low bedrock permeability, if the soil becomes completely saturated, then surface runoff will occur, which is described in included FEP 2.3.11.02.0A (Surface Runoff and Evapotranspiration). In areas that have low bedrock permeability, interflow can occur, but this flow is limited by the lateral permeability of the over-lying soil, and this layer of water is subject to depletion by evapotranspiration if the depth to bedrock is less than or equal to the rooting depth (SNL 2008 [DIRS 182145], Section 6.3.3). If interflow occurs in certain areas, as a result of low bedrock permeability, and subsequent increased net infiltration in down-gradient areas of the interflow with high bedrock permeability, this increased localized net infiltration will have an insignificant effect on seepage, as a result of the damping and homogenizing of downward-moving transient pulses by the Paintbrush nonwelded hydrogeologic unit (SNL 2007 [DIRS 184614], Section 6.1.2).

Based on the previous discussion, omission of FEP 2.2.07.01.0A (Locally Saturated Flow at Bedrock/Alluvium Contact) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.07.02.0A

FEP NAME:

Unsaturated Groundwater Flow in the Geosphere

FEP DESCRIPTION:

Groundwater flow occurs in unsaturated rocks in most locations above the water table at Yucca Mountain, including at the location of the repository. See related FEPs for discussions of specific issues related to unsaturated flow.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP is included in the unsaturated zone process models for mountain-scale flow, radionuclide transport, drift seepage, and seepage chemistry. The mountain-scale flow model is for three-dimensional, steady flow in a heterogeneous dual-permeability system that includes discrete fault zones (SNL 2007 [DIRS 184614], Sections 6.1, 6.2, and 6.6). Flow fields generated by the UZ flow model are included in the TSPA via the abstractions for drift seepage (SNL 2007 [DIRS 181244], Section 6.6.5.1 and Table 4-1[a]) and radionuclide transport simulations (SNL 2008 [DIRS 184748], Addendum Section 6.5.1).

Parameter values needed to describe unsaturated flow are developed in several reports. Data input for model calibration is developed in *Analysis of Hydrologic Properties Data* (BSC 2004 [DIRS 170038], Section 6). The van Genuchten α and m parameter values, respectively for the saturation–capillary pressure and relative permeability functions, and the active-fracture parameter γ value for each model layer of the fracture and matrix continua are developed in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3). Further calibration of the parameters using the three-dimensional site-scale flow model is presented in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.2). The active fracture model is described and validated in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Sections 6.3.7 and 7). TSPA implementation for the UZ flow parameters is described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Sections 6.8, 8.6, and 8.8).

Unsaturated groundwater flow in the unsaturated zone is the driving force for radionuclide transport through the unsaturated zone. This FEP is addressed through the use of unsaturated zone flow fields (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) in TSPA multirealization simulations, as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Addendum Section 6.5.1). Local radionuclide transport velocities in the rock matrix and fractures are computed using the water flux and saturations provided by the UZ flow model (SNL 2008 [DIRS 184748], Addendum Section C1). This includes advective velocities within the fracture continuum and

matrix continuum, as well as advective velocities between the fracture and matrix continua (SNL 2008 [DIRS 184748], Addendum Section 6.4.3).

Seepage-relevant parameters for the drift-scale seepage model are based on measurements reported in *In Situ Field Testing of Processes* (BSC 2004 [DIRS 170004, Sections 6.1 and 6.2) and developed in *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.6.3.2 and 6.6.3.3). Unsaturated flow processes are accounted for in the seepage abstraction by using results from process models that account for various relevant aspects of unsaturated groundwater flow. All the seepage process models that feed into seepage abstraction simulate groundwater flow processes in unsaturated rock (SNL 2007 [DIRS 181244], Section 6.4). Percolation flux distributions are provided to the seepage abstraction model by the UZ flow model (SNL 2007 [DIRS 184614], Section 6.6.2.4), which accounts for groundwater flow on a larger scale than is treated by the drift-scale seepage model, influenced by climate changes, infiltration variability, and stratigraphy effects. For ambient seepage, the fracture flow processes in the drift vicinity and the resulting seepage rates are predicted by model simulations from the seepage model for performance assessment (BSC 2004 [DIRS 167652], Sections 6.2.1 and 6.6), and abstracted in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.2). Results are available as lookup tables in DTNs: LB0702PASEEP01.001 [DIRS 179511] and LB0702PASEEP02.001 [DIRS 181635]. These are used in the TSPA model to calculate ambient seepage, by sampling parameter cases of seepage-relevant parameters from the probability distributions defined in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.7.1).

During the thermal period, the ambient seepage rates will be adjusted based on the thermal-hydrologic-modeling results from *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.2), which simulates thermally perturbed groundwater flow processes. Results are given in DTN: LB0301DSCPTHSM.002 [DIRS 163689]. THM and THC effects on fracture flow processes are evaluated with process models that account for groundwater flow processes affected by THM and THC parameter alterations (SNL 2007 [DIRS 181244], Sections 6.4.4.1, 6.4.4.2, and 6.5[a]). It was demonstrated that these potential alterations can be neglected in the TSPA, as the expected changes would lead to less seepage (SNL 2007 [DIRS 181244], Sections 6.5.1.4 and 6.5[a]). See also excluded FEPs 2.1.09.12.0A (Rind (Chemically Altered Zone) Forms in the Near-Field) and 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository).

The effects of unsaturated groundwater flow are also included in the model for seepage water chemistry. The approach used is a plug flow model that has a transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4). The effects of flow on the water chemistry are evaluated in terms of the amount of feldspar dissolution that occurs during flow through the TSw (SNL 2007 [DIRS 177412], Sections 6.3.2.4.4 and 6.3.2.4.5). This is a function of the ambient feldspar dissolution rate, the dissolution rate temperature dependence, the model for the thermal field, and the plug flow model for transport through the TSw (SNL 2007 [DIRS 177412], Section 6.3.2.4.5). The starting point for evaluating potential water compositions in the near field is the composition of ambient pore waters in the TSw. The available pore-water data from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and grouped into four compositional groups (SNL 2007 [DIRS 177412], Section 6.3.2.3). The amount of feldspar

dissolution is passed to TSPA in a lookup table, as the WRIP (SNL 2007 [DIRS 177412], Section 6.3.2.4.5; DTN: SN0703PAEBSPCE.006 [DIRS 181571]).

Uncertainty in unsaturated zone flow has been found to be primarily a result of the uncertainty in infiltration rates (SNL 2007 [DIRS 184614], Section 6.10). The uncertainty in infiltration is incorporated into unsaturated zone flow results through the use of a range of four infiltration boundary conditions (SNL 2007 [DIRS 184614], Section 6.1.4). Therefore, there are four unsaturated zone flow fields for each climate (present-day, monsoon, and glacial-transition) during the first 10,000 years (SNL 2007 [DIRS 184614], Section 6.1.4). The probabilities of each flow field are conditioned on results from the infiltration model, as well as temperature and chloride observations from the unsaturated zone (SNL 2007 [DIRS 184614], Section 6.8). For the post-10,000-year period, the infiltration is accounted for by prescribing the NRC-specified percolation rate at the repository horizon, using a range of four infiltration boundary conditions that approximate a log-uniform distribution of percolations rates from 13 to 64 mm/yr at the repository as specified by proposed 10 CFR 63.342(c) (70 FR 53313 [DIRS 178394]) (SNL 2007 [DIRS 184614], Section 6.1.4).

FEP: 2.2.07.03.0A

FEP NAME:

Capillary Rise in the UZ

FEP DESCRIPTION:

Capillary rise involves the drawing up of water, above the water table or above locally saturated zones, in continuous pores of the unsaturated zone until the suction gradient is balanced by the gravitational pull downward.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Capillary forces are included in the UZ flow model. These forces affect the distribution of water in the unsaturated zone through capillary effects on water flow, also known as capillary wicking (included FEP 2.2.07.02.0A, Unsaturated Groundwater Flow in the Geosphere). Parameters used for modeling capillarity are incorporated within the matrix properties (DTN: LB0207REVUZPRP.002 [DIRS 159672]) and fracture properties (DTN: LB0205REVUZPRP.001 [DIRS 159525]), as described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.1.5). These parameters are used as direct input to the UZ flow model and are incorporated into the output flow fields used in the TSPA model (flow fields are in DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]).

Capillary forces are also incorporated into the capillary-strength parameter ($1/\alpha$) that is implemented in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652]). All the seepage process models that feed into the seepage abstraction simulate groundwater flow processes in unsaturated rack (SNL 2007 [DIRS 181244], Section 6.4). Percolation flux distributions are provided to the seepage abstraction model by the UZ flow model (SNL 2007 [DIRS 184614], Section 6.6.2.4), which accounts for groundwater flow on a larger scale than is treated by the drift-scale seepage model, influenced by climate changes, infiltration variability, and stratigraphy effects. For ambient seepage, the fracture flow processes in the drift vicinity and the resulting seepage rates are predicted by model simulations from the seepage model for performance assessment (BSC 2004 [DIRS 167652], Sections 6.2.1 and 6.6), and abstracted in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.2). Results are available as lookup tables in DTNs: LB0702PASEEP01.001 [DIRS 179511] and LB0702PASEEP02.001 [DIRS 181635], which are used in the TSPA model to calculate ambient seepage by sampling parameter cases of seepage-relevant parameters from the probability distributions defined in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.7.1).

FEP: 2.2.07.04.0A

FEP NAME:

Focusing of Unsaturated Flow (Fingers, Weeps)

FEP DESCRIPTION:

Unsaturated flow can differentiate into zones of greater and lower saturation (fingers) that may persist as preferential flow paths. Heterogeneities in rock properties, including fractures and faults, may contribute to focusing. Focused flow may become locally saturated.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Preferential flow paths, a possible result of heterogeneities in rock properties (including fractures and faults and their spatial variabilities), are accounted for in the predictive models that simulate flow and transport processes in the unsaturated zone. Mountain-scale models, such as the UZ flow model or the UZ transport model, address preferential flow in a different manner than near-field models (or drift-scale models), such as the seepage prediction models or the coupled-processes models for thermal-hydrological and THC processes. The respective ways of treating preferential flow processes for mountain-scale and drift-scale models are explained below.

The UZ flow model, a mountain-scale model comprising the entire unsaturated zone at Yucca Mountain, represents the redistribution of infiltrating water originated from the ground surface in the unsaturated zone, with the stratigraphic layers and their fracture characteristics as well as major faults explicitly taken into account (SNL 2007 [DIRS 184614], Sections 6.1.2, 6.6.2, and 6.7.3). The flux redistribution is based on tuff layer properties including the effects of fracture and matrix interaction. Faults are included in the UZ flow model as discrete features; therefore, flow in faults is also included in the UZ flow model (SNL 2007 [DIRS 184614]). Flow model results indicate that as flow moves downward through the unsaturated zone, the flow tends to focus into fault zones, with the fraction of flow in the faults increasing from about 30% to 40% at the repository horizon to about 60% at the water table (SNL 2007 [DIRS 184614], Section 6.6.2). Because of the resolution of the model, with grid block sizes on the order of tens of meters, small-scale preferential flow (such as the channelling of unsaturated flow into relatively few flowing fractures) is not explicitly simulated in the UZ flow model. Rather, the averaged effect of this small-scale preferential flow is captured in the active fracture model described and validated in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Sections 6.1.7 and 6.3.7, description; Section 7, validation). The active-fracture parameter values for different model layers are calibrated in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Tables 6-6 through 6-9 and 6-13 through 6-16).

For radionuclide transport in the unsaturated zone, the effect of preferential flow is implicitly included through the use of flow fields contained in DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507] for simulations (SNL 2008 [DIRS 184748], Addendum Section 6.5.1 and Section 6.6.2[b]). In TSPA model runs, flow fields are used directly by the transport modeling code FEHM (FEHM V. 2.21 [DIRS 165741], STN: 10086-2.21-00). *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748]) provides transport parameters in DTNs: LA0701PANS02BR.003 [DIRS 180497] and LB0702PAUZMTDF.001 [DIRS 180776] for use in the TSPA model, and provides transfer function data for the particle tracking algorithm for use in the TSPA model in DTN: MO0704PAPTTFBR.002 [DIRS 180442].

Drift-scale models focus on the vicinity of emplacement drifts. These models typically have a more refined grid resolution on the order of a few centimeters to decimeters that allows for explicit representation of preferential flows. Seepage models, for example, represent preferential flow of water into drifts (i.e., in "weeps") on two different scales. First, intermediate-scale focusing of flow from the site scale to the drift scale is accounted for in the seepage abstraction by using appropriate flow-focusing factors. These flow focusing factors increase the percolation fluxes predicted by the UZ flow model in some areas and reduce them in others, to generate appropriate flux boundary conditions for seepage models (SNL 2007 [DIRS 181244], Section 6.6.5.2). The distribution of flow-focusing factors used for seepage calculations is developed in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Sections 6.8), using property values calibrated in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3.2). Second, small-scale preferential flow is explicitly simulated in the seepage process model, developed in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.8), by use of heterogeneous fracture-permeability fields (SNL 2007 [DIRS 181244], Sections 6.4.1.1 and 6.4.2.1). Thus, preferential flow is inherently embedded in the seepage lookup tables for ambient seepage given in DTN: LB0702PASEEP01.001 [DIRS 179511]. Uncertainty in flow focusing is therefore propagated to TSPA models through the use of distributions of flow-focusing factors and lookup tables for seepage.

A similar methodology for representing preferential flows, using flow focusing factors and explicit representation of internal small-scale heterogeneity, is applied in the process model for thermal seepage, which evaluates seepage during thermally perturbed conditions, as described in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]). Thus, preferential flow is also inherently embedded in the thermal seepage results provided in DTN: LB0301DSCPTHSM.002 [DIRS 163689]. Furthermore, instead of using a continuum representation for fracture and matrix flow, an alternative conceptual model was developed that explicitly analyzed the episodic penetration of a single finger flow event in a heated fracture (BSC 2005 [DIRS 172232], Section 6.3). Results from this alternative conceptual model, which are not used in TSPA, are consistent with results from the thermal-hydrologic seepage model used for this abstraction (SNL 2007 [DIRS 181244], Section 6.4.3.2). The abstraction methodology for ambient and thermal seepage is described in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.7.1).

Preferential-flow effects have also been evaluated in *THC Sensitivity Study of Heterogeneous Permeability and Capillarity Effects* (SNL 2007 [DIRS 177413]). The THC seepage model described in this report determines: (1) the effect of THC processes on water chemistry, and (2) the impact of mineral alteration on near-field hydrologic properties and seepage. Flow focusing and fracture permeability heterogeneity were determined to not significantly affect seepage water chemistry (SNL 2007 [DIRS 177413], Section 6.6.3). Also, mineral alteration was shown to have no significant effect on future seepage rates. Therefore, inclusion of these THC effects in the TSPA model was considered unnecessary.

FEP 2.2.07.4.0A (Focusing of Unsaturated Flow (Fingers, Weeps)) is included in the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394]) and with 10 CFR 63.331 [DIRS 180319]. Flow focusing at the intermediate scale is not included in the performance assessment conducted to demonstrate compliance with proposed 10 CFR 63.321 (human intrusion) (70 FR 53313 [DIRS 178394]). Large scale focusing is included in human intrusion scenarios because percolation flux in the unsaturated zone above the repository at the base of the PTn is used to determine the flux downward through the borehole. Intermediate-scale focusing is not included in human intrusion because the seepage model is not implemented for that assessment.

FEP: 2.2.07.05.0A

FEP NAME:

Flow in the UZ from Episodic Infiltration

FEP DESCRIPTION:

Episodic flow could occur in the UZ as a result of episodic infiltration. Episodic flow may affect radionuclide transport.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Although episodes of high precipitation and water percolation are expected to occur during future rain storms, modeling demonstrates that the porous rock matrix in the Paintbrush Tuff nonwelded hydrogeologic unit (PTn), which lies above the Topopah Spring welded hydrogeologic unit (TSw) containing the repository, would attenuate episodic percolation fluxes, smoothing out any near-surface transients (SNL 2007 [DIRS 184614], Section 6.9[a]). As a result, steady groundwater flow is predicted to occur below the PTn in the unsaturated zone. The influence of rapid flow through preferential pathways formed by fractures in the PTn is considered to be volumetrically insignificant compared to flow through the matrix (BSC 2004 [DIRS 169861], Appendix H). Episodic infiltration would therefore have no significant effect on radionuclide releases to the accessible environment (SNL 2007 [DIRS 184614], Section 6.9[a]). Climate change, which leads to transients with durations of hundreds to thousands of years, is addressed in included FEP 1.3.01.00.0A (Climate Change).

The process that drives infiltration is precipitation, which is episodic in nature. However, studies of episodic infiltration and percolation have found that groundwater flow in the PTn is dominated by porous flow (SNL 2007 [DIRS 184614], Section 6.9[a]). The PTn primarily consists of nonwelded to partially welded tuffs and extends from the base of the densely to moderately welded Tiva Canyon welded tuff (TCw) to the top of the TSw, which is densely welded (BSC 2004 [DIRS 169734], Section 3.3.6). Within the repository area, the thickness of the PTn unit ranges from approximately 21 m (70 ft) to over 120 m (400 ft) (Figure D-3). Water flow in the southern part of Solitario Canyon may be transient because the PTn unit is completely offset by the Solitario Canyon Fault in this area. Nevertheless, in these areas, episodic flow is not expected to be significant to performance assessment because the emplacement drifts are located away from Solitario Canyon (SNL 2007 [DIRS 179466], Table 4-1, Parameter 01-01). Furthermore, the southern part of Solitario Canyon Fault does not have a significant role in radionuclide transport (SNL 2007 [DIRS 177396], Figures 6-7 and 6-9 to 6-28). As a whole, the PTn unit exhibits different hydrogeologic properties than the TCw and TSw units that bound it respectively above and below. The TCw and the TSw units both display the low porosity and intense fracturing typical of the densely welded tuffs at Yucca Mountain (BSC 2004 [DIRS 170038], Tables 6-5 and 6-6). In contrast, with its high porosity and low fracture intensity, the PTn rock matrix has a large capacity for storing groundwater and

effectively damps percolation transients at the base of the TCw unit. Water imbibing into the PTn rock matrix, from rapid fracture flow in the TCw above, results in a more uniform distribution of groundwater flux at the base of the PTn after traveling through the entire PTn unit (SNL 2007 [DIRS 184614], Section 6.9[a]). Porous flow through the PTn rock matrix damps out the transient nature of the percolation such that unsaturated zone groundwater flow below the PTn is essentially steady (SNL 2007 [DIRS 184614], Section 6.9[a]).

The effects of transient infiltration events were investigated using a one-dimensional flow model (SNL 2007 [DIRS 184614], Section 6.9[a]). The episodic infiltration calculations used an average infiltration rate of 32 mm/yr, which is the mean percolation flux averaged over the repository for the post-10,000-year period (70 FR 53313 [DIRS 178394], p. 53316). Infiltration flux and percolation flux over the repository footprint have been shown to be quantitatively similar (SNL 2007 [DIRS 184614], Section 6.1.4). The calculations used episodic infiltration pulses of about 10,000 mm/yr over one week every 50 years in combination with a steady background infiltration flux of 28.1 mm/yr to give an average flux of 32 mm/yr (SNL 2007 [DIRS 184614], Section 6.9[a]). This boundary condition was used at two locations having different PTn thicknesses, 21 m and 81 m, representing the range in thickness for this unit over the model domain (SNL 2007 [DIRS 184614], Section 6.9[a]). The results of the episodic flow analyses show that episodic flow damping reduces the effects of episodic flow below the PTn to a maximum range of about 17 mm/yr, which is substantially less than the overall percolation flux uncertainty for the post-10,000-year period of 51 mm/yr (SNL 2007 [DIRS 184614], Figures 6.9-2 and 6.9-3[a] and Table 6.1-3). Lower average infiltration rates, which are representative of present-day, monsoon, and glacial-transition climates for the first 10,000 years, have also been investigated and show similar flow damping effects (BSC 2004 [DIRS 169861], Appendix G). The damping of episodic flow in the PTn is supported by additional calculations (Wu et al. 2000 [DIRS 154918], Section 4.1; Wu et al. 2002 [DIRS 161058]). Furthermore, the PTn overlies the entire repository block (Figure D-3). This damping of transient flow is due to capillary forces and high matrix permeability in the PTn that result in imbibition of water from fractures into the rock matrix. The concept of transient flow attenuation in the PTn is also supported by results of a water-release test at Alcove 4 and the results of line surveys of fracture minerals in the ESF and ECRB Cross-Drift (BSC 2004 [DIRS 170004], Sections 6.7 and 6.14.1).

A further systematic modeling study of damping effects in the unsaturated zone was conducted by Zhang et al. (2006 [DIRS 180273]), using both three-dimensional mountain-scale and one-dimensional vertical column models. The three-dimensional model incorporates a wide variety of field-specific data for the highly heterogeneous formation at the site and provides a more realistic representation, while the simplified one-dimensional flow and transport models are useful for examining the long-term response of the flow system to different infiltration pulses. In the three-dimensional model, the top pulse-infiltration boundary condition is set by concentrating a total amount of net infiltration that would occur in a 50-year period into a one-week infiltration pulse for an average infiltration rate of 4.43 mm/yr. The model's top boundary is subject to nonzero infiltration with a pulse of 2,609 times present-day mean infiltration (Zhang et al. 2006 [DIRS 180273], p. 238) for only one week every 50 years, while during the rest period of every 50 years, the surface boundary is subject to zero infiltration. The modeling results indicate that the PTn unit can attenuate the episodic infiltration flux significantly (Zhang et al. 2006 [DIRS 180273], Figures 5 and 6). Model results show that the total percolation fluxes at the PTn bottom gradually approach the average value of mean infiltration rate for the whole period, and

that eventually the system should reach a dynamic equilibrium condition under the uniform pulses of infiltration. In the areas without faults, vertical flux at the PTn bottom does not rapidly respond to top boundary infiltration pulses. The results indicate that the damping effect happens at the PTn1 through PTn4 subunits. Episodic infiltration pulses directly entering fault zones were found to penetrate to the base of the PTn with less attenuation than other locations, but reductions in peak flux rates were still on the order of 99% (Zhang et al. 2006 [DIRS 180273], Figure 6). Results from the one-dimensional model with higher-rate infiltration scenarios confirm that the damping effect will not be weakened by higher-rate infiltration pulses. The results also show that most percolating water is damped by the subunits at the top of PTn, and that a small percentage of percolation flux is diverted into faults. The highly porous PTn unit attenuates episodic infiltration flux by imbibing water into the rock matrix. Flux allocation analyses suggest that the damping effect at nonfault columns is mainly caused by matrix rock water storage, absorbing and releasing water at different periods. Along fault columns, both lateral flow and rock water storage play an integral role, with the relative importance of these two damping components being location-dependent.

Relatively small amounts of fracture flow may penetrate as fast pathways through fault zones between the ground surface and the repository elevation as evidenced by high ^{36}Cl concentrations in samples taken from the ESF (BSC 2006 [DIRS 179489]). Higher concentrations of this isotope found in the ESF are explained through surface deposition of ^{36}Cl from nuclear weapons testing and subsequent aqueous transport to certain ESF sampling locations in a period of approximately 50 years. Rapid transport could occur as a result of either steady or transient flow. In either case, the key to fast transport through the PTn is for solutes to move through fractures, thus bypassing transport through the rock matrix. However, the flow and transport models indicate that the quantity of water and dissolved constituents that penetrate the PTn as a result of fast pathways (approximately 1% of the total infiltration) is negligible with respect to repository performance (BSC 2004 [DIRS 169861], Appendix H).

Episodic flow resulting from episodic infiltration in the unsaturated zone at Yucca Mountain has also been investigated by Manepally et al. (2007 [DIRS 182155]), in which, longer-term transients that span up to thousands of years were investigated for a range of fluxes that roughly correspond with the 10,000-year percolation flux range required by the proposed regulations for time periods beyond 10,000 years after repository closure (Manepally et al. 2007 [DIRS 182155], Table 4-3; SNL 2007 [DIRS 184614], Section 6.1.4). As for the case with climate change, longer-term transients are expected to penetrate the PTn because of the finite storage capacity of the unit. The magnitude of the transients in the study by Manepally et al. (2007 [DIRS 182155], p. 5-2) were found to be characterized by a standard deviation of about 20% of the mean flux and a maximum range of 50%. By comparison, the standard deviation in the mean flux implemented for the post-10,000-year climate is about 60% and the range is 127% of the mean flux (SNL 2007 [DIRS 184614], Tables 6.1-3 and 6.8-1) over the repository footprint. Therefore, the transient fluctuations are small in comparison with the uncertainty in the mean already incorporated in the TSPA.

The analysis presented here indicates that episodic flow will be attenuated in the PTn, resulting in approximately steady-state flow in the repository host rock and below. Furthermore, the volume of flow through pathways that could lead to episodic flow in the repository host rock has been shown to be small.

Based on the previous discussion, omission of FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.07.06.0A

FEP NAME:

Episodic or Pulse Release from Repository

FEP DESCRIPTION:

Episodic or pulse release of radionuclides from the repository and radionuclide transport in the UZ may occur both because of episodic flow into the repository, and because of pulse releases from failed waste packages.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Episodic or pulse release of radionuclides is of potential significance to the TSPA because this behavior could lead to the release of large quantities of radionuclides over relatively short time spans. Such behavior could occur as a result of fluctuations in the repository conditions and/or changes in the integrity of the EBS, which would affect flow and transport properties. If episodic or pulse release of radionuclides occurs, it could significantly impact the dose to the RMEI or the extent of release of radionuclides to the accessible environment.

Episodic and pulsed release of radionuclides is evaluated within the model developed in *EBS Radionuclide Transport Abstraction* (RTA) (SNL 2007 [DIRS 177407]). The abstraction outlines the principles and assumptions that guided the development of flow and transport models for the TSPA and is used to quantify the time-dependent radionuclide releases from a failed waste package and subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage influx, the environmental conditions in the drift (temperature, relative humidity, water chemistry), and the degradation state of the EBS components. Step changes in the seepage chemistry, such that the solubility of radionuclides might increase or decrease, are also considered. Outputs consist of the rates of radionuclide release to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The RTA model is implemented directly into the TSPA GoldSim model to compute radionuclide release rates from the EBS (SNL 2007 [DIRS 177407], Section 6.1).

The primary source of potential episodic or pulse inflow into the EBS is seepage and condensation flux that drips from the crown (roof) of the drift. Subsequent discussion in this FEP addresses specific sources of episodic or pulse release and their impact on the TSPA.

The RTA considered a “bathtub” model of flow as an alternative conceptual model to the continuous flow-through model that is implemented. The bathtub model simulates episodic releases of radionuclides (SNL 2007 [DIRS 177407], Sections 6.4.1 and 6.6.1) due to the uneven distribution of corroded patches and stress corrosion cracks on the surface of the waste package,

which may, in some cases, cause the accumulation of seepage water in the waste package after initial failure. However, if seepage water accumulates in a waste package prior to formation of a corroded patch below the water level, episodic release could occur, which would be well represented in the TSPA by the "bathtub" flow model. In this situation, matrix imbibition, sorption, and diffusion processes will damp out the effects of this episodic process, so it is of low consequence. The same processes are also expected to render variations in the time at which waste packages fail (due to variations in corrosion rates) to be inconsequential in terms of episodic or pulse releases. These processes are discussed in more detail in included FEP 2.2.07.09.0A (Matrix Imbibition in the UZ), excluded FEP 2.2.08.05.0A (Diffusion in the UZ), and included FEP 2.2.08.09.0B (Sorption in the UZ).

The effect of small-scale variation in permeability on flow channeling near the repository horizon is addressed by the UZ TH seepage model in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.3.1; see also excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). Although precipitation and infiltration are episodic, the percolation flux in the unsaturated zone is effectively steady at the repository horizon (below the PTn) and along radionuclide transport pathways (SNL 2007 [DIRS 181244], Section 6.6.5.1). This basis is developed in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.1.2 and 6.9), which shows that the PTn unit is expected to dampen and homogenize downward-moving transient pulses arising from episodic surface infiltration events. This conclusion is based on a study by Wu et al. (2000 [DIRS 154918], Section 4.1 and Figure 4.1-11). Because the flow in the unsaturated zone at the repository horizon is steady, it follows that the seepage flux that enters the crown of the drift is relatively steady (SNL 2007 [DIRS 181244], Section 6.6.5.1).

In summary, episodic or pulse release of radionuclides from the repository and episodic or pulse transport in the unsaturated zone are excluded from the TSPA on the basis of low consequence. Any episodic/pulse release from the waste package, if it occurs, is expected to be damped out by imbibition, sorption, and diffusion processes in the EBS and unsaturated zone. Episodic precipitation and infiltration will have little effect on the seepage flux into the drift, so it can also be excluded on the basis of low consequence.

Based on the preceding discussion, omission of FEP 2.2.07.06.0A (Episodic or Pulse Release from Repository) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.07.06.0B

FEP NAME:

Long-Term Release of Radionuclides from the Repository

FEP DESCRIPTION:

The release of radionuclides from the repository may occur over a long period of time, as a result of the timing and magnitude of the waste packages and drip shield failures, waste form degradation, and radionuclide transport through the invert.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The effects of waste package failures over a long period of time are included in the source term model for TSPA (SNL 2008 [DIRS 178871], Section 6.3.8). This is done by modeling the environmental conditions of the waste packages in different parts of the repository and by modeling corrosion processes under these environmental conditions that lead to waste package failure. The model developed in *EBS Radionuclide Transport Abstraction* (RTA) (SNL 2007 [DIRS 177407], Section 6.1) is used to quantify the time-dependent radionuclide releases from a failed waste package and subsequent transport through the EBS to the emplacement drift wall/unsaturated zone interface. The basic inputs to the RTA model consist of the drift seepage and drift wall condensation flux, the environmental conditions in the drift (temperature, relative humidity, water chemistry), and the degradation state of the EBS components. Outputs consist of the rates of radionuclide releases to the unsaturated zone as a result of advective and diffusive transport, accounting for the impact of colloids, radionuclide solubility, retardation, and the degree of liquid saturation of the waste form and invert materials. The RTA model, which is implemented directly into the TSPA GoldSim model, allows quantification of radionuclide releases from a failed waste package over the entire compliance period.

Releases from the waste package and engineered barrier system serve as a time-dependent boundary condition to the mountain-scale radionuclide transport model as discussed in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.7). This allows for a general time-dependent radionuclide source term that accounts for long-term releases. Releases from the waste package and engineered barrier system serve as a time-dependent boundary condition to the mountain-scale radionuclide transport model, regardless of when the release occurs, thus allowing for a general time-dependent radionuclide source term that accounts for long-term releases (SNL 2008 [DIRS 184748], Sections 6.4.6 and 6.4.7).

FEP: 2.2.07.07.0A

FEP NAME:

Perched Water Develops

FEP DESCRIPTION:

Zones of perched water may develop above the water table. If these zones occur above the repository, they may affect UZ flow between the surface and the waste packages. If they develop below the repository, e.g., at the base of the Topopah Spring welded unit, they may affect flow pathways and radionuclide transport between the waste packages and the saturated zone.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The seepage abstraction model contains a wide range of seepage possibilities, including flow focusing and spatial variability (SNL 2007 [DIRS 181244], Section 6). Therefore, the potential for effects of perched water above the repository (diversion and subsequent drainage of flow) are indirectly captured in the seepage abstraction model through cases with high percolation flux, which can be as high as seven times the nominal flux (DTNs: LB06123DPDUZFF.001 [DIRS 178587], LB07013DMOUZFF.001 [DIRS 179064], LB07013DGTUZFF.001 [DIRS 179066], LB0702UZP10KFF.002 [DIRS 179324], LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) as described in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6). However, the flow fields predicted by the UZ flow model do not contain perched water bodies above the repository, and no perched water was observed in boreholes drilled through the unsaturated zone above the repository (BSC 2004 [DIRS 169734], Section 5.2.2.4.1).

The effects of existing perched water zones below the repository are also included, and potential changes in these perched-water zones caused by climate changes are also included in the mountain-scale UZ flow model (SNL 2007 [DIRS 184614], Sections 6.2.2, 6.2.5, and 6.6.2). The potential for this effect is captured in the output flow fields developed for use in the TSPA (output flow fields are in DTNs: LB06123DPDUZFF.001 [DIRS 178587], LB07013DMOUZFF.001 [DIRS 179064], LB07013DGTUZFF.001 [DIRS 179066], and LB0702UZP10KFF.002 [DIRS 179324]). UZ flow model results indicate that large-scale lateral diversion occurs in the vicinity of perched water zones because of the low fracture permeability associated with zeolitic alteration (SNL 2007 [DIRS 184614], Section 8.6). Lateral diversion can impact radionuclide transport to the water table, which is included in TSPA models.

This FEP is also included in the preliminary flow fields generated for radionuclide transport simulations in the unsaturated zone (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and

LB0702PAFEM10K.002 [DIRS 179507]). In TSPA model simulations, preliminary flow fields were used by FEHM and used in UZ transport simulations as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Addendum Section 6.5.1).

Uncertainty in the extent of perched water is captured through the use of a range of infiltration rates (SNL 2007 [DIRS 184614], Section 6.8.5). The resulting flow fields reflect the uncertainty in the infiltration rates, which subsequently impact the extent of perched water developoment in the flow fields used for TSPA.

This FEP is included in the performance assessments conducted to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the groundwater protection standard (10 CFR 63.331 [DIRS 180319]). However, the development of perched water is not included in the human-intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because the flow and transport pathway considered in that assessment (through a borehole between the repository and saturated zone) is not impacted by the presence of perched water or low permeability layers in the unsaturated zone.

FEP: 2.2.07.08.0A

FEP NAME:

Fracture Flow in the UZ

FEP DESCRIPTION:

Fractures or other analogous channels may act as conduits for fluids to move into the subsurface to interact with the repository and as conduits for fluids to leave the vicinity of the repository and be conducted to the saturated zone. Water may flow through only a portion of the fracture network, including flow through a restricted portion of a given fracture plane.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The UZ flow model is based on the dual-permeability concept, with the fractures represented by a continuum (BSC 2004 [DIRS 170035], Section 6.3; SNL 2007 [DIRS 184614], Section 6.1.2). The fracture continuum represents the spatially averaged flow through discrete fractures. The fracture continuum interacts with the matrix continuum, which represents matrix blocks separated by fractures. Fracture continuum properties, including permeability, porosity, fracture-matrix interface area per unit rock volume, van Genuchten α and m parameters for the saturation–capillary pressure and relative permeability functions, and active fracture parameter γ, for each unsaturated zone model layer, are used as input to the UZ flow model (DTNs: LB0205REVUZPRP.001 [DIRS 159525], LB0611MTSCHP10.001 [DIRS 178586], LB0611MTSCHP30.001 [DIRS 180293], LB0612MTSCHP50.001 [DIRS 180294], and LB0612MTSCHP90.001 [DIRS 180295]) listed in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Table 4.1-1). Permeabilities and values for van Genuchten α are calibrated as described in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3). The fracture-continuum properties are used as inputs to the UZ flow model, and their effects are incorporated into the output flow fields developed for use in the TSPA (output flow fields are in DTNs: LB06123DPDUZFF.001 [DIRS 178587], LB07013DMOUZFF.001 [DIRS 179064], LB07013DGTUZFF.001 [DIRS 179066], and LB0702UZP10KFF.002 [DIRS 179324]). Output flow fields for the fracture continuum are presented in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.6.2).

The top boundary condition for the UZ flow model is set by the infiltration maps output by *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5). When the water content at soil–bedrock contact reaches field capacity, fracture flow is initiated in the bedrock (SNL 2008 [DIRS 182145], Section 6.3.3). Channeling in the unsaturated zone fracture continuum is captured as discussed for included FEP 2.2.07.04.0A (Focusing of Unsaturated Flow (Fingers, Weeps)), including the use of the active fracture model in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Section 6.3), and the development of the distribution of flow-focusing factors in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.6.5).

In the unsaturated zone, fracture flow plays an important role in the transport of radionuclides. In TSPA model simulations, the effect of fracture flow on radionuclide transport (advection) is included through FEHM's use of pregenerated flow fields (DTNs: LB0612PDFEHMFF.001 [DIRS 179296]; LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) in unsaturated zone transport simulations as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Addendum Section 6.5.1). *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748]) provides transport parameters in DTNs: LA0701PANS02BR.003 [DIRS 180497] and LB0702PAUZMTDF.001 [DIRS 180776] for use in the TSPA, and provides transfer function data for the particle tracking algorithm for use in the TSPA in DTN: MO0704PAPTTFBR.002 [DIRS 180442].

Percolation flux distributions are provided by the UZ flow model for use in the seepage abstraction model (SNL 2007 [DIRS 181244], Section 6.6.5.1). The UZ flow model accounts for fracture flow on a larger scale (influenced by climate changes), infiltration variability, and stratigraphy effects. Flow-focusing effects (channeling) are included, as discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.6.5.2). Flow processes in fractures or other channels are important for the seepage abstraction, because the amount of seepage is determined by the capacity of the fracture network to divert flow around the drifts as a result of capillary forces (SNL 2007 [DIRS 181244], Section 6.3.1). All the seepage process models that feed into seepage abstraction simulate flow processes in fractured rock (SNL 2007 [DIRS 181244], Section 6.4). Spatial variability in the fracture flow, potentially leading to water flow through only a portion of the fracture network, is accounted for by using a stochastic continuum representation. For ambient seepage, the fracture flow processes in the drift vicinity and the resulting seepage rates are predicted by model simulations from the seepage model for performance assessment (BSC 2004 [DIRS 167652], Sections 6.3.2 and 6.3.3) and abstracted in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.4.2 and 6[a]). Results are available as look-up tables in DTN: LB0702PASEEP01.001 [DIRS 179511]. These will be used in the TSPA to calculate ambient seepage; uncertainty in ambient seepage is accounted for by sampling parameter cases of seepage-relevant parameters from the probability distributions defined in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Sections 6.7.1 and 6.3[a]).

During the thermal period, the ambient seepage rates will be adjusted based on the TH-modeling results from *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]), which simulates thermally perturbed fracture flow conditions. In the TSPA model, thermal effects on seepage are represented in a simplified manner. When the temperature is under 100°C, ambient seepage is used. When the temperature is 100°C or above, seepage is not considered. Results are given in DTN: LB0301DSCPTHSM.002 [DIRS 163689]. The abstraction methodology for thermal seepage is developed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2). THM and THC effects on fracture flow processes are evaluated with process models that account for fracture flow affected by THM and THC parameter alterations (SNL 2007 [DIRS 181244], Section 6.4.4). It was demonstrated that these potential alterations need not be addressed in the TSPA model (SNL 2007 [DIRS 181244], Section 6.5.1.4); see also excluded FEP 2.1.09.12.0A (Chemistry of Water Flowing into the Drift), excluded FEP 2.2.10.06.0A (Thermo-chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)), and excluded FEP 2.2.10.04.0A (Thermo-mechanical Stresses Alter Characteristics of Faults near Repository).

Flow processes in fractures or other channels affect modeled THC coupled processes because of: (1) their strong effect on TH behavior (SNL 2007 [DIRS 181244], Section 6.4.4), and (2) their strong effect on water and gas chemistry (SNL 2007 [DIRS 177404], Section 6.2.1). The latter primarily involves volatilization of steam and CO_2 from the rock matrix-water and subsequent transport and condensation in fractures. The amount of mobilized CO_2 with steam directly affects the pH of the condensate, which in turn affects the degree of water–rock interaction and water chemistry. These THC processes are influenced by the fracture characteristics, such as orientation, aperture, asperity, length, connectivity, and fillings. The seepage chemistry abstraction uses a plug flow model that has a transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4). The effects of flow on the water chemistry are evaluated in terms of the amount of feldspar dissolution that occurs during flow through the TSw (SNL 2007 [DIRS 177412], Sections 6.3.2.4.4 and 6.3.2.4.5). This is a function of the ambient feldspar dissolution rate, the dissolution rate temperature dependence, the model for the thermal field, and the plug flow model for transport through the TSw (SNL 2007 [DIRS 177412], Section 6.3.2.4.5). The starting point for evaluating potential water compositions in the near field is the composition of ambient pore waters in the TSw. The available pore-water data from the four repository host units (Tptpul, Tptpmn, Tptpll, Tptpln) were evaluated and grouped into four compositional groups (SNL 2007 [DIRS 177412], Section 6.3.2.3). The amount of feldspar dissolution is passed to TSPA in a lookup table, as the WRIP (SNL 2007 [DIRS 177412], Section 6.3.2.4.5; DTN: SN0703PAEBSPCE.006 [DIRS 181571]). The effects of fracture flow are also included in the treatment of infiltration uncertainty for the TSPA (SNL 2007 [DIRS 184614], Section 6.8). Infiltration uncertainty is represented through four discrete infiltration scenarios (ranging from low to high infiltration), which are sampled in the TSPA model according to flow weighting factors (SNL 2007 [DIRS 184614], Section 6.8). This FEP is included in the determination of the flow weighting factors fed to the TSPA model (SNL 2007 [DIRS 184614], Section 6.8; DTN: LB0701PAWFINFM.001 [DIRS 179283]).

FEP: 2.2.07.09.0A

FEP NAME:

Matrix Imbibition in the UZ

FEP DESCRIPTION:

Water flowing in fractures or other channels in the unsaturated zone may be imbibed into the surrounding rock matrix. This may occur during steady flow, episodic flow, or into matrix pores that have been dried out during the thermal period.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Matrix imbibition is included in the process model for unsaturated zone flow at the mountain scale (SNL 2007 [DIRS 184614], Section 6.1.2). Matrix imbibition refers to the movement of water into the matrix as a result of capillary forces. This process affects the distribution of flow between fractures and matrix in a dual-permeability flow model for fractured rock. The flow simulations in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.6) are for steady-state flow. Imbibition is captured in the UZ flow model through capillarity modeling, which uses matrix and fracture properties as model input. Therefore, the effect of imbibition is incorporated in the output flow fields (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) used in the TSPA. Matrix imbibition is reflected in the increase in matrix saturation that is simulated when changing to a wetter climate state. Matrix imbibition is also important in damping the effect of episodic infiltration, as discussed in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.9[a]). Also, see FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration), which is excluded from TSPA on the basis of low consequence. Matrix imbibition is also captured in the site-scale UZ flow model and the UZ flow fields that are used to prescribe the upper boundary condition water fluxes to the MSTHM process model simulations (SNL 2007 [DIRS 184614], Section 6.9[a]). The output flow fields DTNs given above are used by FEHM in unsaturated zone transport simulations as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.1 in AD01).

The effects of matrix imbibition are also included in the model for seepage water chemistry through changes in the percolation flux rates. The percolation flux values used in the model are based on fluxes at the PTn/TSw boundary predicted by the UZ flow model representing each climate state (SNL 2007 [DIRS 184614], Section 6.9[a]). The approach used is a plug flow model that has a transport velocity equal to the percolation flux divided by the product of the average porosity and the average water saturation (SNL 2007 [DIRS 177412], Section 6.3.2.4.4).

Ambient seepage into the repository drifts is mainly governed by flow in the fractures in the units of the repository horizon, as discussed in *Abstraction of Drift Seepage* (SNL 2007

[DIRS 181244], Section 6.4.1.1). Thus, in the predictive model for ambient seepage, that is, the seepage calibration model (BSC 2004 [DIRS 171764], Section 6.3.3.2) and the seepage model for performance assessment (BSC 2004 [DIRS 167652], Section 6.3), matrix imbibition is not modeled.

In contrast, *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.2.1.1.1) explicitly accounts for matrix imbibition using appropriate dual-permeability modeling concepts. This is needed because the thermal perturbation of the unsaturated rock results in significant transfer of liquid and gas from the matrix into the fractures and vice versa. The UZ flow model (which provides the percolation flux distributions used for seepage calculations; see SNL 2007 [DIRS 181244], Section 6.6.5.1) also accounts for the impact of matrix imbibition in an explicit manner. Thus, matrix imbibition effects are taken into account for seepage under thermal conditions as used in the seepage abstraction. Matrix imbibition tests are reported in *In-Situ Field Testing of Processes* (BSC 2004 [DIRS 170004], Section 6.4). The matrix properties used to simulate matrix imbibition are developed in *Calibrated Unsaturated Zone Properties* (SNL 2007 [DIRS 179545], Section 6.3).

FEP: 2.2.07.10.0A

FEP NAME:

Condensation Zone Forms Around Drifts

FEP DESCRIPTION:

Condensation of the two-phase flow generated by repository heat may form in the rock where the temperature drops below the local vaporization temperature. Waste package emplacement geometry and thermal loading may affect the scale at which condensation caps form (over waste packages, over panels, or over the entire repository), and the extent to which "shedding" will occur as water flows from the region above one drift to the region above another drift or into the rock between drifts.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The coupled thermal-hydrologic processes resulting in water evaporation, vapor transport, and the formation of a condensation zone (or "condensation cap") in the fractured rock above the drifts are explicitly simulated, using an 81-m drift spacing (SNL 2007 [DIRS 179466], Parameter Number 01-13), with the TH seepage model as discussed in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.2). As discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2), the abstraction of thermal seepage (seepage at temperatures above ambient) uses the TH seepage modeling results to develop an appropriate thermal-seepage abstraction methodology. Thus, the TH modeling results include these effects. Using the TH seepage model, the impact of condensation and "shedding" between drifts (that is, diversion of vapor to cooler regions and drainage of condensation through the cooler region between drifts) on seepage is assessed for various simulation cases (SNL 2007 [DIRS 181244], Section 6.4.3.3) covering the expected range of values for rock capillarity, permeability, and percolation flux. These parameters control the development and magnitude of the condensation zone, and the relative importance of shedding. TSPA calculations incorporate thermal-hydrologic seepage model uncertainty through use of ambient seepage rates, which are shown to bound the seepage under thermal conditions (SNL 2007 [DIRS 181244], Section 6.4.3).

The coupled processes of vapor condensation forming a condensation cap above the drifts and occurrence of shedding between drifts are explicitly simulated with the THC seepage model (SNL 2007 [DIRS 177404], Sections 6.2.1 and 6.5.5.2). Using this model, the impact of condensation and drainage on seepage water chemistry is assessed for various simulation cases (SNL 2007 [DIRS 177404], Sections 6.2, 6.5, and 6.6). Condensation results in dilute pore waters in high saturation zones above the drift during the boiling period, but has negligible effect on water compositions once drift wall temperatures drop below 100°C. The effects of evaporation or condensation are negligible after the boiling period, and potential seepage waters rapidly return to ambient or near-ambient pore-water ionic strengths (SNL 2007 [DIRS 177404],

Section 6.5). These data provide the technical basis for the implementation of potential seepage chemistry in the near-field chemistry model in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.2), which does not evaluate condensation. The near-field chemistry model provides potential seepage compositions to the seepage dilution/evaporation model, which generates lookup tables of in-drift water chemistry for use in the TSPA model (SNL 2007 [DIRS 177412], Sections 6.3.3 and 6.9).

Multiscale Thermohydrologic Model (SNL 2008 [DIRS 184433]) incorporates vapor condensation in the rock surrounding the drifts in calculating near field and in-drift thermal hydrology. This model provides in-drift temperature and relative humidity inputs used by TSPA to extract water composition data from the seepage/evaporation model lookup tables. Hence, the effects of vapor condensation in the rock surrounding the drift are implicitly incorporated in TSPA predictions of in-drift water chemistry through the multiscale model. The effect of uncertainties in the development and magnitude of a condensation zone are captured through the use of simulation results with different rock thermal conductivities and a suite of percolation flux values (SNL 2008 [DIRS 184433], Sections 6.3.15[a] and 6.3.16[a]). Uncertainties in rock hydrologic properties, ventilation heat removal efficiency, and the effects of axial vapor transport (SNL 2008 [DIRS 184433], Sections 6.3.11[a], 6.3.12, and 6.3.18[a]) were evaluated using sensitivity analyses and found to be insignificant with respect to predicted in-drift conditions.

FEP: 2.2.07.11.0A

FEP NAME:

Resaturation of Geosphere Dry-Out Zone

FEP DESCRIPTION:

Following the peak thermal period, water in the condensation cap may flow downward into the drifts. Influx of cooler water from above, such as might occur from episodic flow, may accelerate return flow from the condensation cap by lowering temperatures below the condensation point. Percolating groundwater will also contribute to resaturation of the dry-out zone. Vapor flow, as distinct from liquid flow by capillary processes, may also contribute.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Resaturation of the dryout zone around drifts, and the potential of return flow from the condensation zone back to the drifts, are explicitly simulated with the TH seepage model (BSC 2005 [DIRS 172232], Section 6.2). As discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.5.2), the abstraction of thermal seepage (seepage at temperatures above ambient) utilizes the TH seepage modeling results to develop an appropriate thermal-seepage abstraction methodology. Thus, the TH modeling results include these effects. Using this model, the impact of resaturation and reflux on seepage is assessed for various simulation cases (SNL 2007 [DIRS 181244], Section 6.4.3.3) covering the expected range of values for rock capillarity, permeability, and percolation flux. These parameters control resaturation of the dryout zone by both liquid flow and capillary condensation of water vapor. TSPA calculations incorporate seepage model uncertainty by sampling probability distributions for these parameters and interpolating between the results of the model simulations (SNL 2007 [DIRS 181244], Section 6.6). The impact of episodic flow, potentially resulting in finger flow penetrating the above-boiling dryout zone, was addressed with an alternative conceptual model for thermal seepage, as discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.3). It was shown that results from this alternative conceptual model are consistent with the process model results from the TH seepage model used for this abstraction.

During resaturation of the dryout zone, salts precipitated during dryout may redissolve and affect the chemistry of potential seepage waters. This transient process is screened from consideration in TSPA as discussed in excluded FEP 2.2.08.04.0A (Re-Dissolution of Precipitates Directs More Corrosive Fluids to Waste Packages).

Multiscale Thermohydrologic Model (SNL 2008 [DIRS 184433]) incorporates resaturation of the dryout zone around the drift, by both liquid flow and capillary condensation of water vapor, in calculating near-field and in-drift thermal hydrology. This model provides in-drift temperature and relative humidity inputs used by TSPA to extract water composition data from lookup tables generated by the seepage dilution/evaporation model (SNL 2007 [DIRS 177412], Sections 6.3.3

and 6.9), which evaluates in-drift processes and provides lookup tables for in-drift aqueous chemistry to TSPA. The effect of uncertainties in the development of the dryout zone and the timing of resaturation are captured through the use of multiscale model simulation results with different rock thermal conductivities and a suite of percolation flux values (SNL 2008 [DIRS 184433], Sections 6.3.15[a] and 6.3.16[a]). Uncertainties in rock hydrologic properties, ventilation heat removal efficiency, and the effects of axial vapor transport (SNL 2008 [DIRS 184433], Sections 6.3.11[a], 6.3.12, and 6.3.18[a]) were evaluated using sensitivity analyses and found to be insignificant with respect to predicted in-drift conditions. Hence, the effects of resaturation of the dryout zone are incorporated in TSPA predictions of in-drift chemistry through the multiscale model.

FEP NAME:

Saturated Groundwater Flow in the Geosphere

FEP DESCRIPTION:

Groundwater flow in the saturated zone below the water table may affect long-term performance of the repository. The location, magnitude, and direction of flow under present and future conditions and the hydraulic properties of the rock are all relevant.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Flows through geologic (rock) units below the water table (saturated) are the principal pathways for radionuclides released from the repository. Steady-state, saturated, three-dimensional, groundwater flow in the Yucca Mountain vicinity is modeled in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]) with output data used by *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Section 6.3) to estimate radionuclide transport. Both models are based on the numerical code FEHM (FEHM V. 2.24-02 [DIRS 179539], STN: 10086-2.24-02). Specified mass flow (kg/s) is assigned at the water table of the SZ site-scale flow model (SNL 2007 [DIRS 177391], Sections 6.3.1.7 and 6.4.3.9) using the technique outlined in *Recharge and Lateral Groundwater Flow Boundary Conditions for the Saturated Zone Site-Scale Flow and Transport Model* (BSC 2004 [DIRS 170015], Section 6). Specified mass flow data at the water table are derived from the 2004 Death Valley Regional Flow System model (Belcher 2004 [DIRS 173179]), the UZ flow model (SNL 2007 [DIRS 184614]), and data from Savard (1998 [DIRS 102213]). The hydrogeologic framework (SNL 2007 [DIRS 174109]) and additional faults and features (SNL 2007 [DIRS 177391], Section 6.4.3.7) are the strongest controlling factors on saturated zone flow (included FEPs 2.2.03.02.0A (Rock Properties of Host Rock and other Units) and 2.2.07.13.0A (Water-conducting Features in the SZ)). Saturated zone aquifers that are expected to transport radionuclides released from the repository include the volcanic Crater Flat Tuff hydrogeologic units and the shallow alluvial aquifer of Fortymile Wash. Targets for lateral flow at model boundaries are derived from the 2004 Death Valley Regional Flow System model (Belcher 2004 [DIRS 173179]).

As discussed in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014]), only a subset of existing fractures is observed to transmit flow in the saturated zone. Flow through fractures is modeled as an effective continuum (SNL 2007 [DIRS 177391], Section 6.4.1). Uncertainty in the saturated flow through fractures is incorporated in the flow model abstraction with parameters of flowing interval spacing, specific discharge, and the horizontal anisotropy (SNL 2008 [DIRS 183750], Sections 6.5.2.3[a], 6.5.2.1[a], and 6.5.2.10). These parameters are described by probability distributions and sampled across multiple realizations to develop a range in radionuclide breakthroughs specified by a calculated

probability distribution function. For example, an uncertain parameter in saturated zone flow modeling is the groundwater specific discharge multiplier that ranges from 1/8.93 to 8.93 (SNL 2008 [DIRS 183750], Figure 6-2[a]).

Uncertainty in groundwater specific discharge in the alluvium is discussed in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Section 6.5) and in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.7).

The impact of future climatic conditions on flow is modeled in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.6.4), *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Section 6.6), and *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5[a]). The radionuclide breakthrough curves are generated using glacial-transition climate flow rates and they are scaled back for present-day and monsoonal conditions using the convolution integral method. The simulated radionuclide mass breakthrough curves from the SZ flow and transport abstraction model are coupled to the TSPA analyses using the convolution integral method (SNL 2008 [DIRS 183750]). That is, plots of radionuclide normalized cumulative mass releases at the 18-km compliance boundary are developed from Latin-Hypercube-Sampled parameters with uncertainty distributions as specified in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5[a]) and are used by the convolution integral implementation in the TSPA analysis.

FEP: 2.2.07.13.0A

FEP NAME:

Water-Conducting Features in the SZ

FEP DESCRIPTION:

Geologic features in the saturated zone may affect groundwater flow by providing preferred pathways for flow.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Geologic features in the saturated zone that may represent preferred pathways for flow are described in the *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109]), which updates the hydrogeologic framework model used in flow and transport modeling. These water-conducting features in the saturated zone are addressed in and incorporated into the *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]). Faults and features in the model domain are explicitly included through 10 discrete geologic features incorporated in the SZ site-scale flow model (SNL 2007 [DIRS 177391], Section 6.4.3.7 and Figure 6-12).

The impacts of these various features on saturated zone transport are evaluated in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Sections 6.2, 6.3, and 6.4). The variability and uncertainty due to the presence of fracture clusters, flowing intervals, and rubblized zones (all possible subsets of water-conducting features within the faulted and fractured system) are modeled in the SZ flow and transport abstraction model and the SZ one-dimensional transport model, both described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]). The variability and uncertainty are quantified through the stochastically sampled probability distribution functions for values of several parameters in the performance assessment calculations. The parameters treated in such a manner include: groundwater specific discharge multiplier, flowing interval spacing in volcanic units, horizontal anisotropy in permeability, flowing interval porosity in volcanic units, and longitudinal dispersivity, as developed in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2 and 6.5.2[a], and Tables 6-8 and 6-7[a]). The ranges of uncertainty in these parameters encompass the possibility of channelized flow along preferred pathways (SNL 2008 [DIRS 183750], Sections 6.5.2.1, 6.5.2.1[a], 6.5.2.4, 6.5.2.4[a], 6.5.2.5, 6.5.2.9, and 6.5.2.10).

Numerous broad and distinct zones in the SZ flow model are categorized as features and, depending upon their physical properties, these act as either barriers or conduits to saturated zone groundwater flow. These zones are directly or indirectly affected by faults, zones of mineralogical alteration along faults, or contact zones between units (SNL 2007 [DIRS 177391], Section 6.4.3.7). In total, there are 10 features defined in *Saturated Zone Site-Scale Flow Model*

for Yucca Mountain (SNL 2007 [DIRS 177391], Table 6-7) in addition to those geologic units specified in the hydrogeologic framework model (with 27 surfaces) employed as described in *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Section 6). Most of the 10 features are vertical, but some are areally extensive (SNL 2007 [DIRS 177391], Figure 6-12). Depending upon their hydrologic impact on groundwater flow patterns, these features fall under several distinct categories as follows: (1) zones of permeability enhancement parallel to faults, and zones of permeability reduction perpendicular to faults; (2) fault zones with generalized enhanced permeability; (3) juxtapositions of hydrogeologic units with different values of permeability; (4) the altered northern region and; (5) zones of enhanced or anisotropic permeability (SNL 2007 [DIRS 177391], Table 6-7). These features control the flow pattern in the saturated zone and also the specific discharge. Uncertainty in specific discharge is propagated through to TSPA in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Table 6-8) through the uncertain parameter for groundwater specific discharge multiplier.

Smaller-scale water conducting features are assessed as flowing intervals in the fractured volcanic units, as described in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014]). In-situ testing of smaller scale water conducting features was performed at the C-wells complex, as documented in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Sections 6.2 and 6.3). These reports contain data used to formulate the flowing interval spacing parameter.

FEP: 2.2.07.14.0A

FEP NAME:

Chemically-Induced Density Effects on Groundwater Flow

FEP DESCRIPTION:

Chemically-induced spatial variation in groundwater density may affect groundwater flow.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Large-scale, chemically induced variations in the density of groundwater, such as those related to the presence of natural brine, do not exist in the groundwater flow system at Yucca Mountain. Minor or transient variations in the chemical composition of groundwater related to unsaturated flow or repository thermal effects will occur in the flow system, but these will be of low consequence with regard to repository performance.

Water entering the saturated zone from the unsaturated zone under ambient conditions will tend to have a higher total dissolved solids concentration, and hence a higher density, than saturated zone groundwater because of evaporation in the unsaturated zone. However, the density differences are not expected to be large enough to result in density-driven flow of unsaturated zone water in the saturated zone. Indeed, unsaturated zone pore waters, though quite variable in composition, have total dissolved solids concentrations ranging from about 200 mg/L to as much as 1,300 to 1,400 mg/L, with an average of about 500 mg/L (derived from DTNs: GS020408312272.003 [DIRS 160899], GS020808312272.004 [DIRS 166569], GS030408312272.002 [DIRS 165226], GS031008312272.008 [DIRS 166570], GS041108312272.005 [DIRS 178057], and GS0703PA312272.001 [DIRS 182478]; the chemical constituent concentration data from analyses of unsaturated zone water samples in these data packages were summed to obtain total dissolved solids concentrations) whereas saturated zone samples from the volcanics near Yucca Mountain have an average total dissolved solids concentration of about 275 mg/L with a range from 246 to 288 mg/L (derived from DTNs: GS040108312322.001 [DIRS 179422] and GS980908312322.008 [DIRS 145412]; the chemical constituent concentration data from analyses of saturated zone water samples in these data packages were summed to obtain total dissolved solids concentrations.). Density contrasts of ~2,000 mg/L or greater are necessary for density-driven flow to occur (Zhang and Schwartz 1995 [DIRS 183479], pp. 837 to 847). Furthermore, perched waters in the unsaturated zone, which are considered to have water chemistries more representative of water that will flow through fractures in the unsaturated zone, tend to have total dissolved solids concentrations that are closer to that of saturated zone waters (derived from DTN: GS951208312272.004 [DIRS 165858]; the chemical constituent concentration data from analyses of perched water samples in this data package was summed to obtain total dissolved solids concentrations) than the more highly evaporated water from unsaturated zone rock matrices.

Once waste is emplaced in the repository, water seeping through the unsaturated zone and engineered barrier system will pick up additional dissolved solids as a result of evaporation (due to the radioactive decay heat in the near field) and interactions with host rock, waste package materials, invert materials, and dust introduced during mining and waste emplacement operations (SNL 2007 [DIRS 177412], Sections 6.3, 6.8, 6.9, 6.10 and 6.13). Depending on the extent of evaporation and the length of time the water remains in contact with these materials (a function of temperature and local water fluxes), dissolved solids concentrations could become high enough to result in brines in the near field (SNL 2007 [DIRS 177412], Section 6.3.3). However, the brines are predicted to persist for only a few thousand years or less after waste emplacement because of flushing by percolation flux that returns to the near field once temperatures drop below the water boiling point (SNL 2007 [DIRS 177412], Figure 7.1-11 (for predicted time periods of altered chemistry); and DTN: SN0701PAEBSPCE.001 [DIRS 180523], folder: "Lookup Tables" (for predicted temperature and concentration histories)). A short-duration pulse of brackish water (as much as 5,000 to 10,000 mg/L dissolved solids) may drain through the host rock when this flushing begins because of the dissolution of dry salts left behind by evaporation during the thermal pulse (SNL 2007 [DIRS 177404], Section 6.5.5.4. The dissolved solids concentrations were calculated from the peak molal concentrations plotted in Figures 6.5-13 to 6.5-23 of Section 6.5.5.4, with moles/kg converted to mg/L using appropriate values of elemental atomic weights and water density. The concentrations are presented here as a range because of the approximate nature of the values read from the plots and the uncertainties in the model predictions in Section 6.5.5.4.).

After the high temperature pulse has diminished and relatively steady-state flow is established through the repository, concentrated solutions may still develop in the immediate vicinity of waste packages due to water interactions with waste package materials and waste forms. The degree of dissolved solids buildup under these lower temperature conditions is predicted to be roughly inversely proportional to the water flux through the waste forms (SNL 2007 [DIRS 180506], Section 6.6.4[a]), and it has been shown that the water does not become highly concentrated at water fluxes greater than about 100 L/yr per waste package (SNL 2007 [DIRS 180506], Figures 6-27[a], 6-29[a], and 6-31[a]). Thus, only relatively low overall fluxes of high density solutions are possible out of the near-field environment.

The net result of all these processes is that radionuclide-bearing water leaving the unsaturated zone has the potential to be more dense than ambient saturated zone water and could thus tend to sink by density-driven flow when it enters the saturated zone. Such effects will be localized in the area beneath the repository and will be attenuated by dilution over the scale of transport from the repository to the accessible environment. The extent of this sinking will depend on a number of variables, including the density contrast between the waters, the downward water flow rate in the unsaturated zone relative to the horizontal flow rate at the top of the saturated zone, solute diffusivities and dispersivities, and the spatial heterogeneity in permeability at the top of the saturated zone (including fractures and horizontal layering).

The justification for excluding chemically induced density effects on groundwater flow relies on several consequence-based justifications:

1. The density contrast between unsaturated zone water entering the saturated zone and saturated zone water is not expected to be large enough to cause significant

density-driven flow except for possibly during the relatively short pulse associated with the repository thermal pulse. Zhang and Schwartz (1995 [DIRS 183479]) showed that for significant density-driven sinking of a plume entering a saturated zone to occur (their calculations were for a specific discharge of ~30 m/yr through a homogeneous isotropic porous medium with a flow porosity of 0.25, yielding a horizontal seepage velocity of ~120 m/yr), the concentration of the leachate (or contaminant plume) had to be at least 2,000 mg/L in a very dilute native groundwater at 20°C. Specifically, density-driven flow was evident only when they assumed a NaCl concentration greater than 2,000 mg/L, which corresponded to a solution density of 999.7 kg/m^3 at 20°C, in a native groundwater with a density of 998.2 kg/m^3 at 20°C (i.e., a density contrast of ~0.15%) (Zhang and Schwartz 1995 [DIRS 183479], pp. 839, 840, 843, and 844). For the temperatures and native dissolved solids concentrations in the upper part of the saturated zone at Yucca Mountain, a similar incremental dissolved solids concentration of 2,000 mg/L would be required for density-driven flow to occur. This incremental difference is greater than that expected and greater than what exists currently at Yucca Mountain under ambient conditions based on chemical analyses of unsaturated zone and saturated zone pore waters, which indicate, at most, a difference of about 1,000 mg/L (see above).

2. The higher density seepage water associated with the repository thermal pulse will move through the unsaturated zone soon after the repository near field becomes rewetted (between 1,000 and 10,000 years). However, this pulse is expected to be a one-time localized transient of relatively low volume (BSC 2007 [DIRS 177404], Section 6.5.5.2). In addition, the concentrated solutions that can potentially form in the vicinity of the drift after repository temperatures decrease below the boiling point of water will tend to become diluted by mixing with dilute unsaturated zone water. This mixing will occur over the several hundred meters that these waters must travel from the repository horizon to the water table or at the water table itself. The net result will be dilution of the concentrated solutions toward ambient pore-water concentrations before reaching the water table.

3. Even if relatively little mixing occurs in the unsaturated zone, the flux of the concentrated water reaching the saturated zone will be only a very small fraction of the horizontal flux in the saturated zone resulting from infiltration of dilute water and horizontal flux from through-flowing water. Indeed, percolation within the unsaturated zone flow model domain (which includes all of the repository horizon) amounts to only ~1% of the flow through the lateral boundaries of the site-scale saturated zone flow model domain, and it is only ~13% of the total recharge over the entire saturated zone flow model domain (SNL 2007 [DIRS 177391], Section 6.4.3.9). Under these conditions, a dense plume will not develop in the saturated zone because the solutes will be swept away faster than they arrive. Even in the unexpected event that the overall infiltration flux through the unsaturated zone *all* comes in contact with waste packages and is also low enough to result in elevated dissolved solids concentrations, this flux will be so low that dense plumes will not be able to develop except where the saturated zone water is nearly stagnant. In this case, the dense plume will move down through the stagnant zone until it reaches a horizontal flow zone, at which point sweeping/dilution will prevent further downward migration of the plume.

4. Although not expected for the reasons given in the three preceding paragraphs, if density-driven flow did occur, it would result in either an increase or a decrease in the rate of radionuclide migration through the fractured volcanics, depending on whether the increased downward flow causes radionuclides to move past a shallow high-flow layer/feature or to more quickly reach a deeper high-flow layer/feature. Thus, the consequences of density-driven flow in the saturated zone will ultimately be expressed as increased or decreased radionuclide travel times through the volcanics. The uncertainty in groundwater flow rates resulting from density-driven flow is small relative to the ranges of uncertainty in specific discharge and flowing interval porosity in the volcanic units of the saturated zone, as incorporated in the parameter uncertainty distributions for these parameters (SNL 2008 [DIRS 183750], Sections 6.5.2.1[a] and 6.5.2.5). Thus, while density-driven flow is not directly modeled or accounted for in TSPA, its consequences are expected to be minor relative to and, therefore, bounded by the modeled uncertainty in groundwater travel times through the volcanics that results from uncertainty in specific discharge and flowing interval porosity.

The TSPA model calculates the concentration of contaminants in groundwater by capturing all of the contaminants that annually cross the regulatory boundary (SNL 2008 [DIRS 183750], Section 6.3.3). This approach will tend to dampen any effects that density-driven flow may have on the contaminant plume (which would occur predominantly near the source because it is not considered plausible that density contrasts large enough to cause density-driven flow will persist in the saturated zone all the way to the compliance boundary). Although the timing of contaminant arrival at the compliance boundary could potentially be affected by density-driven flow near the source, the possible influence of density-driven flow on travel times is well bounded by the treatment of uncertainty in parameters that govern flow velocity in the saturated zone (see item 4).

In conclusion:

1 Density-driven flow will not occur under ambient unsaturated zone flow conditions because of insufficient density contrast between unsaturated zone and saturated zone pore waters.

2 The higher density seepage water associated with the repository thermal pulse will be a small flux, localized, and transient. These higher density seepage waters will mix with more dilute water in the unsaturated zone prior to reaching the water table such that the concentrated solutions will tend to shift toward ambient pore water concentrations before reaching the water table.

3. Even if relatively little mixing occurs in the unsaturated zone, the flux of the concentrated water reaching the saturated zone is expected to be only a small fraction of the horizontal flux in the saturated zone resulting from infiltration of dilute water and from through-flowing water.

4. While density-driven flow is not directly modeled or accounted for in TSPA, its consequences are expected to be minor relative to and, therefore, bounded by the

modeled uncertainty in groundwater travel times through the volcanics that results from uncertainty in specific discharge and flowing interval porosity.

Based on the previous discussion, omission of FEP 2.2.07.14.0A (Chemically-Induced Density Effects on Groundwater Flow) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.07.15.0A

FEP NAME:

Advection and Dispersion in the SZ

FEP DESCRIPTION:

Advection and dispersion processes may affect radionuclide transport in the saturated zone.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Advection and longitudinal dispersion of radionuclides in the saturated zone are explicitly included in the conceptual and mathematical models for radionuclide transport in the saturated zone (SNL 2008 [DIRS 184806], Sections 6.3 and 6.4). The numerical code FEHM is used to obtain a three-dimensional advective flow field that is calibrated to head observations and model boundary fluxes by adjusting permeabilities of geologic units within the model domain (SNL 2007 [DIRS 177391]). The estimated groundwater flow rates into the SZ site-scale flow model domain, both as recharge (infiltration) at the upper boundary (water table) and as underflow at the lateral boundaries, are determined from a larger scale regional model reported in *Recharge and Lateral Groundwater Flow Boundary Conditions for the Saturated Zone Site-Scale Flow and Transport Model* (BSC 2004 [DIRS 170015], Section 6). FEHM also implements, as part of the SZ site-scale transport model (SNL 2008 [DIRS 184806]), the dispersion tensor and random walk particle tracking method to simulate radionuclide dispersion in the saturated zone.

To address uncertainty in the flow field produced by the SZ site-scale flow model (SNL 2007 [DIRS 177391]), the HAVO (horizontal flow anisotropy in the volcanics) parameter is stochastically sampled to produce 200 unique three-dimensional permeability fields that result in 200 unique flow fields (SNL 2008 [DIRS 183750], Section 6.5.3.1), which are used in TSPA. This parameter determines the degree of anisotropy in permeability for the volcanic units, and its range of values is based on field-test analyses discussed in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Section 6.2.6) as well as numerical analysis discussed in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.5.3). For each of the 200 flow field realizations, the recharge fluxes, boundary fluxes, and calibrated permeability field are scaled with the stochastically sampled parameter, GWSPD, to address uncertainty in advective transport velocities within the saturated zone model domain (SNL 2008 [DIRS 183750], Section 6.5.2.1[a]). The simultaneous scaling of the fluxes and permeabilities preserves the flow model calibration. GWSPD scales permeabilities in both the volcanic and alluvium units. The range for the GWSPD scaling parameter is based on field test analyses (SNL 2007 [DIRS 177394]), calibration of the "base-case" flow field to measured heads (SNL 2007 [DIRS 177391], Section 6.6.1.3), and expert elicitation (CRWMS M&O 1998 [DIRS 100353], Section 3.2). Detailed discussions of the GWSPD and HAVO parameter implementation are

provided in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2.1[a] and 6.5.2.10).

Uncertainty in the dispersion tensor is modeled by stochastically varying the LDISP (SNL 2008 [DIRS 183750], Section 6.5.2.9[b]). The distribution of values for the LDISP is based on recommendations from the expert elicitation panel (CRWMS M&O 1998 [DIRS 100353], Section 3.2).

The transverse and vertical dispersivities are not varied independently but are scaled as a multiple (significantly less than 1) of the stochastically sampled LDISP. Further discussions on transverse and vertical dispersion are provided in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5.2.9).

FEP: 2.2.07.15.0B

FEP NAME:

Advection and Dispersion in the UZ

FEP DESCRIPTION:

Advection and dispersion processes may affect radionuclide transport in the UZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Radionuclide transport through the unsaturated zone by advection is simulated using the RTTF method documented in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.1). Dispersion is incorporated into the RTTF algorithm through the use of a transfer function based on an analytical solution to the advection–dispersion equation (SNL 2008 [DIRS 184748], Section 6.4.2). In TSPA model runs, advection and dispersion are included through the use of FEHM (Finite Element Heat and Mass Transfer Code) RTTF model and the pregenerated flow fields as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Sections 6.4 and 6.5.1).

The fracture dispersivity is set at a fixed value of 10 m. This is discussed and justified in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Table 6-4).

Uncertainty in advection is handled by incorporating four infiltration scenarios for the first three climate states (present day, monsoon, and glacial-transition) into the UZ flow model (SNL 2008 [DIRS 184614], Section 6.1.4). For the post-10,000-year climate state, four corresponding net infiltration maps representing present-day 90th percentile, glacial-transition 50th percentile, glacial-transition 90th percentile, and monsoon 90th percentile, respectively, are used to develop the four flow fields for incorporation into the UZ abstraction model. Dispersion is represented by a single parameter value (SNL 2008 [DIRS 184748], Section 6.5.2).

FEP: 2.2.07.16.0A

FEP NAME:

Dilution of Radionuclides in Groundwater

FEP DESCRIPTION:

Dilution due to mixing of contaminated and uncontaminated water may affect radionuclide concentrations in groundwater during transport in the saturated zone and during pumping at a withdrawal well.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Dilution of radionuclides as a result of groundwater transport is included in the TSPA in two ways (SNL 2008 [DIRS 183750]): dispersion in flowing groundwater and dilution in the representative volume of groundwater. Dilution of simulated radionuclide concentrations within the contaminant plume is modeled through the longitudinal and transverse hydrodynamic dispersion parameters. Dispersion is caused, in part, by heterogeneities in permeability at all scales (SNL 2008 [DIRS 184806], Section 6.4.2.2). Longitudinal dispersivity will be important primarily at the leading edge of the advancing plume while transverse dispersion will occur along the entire length of the plume. Transverse dispersivity is a function of the stochastically sampled longitudinal dispersivity (SNL 2008 [DIRS 183750], Section 6.5.2.9).

Dilution in the volume of water used to calculate dose to the RMEI, which is defined as 3,000 acre-ft in accordance with 10 CFR 63.312(c) [DIRS 180319], or in the representative volume of groundwater used to demonstrate compliance with the groundwater protection standards, which is also 3,000 acre-ft in accordance with 10 CFR 63.332(a)(3) [DIRS 180319], is documented in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 5(3) and 6.3.3). It is assumed that all of the radionuclide mass crossing the accessible environment boundary in a year is dissolved in this volume of water.

FEP: 2.2.07.17.0A

FEP NAME:

Diffusion in the SZ

FEP DESCRIPTION:

Molecular diffusion processes may affect radionuclide transport in the SZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP addresses diffusive transport processes that are associated with hydrodynamic dispersion (part mechanical dispersion, part diffusion). The process of diffusion into the rock matrix of volcanic units is discussed in included FEP 2.2.08.08.0A (Matrix Diffusion in the SZ).

In the site-scale transport model diffusion is one of two components of a dispersion tensor. This tensor, denoted as D' (SNL 2008 [DIRS 184806], Section 6.4.2.1), is the sum of the mechanical dispersion tensor (D) for the flow system and the coefficient of molecular diffusion (D_0) in porous media. Uncertainty in the process of hydrodynamic dispersion is modeled using a stochastically sampled longitudinal dispersivity factor, LDISP (SNL 2008 [DIRS 183750], Sections 6.5.2.9 and 6.5.2[b]), and the transverse hydrodynamic dispersion parameters, which are a function of LDISP. The effects of molecular diffusion are explicitly included in the displacement matrix described in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Section 6.4.2.3 and Equation 20). The effects of molecular diffusion are, thus, explicitly included in the SZ site-scale transport model. The effects of matrix diffusion in the saturated zone are additionally considered in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Figure 6-3). Moreover, the effective diffusion coefficient (tortuosity multiplied by free water diffusion coefficient) received detailed consideration in the one-dimensional abstraction to the three-dimensional flow model (SNL 2008 [DIRS 183750], Sections 6.5.2.6 and 6.5.2[b]) where radionuclide breakthrough curves are developed for use in TSPA. Molecular diffusion is not applied to colloids in the TSPA model.

FEP: 2.2.07.18.0A

FEP NAME:

Film Flow into the Repository

FEP DESCRIPTION:

Water may enter waste emplacement drifts by a film flow process. This differs from the traditional view of flow in a capillary network where the wetting phase exclusively occupies capillaries with apertures smaller than some level defined by the capillary pressure. A film flow process could allow water to enter a waste emplacement drift at non-zero capillary pressure. Dripping into the drifts could also occur through collection of the film flow on the local minima of surface roughness features along the crown of the drift.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The potential effects of film flow are represented in the data acquired in *In Situ Field Testing of Processes* (BSC 2004 [DIRS 170004], Section 6.2), and developed by *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.1.2, 6.3.3, and 6.6.3). Water originating from film flow seeping into the opening during a liquid-release test is reflected in the corresponding seepage data point used for model calibration. Film flow is thus accounted for in the estimated seepage-related capillary-strength parameter from the seepage calibration model (BSC 2004 [DIRS 171764], Table 6-8). Therefore, the impact of film flow on seepage is included in the prediction of seepage into waste emplacement drifts performed in *Seepage Model for PA Including Drift Collapse* (BSC 2004 [DIRS 167652], Section 6.3) and developed for TSPA calculations by *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.1.1), because both of these models use capillary-strength parameter values developed by the seepage calibration model. Uncertainty due to the potential effects of film flow is incorporated into TSPA by sampling a probability distribution for the capillary-strength parameter (SNL 2007 [DIRS 181244], Section 6.6).

This FEP addresses film flow in fractures and pores in the rock around the drift, and does not apply to water films on the drift walls. Water traveling down the drift walls as a film cannot contact the drip shield or waste package, and is assumed to be resorbed by the sloping wall of the drift prior to reaching the invert, because drift wall saturations decrease progressing downwards along the wall (BSC 2005 [DIRS 172232], Section 6.2.2). Hence, water flowing as a film down the drift wall contributes neither to seepage nor to flux through the invert.

Transport of dissolved radionuclides through films in the EBS is discussed in included FEP 2.1.09.08.0B (Advection of Dissolved Radionuclides in EBS).

This FEP is included in performance assessments to demonstrate compliance with the individual protection standard after permanent closure (proposed 10 CFR 63.311 (70 FR 53313

[DIRS 178394])) and the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). It is not included in the human intrusion performance assessment (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])).

FEP: 2.2.07.19.0A

FEP NAME:

Lateral Flow from Solitario Canyon Fault Enters Drifts

FEP DESCRIPTION:

Water movement down Solitario Canyon Fault could enter waste emplacement drifts through lateral flow mechanisms in the Topopah Spring welded hydrogeologic unit. This percolation pathway is more likely to transmit episodic transient flow to waste emplacement locations due to the major fault pathway through the overlying units.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The UZ flow model contains hydrogeologic connections between the Solitario Canyon Fault and the waste emplacement horizon. Therefore, the UZ flow model is capable of computing lateral flow. The connection is captured using a property set of the Paintbrush nonwelded unit (PTn) with calibrated fracture-matrix properties that address expectations for lateral flow (SNL 2007 [DIRS 184614], Sections 6.2.2.1 and 6.2.2.2).

As for all percolation flux arriving at the repository, any water arriving at the repository through lateral flow in the PTn from Solitario Canyon Fault may seep into waste emplacement drifts if the flux is sufficient to overcome the capillary barrier calculated in the drift seepage | model (SNL 2007 [DIRS 181244]); however, this FEP is not explicitly called out in Table 6-1 of that report. Any associated lateral flow effect is implicitly incorporated in the output flow fields developed in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 8.6). The effects of lateral flow from Solitario Canyon Fault on the percolation flux arriving at the waste emplacement drifts are included through the UZ flow model output of percolation flux at the PTn/TSw interface (DTNs: LB0612PDPTNTSW.001 [DIRS 179150], LB0701MOPTNTSW.001 [DIRS 179156], LB0701GTPTNTSW.001 [DIRS 179153], and LB0702UZPTN10K.002 [DIRS 179332]). This flux is the boundary condition used by the seepage abstraction in TSPA (SNL 2007 [DIRS 181244], Section 6.6.5.1). The effects of lateral flow from Solitario Canyon Fault on the percolation flux within the unsaturated zone model domain affect flow fields used by the radionuclide transport abstraction in TSPA (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]).

Other aspects of flow focusing in faults (preferential flow in faults) are discussed in included FEP 2.2.07.04.0A (Focusing of Unsaturated Flow (Fingers, Weeps)). Perched water is discussed in included FEP 2.2.07.07.0A (Perched Water Develops). The potential effects of episodic flow through Solitario Canyon Fault are discussed in excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration). FEP 2.2.07.19.0A (Lateral Flow from Solitario Canyon Fault Enters Drifts) is included in the performance assessments conducted to demonstrate compliance with

proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319].

FEP: 2.2.07.20.0A

FEP NAME:

Flow Diversion Around Repository Drifts

FEP DESCRIPTION:

Flow in unsaturated rock tends to be diverted by openings such as waste emplacement drifts due to the effects of capillary forces. The resulting diversion of flow could have an effect on seepage into the repository. Flow diversion around the drift openings could also lead to the development of a zone of lower flow rates and low saturation beneath the drift, known as the drift shadow.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The drift diameter and the circular shape of the drift (SNL 2007 [DIRS 179354], Parameter Number 01-10) are used in the calculations of drift seepage and thermal-hydrologic conditions inside the drift. The drift spacing (SNL 2007 [DIRS 179354], Table 4-1, Parameter Number 01-13) is also considered for determining thermal-hydrologic conditions in the drift.

Liquid release tests performed at several locations at the Exploratory Studies Facility (ESF) were used to gain an understanding of the unsaturated zone flow process in the presence of openings, including flow diversion around drifts and seepage (BSC 2004 [DIRS 170004], Section 6.2; BSC 2004 [DIRS 171764], Section 6.5). These measured data sets were used in calibration and validation of seepage-relevant hydrologic parameters of the formation surrounding drifts. The calibrated seepage-relevant parameters were used in downstream seepage process models, which were designed to explicitly consider impact of underground openings (including flow diversion and seepage) (BSC 2004 [DIRS 171764], Sections 6.3, 6.6, and 6.8; BSC 2004 [DIRS 167652], Sections 6.2.1, 6.3.2, and 6.7; BSC 2005 [DIRS 172232]; SNL 2007 [DIRS 177404]). *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244]), which is based on the seepage procees models that capture the impact of underground openings, provides seepage predictions in the form of lookup tables and probability distributions of seepage-relevant parameters to be used in the TSPA. These lookup tables and probability distributions of seepage-relevant parameters also quantify the uncertainty in drift seepage propagated into the TSPA.

A drift shadow is a region of reduced flow velocity and water saturation that forms beneath the drift as a result of flow diversion around drifts. The formation of the drift shadow beneath drift openings is represented in the seepage simulations in *Seepage Calibration Model and Seepage Testing Data* (BSC 2004 [DIRS 171764], Sections 6.3, 6.6, and 6.8). The effect of a drift shadow on transport of radionuclides is not included in the TSPA (see excluded FEP 2.2.07.21.0A (Drift Shadow Forms Below Repository)).

The impact of flow diversion around the drifts due to capillary pressure differences and its relevance for thermal-hydrologic conditions in the EBS are captured in the MSTHM process

model simulations (SNL 2008 [DIRS 184433]). These simulations are used to develop the MSTHM abstraction implemented in TSPA.

FEP: 2.2.07.21.0A

FEP NAME:

Drift Shadow Forms Below Repository

FEP DESCRIPTION:

Flow in unsaturated rock tends to be diverted by openings such as waste emplacement drifts due to the effects of capillary forces. Flow diversion around the drift openings could lead to the development of a zone of lower flow rates and low saturation beneath the drift, known as the drift shadow. Radionuclide transport rates through the unsaturated rock may be dependent on whether or not radionuclide releases occur from drifts that are underlain by a drift shadow.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

As discussed in included FEP 2.2.07.20.0A (Flow Diversion Around Repository Drifts), flow diversion around drifts is explicitly captured in the data acquired for seepage process models, and is therefore implicitly included in the TSPA. In contrast, drift shadow formation is not incorporated in the TSPA and has been excluded on the basis of low consequence. In particular, the reduction in flow over a region beneath the waste emplacement drift of the approximate size of the drift is not further considered.

A repository drift shadow is a region of reduced flow velocity and water saturation beneath the drift (Philip et al. 1989 [DIRS 105743], pp. 21 to 22, Figure 1). The drift shadow effect is a result of flow diversion around drifts as discussed in included FEP 2.2.07.20.0A (Flow Diversion around Repository Drifts) and in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6). Drift shadow formation is considered within *Drift-Scale Radionuclide Transport* (BSC 2004 [DIRS 170040], Section 6.3). It documents drift-scale radionuclide transport, taking account of the effects of emplacement drifts on flow and transport in the vicinity of the drift, which are not accounted for elsewhere, for example in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614), *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396]), and *Particle Tracking Model and Abstraction of Transport Process* (SNL 2008 [DIRS 184748]). Also, the models presented in *Drift-Scale Radionuclide Transport* (BSC 2004 [DIRS 170040]) are developed under ambient (unheated) conditions. Waste heat will also reduce water saturation in the vicinity of the drift, but the assessment of drift shadow only considers ambient conditions and flow fields. The impacts of waste heat on flow and repository dry-out are considered in included FEP 2.1.08.03.0A (Repository Dry-Out Due to Waste Heat).

The drift shadow model developed in *Drift-Scale Radionuclide Transport* (BSC 2004 [DIRS 170040], Sections 6.3) shows that a dryout zone forms primarily in the fracture continuum below the invert with two drip lobes (zones of increased magnitude of vertical water flux) that form within fractures on the sides of the emplacement drifts (BSC 2004 [DIRS 170040], Figure 6-2). The matrix continuum is less affected by the drift shadow than the

fracture continuum because the ratio of capillary forces to gravitational forces is much larger in the matrix, which reduces the extent of the drift shadow. Diversion of percolating water around a waste emplacement drift results in an environment of greatly diminished flow (seepage) inside the drift, and the primary transport mechanism for radionuclides to migrate from the drift to the surrounding rock is by diffusion in the drift shadow model. Because most of the fluid directly below the drift is within the matrix, radionuclides are released into the matrix. As a result, the transport behavior in the drift shadow model is very similar to transport in an unperturbed model with no drift shadow when radionuclides are released into the matrix (BSC 2004 [DIRS 170040], Figure 6-7). Therefore, the impact of the drift shadow is of low consequence when transport occurs via diffusion from the drift to the surrounding rock matrix. In addition, when advective transport occurs in the drift as a result of drift seepage, condensation, or wicking into the invert, the seepage that percolates to the bottom of the drift will mitigate the effects of a drift shadow, and the impact of the drift shadow during advective seepage is of low consequence as well. In all cases, the overall impact of the drift shadow, if present, will be to retard the transport of radionuclides as a result of the reduced saturation and water flux beneath the drift (BSC 2004 [DIRS 170040], Figure 6-2).

In summary, drift shadow formation below the repository is considered within *Drift-Scale Radionuclide Transport* (BSC 2004 [DIRS 170040]). Based on the previous discussion, omission of FEP 2.2.07.21.0A (Drift Shadow Forms below Repository) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.01.0A

FEP NAME:

Chemical Characteristics of Groundwater in the SZ

FEP DESCRIPTION:

Chemistry and other characteristics of groundwater in the saturated zone may affect groundwater flow and radionuclide transport of dissolved and colloidal species. Groundwater chemistry and other characteristics, including temperature, pH, Eh, ionic strength, and major ionic concentrations, may vary spatially throughout the system as a result of different rock mineralogy.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Chemical characteristics of groundwater in the saturated zone are included in the TSPA model through variations in K_d values, and through variations of BDCF values used in the biosphere modeling.

Variations in temperature, pH, Eh, ionic strength, and major ion concentrations in the groundwater of the saturated zone affect the sorption of radionuclides onto the rock surface and onto colloids, which, in turn, affect the sorption coefficient, K_d, and thus, the retardation factor, R_f, for each radionuclide. Element-specific sorption coefficients and their associated retardation factors are used in the equations that describe radionuclide transport through fractured media (SNL 2008 [DIRS 184806], Section 6.4.2.4.1, Equations 21 (a, b) and 22) and through alluvium and other porous media (SNL 2008 [DIRS 184806], Section 6.4.2.5, Equations 42 and 43). Appropriate ranges and distributions of values for K_d (SNL 2008 [DIRS 184806], Appendices C and C[a]) are chosen based on laboratory measurements, thermodynamic modeling, and professional judgement (SNL 2008 [DIRS 184806], Appendix A). The translation of the laboratory measurements, thermodynamic modeling, and professional judgement into upscaled K_d distributions is described in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Appendices C and C[a]). Distributions are specified for radionuclides or radionuclide groups and for two rock types (volcanic tuff and alluvium). These distributions were developed taking into account both the range of groundwater chemistries and the range of tuff and alluvium mineralogies in the saturated zone (SNL 2008 [DIRS 184806], Appendix A), so they implicitly account for variations in the chemical characteristics of saturated zone waters. The only exception to this is that oxidizing conditions are conservatively assumed to exist everywhere in the saturated zone (SNL 2008 [DIRS 184806], Section 6.3, Items 4 and 7) despite the fact that reducing conditions (which result in larger K_d values for some radionuclides) have been observed in some wells near Yucca Mountain (BSC 2006 [DIRS 178672], Section 3 and Figure 2.1-2). The uncertainty in K_d values is propagated through to modeling results by sampling the K_d uncertainty distributions individually for each saturated zone transport realization so that a unique set of element-specific K_d values is used in each realization (SNL 2008 [DIRS 183750], Sections 6.5, 6.5.1.1[b], 6.5.1.2[b], 6.5.2[b], 6.5.2.1[b], and 6.5.3[b]).

The sorption coefficient parameter ranges are incorporated in the model abstraction through K_d distributions for uranium, neptunium, plutonium, cesium, americium, thorium, protactinium, strontium, radium, selenium, and tin (SNL 2008 [DIRS 183750], Section 6.5.2.8, Table 6-8). The equilibrium sorption partitioning of americium, cesium, plutonium, thorium, protactinium, and tin between the aqueous phase and stationary and colloidal solid phases is also accounted for through K_d distributions that describe sorption of these radionuclides onto colloids (SNL 2008 [DIRS 183750], Section 6.5.2.8 and Table 6-8). Distributions for colloid concentrations in the saturated zone and for colloid retardation factors in the saturated volcanics and alluvium, which inherently reflect the chemical characteristics of saturated zone groundwaters, are also used in the modeling of colloid-facilitated radionuclide transport (SNL 2008 [DIRS 183750], Section 6.5.2.11 and Table 6-8). Correlations in radionuclide K_d values for a given saturated zone transport simulation (realization) are implemented through a correlation matrix (DTN: LA0702AM150304.001 [DIRS 184763]), which is discussed in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.5.2[a] and Table 6-7[a]) and *Site-Scale Saturated Zone Transport Model* (SNL 2008 [DIRS 184806], Section A9).

Regarding spatial variations of groundwater chemical characteristcs, geochemical analysis indicates that current saturated zone groundwater under the repository and along the saturated zone transport path is predominately oxidized paleoclimate recharge water with a swath of reducing conditions directly east of Yucca Mountain in wells H-3, H-4, WT-17, b#1, WT-10, WT-12, and WT-14 (BSC 2006 [DIRS 178672], Figure 2.1-2). This suggests the existence of a north−south zone of reducing groundwaters in the volcanic units (BSC 2006 [DIRS 178672], Section 3 and Figure 2.1-2). However, because of the uncertainty in the spatial extent of this zone and its temporal stability, oxidizing conditions are assumed in the development of radionuclide K_d distributions in the saturated zone. This assumption yields the lowest possible K_d values and hence the least potential retardation of redox-sensitive radioelements such as technetium, neptunium, and uranium in the saturated zone. Based on existing well water analyses, the variability in major ion water chemistry along saturated zone flowpaths (redox conditions notwithstanding) is bracketed reasonably well by the water chemistries of wells J-13 and UE-25p#1 (SNL 2008 [DIRS 184806], Section A3). These two water chemistries were used in batch laboratory sorption experiments to determine radionuclide K_d values, so variability in major ion groundwater chemistry in the saturated zone is implicitly accounted for when using the laboratory data in the development of radionuclide K_d distributions.

The potential effects of temporal variations of groundwater chemical characteristics on radionuclide transport in the saturated zone are considered to be bracketed by the K_d distributions used in TSPA. The possibility that temporal variations could cause radionuclide sorption parameters to go outside the limits of the K_d distributions is excluded, as discussed in FEP 2.2.08.03.0A (Geochemical Interactions and Evolution in the SZ).

The biosphere model for the groundwater exposure scenario implicitly includes this FEP because the model calculates BDCFs for a unit activity concentration in the water, in a manner that is inclusive of the chemical characteristics of groundwater. Several biosphere model input parameters are dependent on the chemical species present in groundwater and in other environmental media contaminated as a result of the groundwater use. These parameters include sorption coefficients (K_ds) (SNL 2007 [DIRS 179993], Section 6.3), soil-to-plant transfer factors (BSC 2004 [DIRS 169672], Section 6.2.1.2), transfer coefficients for animal products

(BSC 2004 [DIRS 169672], Section 6.3.3), bioaccumulation factors (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.4), irrigation interception fraction (SNL 2007 [DIRS 177399], Section 6.4.3.2), translocation factors (BSC 2004 [DIRS 169672], Section 6.2.2.2), and dose coefficients for radionuclide intakes by inhalation (SNL 2007 [DIRS 177399], Section 6.4.8.5).

The approach to developing values for these parameters is as follows. If a sufficient technical basis exists to develop a distribution of parameter values encompassing a range of values that would be expected in the environment for different chemical species, such an approach is preferred (BSC 2004 [DIRS 169672], Sections 6.2.1.1, 6.2.1.2, 6.3.3, and 6.4.3; SNL 2007 [DIRS 177399], Section 6.3). The advantage of this approach is that, where appropriate, such a distribution applies to multiple environmental media (not only for groundwater) and to all chemical species in these environmental media (e.g., transfer coefficients are used to model radionuclide transfer to animal products from water, animal feed, and soil). If a single value has to be assigned to a parameter that depends on chemical characteristics of a radionuclide, a value is selected for use in the biosphere model that is conservative with respect to the risk to the receptor. Such an approach ensures that if a parameter value is dependent on the chemical characteristics of a given environmental medium, including well water, by selecting the conservative value, the risk to the receptor is not underestimated. This approach is used to select the values of dose coefficients for inhalation of radionuclides (SNL 2007 [DIRS 177399], Section 6.4.8.5), and to select the values of empirical constants used in the equation for irrigation interception fraction for foliar uptake by crops (SNL 2007 [DIRS 177399], Section 6.4.3.2). For the parameters that are dependent on chemical properties of the environmental medium including the groundwater, and are fixed values, the model assumes parameter values such that the risk to the receptor is not underrepresented. This FEP is considered in the conceptual and mathematical models for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Table 6.7-1) in the soil, plant, animal, fish, ^{14}C, and inhalation submodels (SNL 2007 [DIRS 177399], Sections 6.4.1 to 6.4.6, and 6.4.8).

The biosphere aspect of this FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. Annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3).

All aspects of the chemical characteristics of groundwater in the saturated zone FEP described above are included in the performance assessments that demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). For the performance assessment that demonstrates compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]), only those components of this FEP that address the geosphere transport are included.

FEP: 2.2.08.01.0B

FEP NAME:

Chemical Characteristics of Groundwater in the UZ

FEP DESCRIPTION:

Chemistry and other characteristics of groundwater in the unsaturated zone may affect groundwater flow and radionuclide transport of dissolved and colloidal species. Groundwater chemistry and other characteristics, including temperature, pH, Eh, ionic strength, and major ionic concentrations, may vary spatially throughout the system as a result of different rock mineralogy. The chemistry of the groundwater in the UZ will affect the drift seepage composition and thereby the potential for localized corrosion on the waste package corrosion barrier.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The groundwater chemical characteristics are important to determining potential in-drift seepage chemical compositions. The results of the near-field chemistry model are processed in TSPA along with the waste package localized corrosion model, where TSPA then calculates the potential for localized corrosion of the waste package corrosion barrier. The starting point for evaluating potential seepage water compositions in the near field was the chemical composition of ambient pore waters in the TSw. The available pore-water data from the four repository host units (Tptpul, Tptpmn, Tptpll, and Tptpln) were evaluated and statistically divided into four compositional groups. Each group is represented in the near-field chemistry model, which considers the water–rock interactions that will alter the composition of the waters percolating through the unsaturated zone. These waters represent potential drift seepage compositions that are the starting points for the in-drift seepage dilution/evaporation abstraction, which provides solution compositions inside the drift as a function of temperature, partial pressure of CO_2, and relative humidity, for use in the TSPA model. This is all done within *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Sections 6.3.2, 6.6, and 6.9). TSPA uses the predicted chemistry of evaporated seepage on the waste package surface to evaluate the potential for localized corrosion of the waste package outer barrier, using the localized corrosion model from *General and Localized Corrosion of the Waste Package Outer Barrier* (SNL 2007 [DIRS 178519], Section 8.3). If localized corrosion is initiated, the affected waste package will eventually be breached and open to advective flow and radionuclide transport.

The effects of groundwater chemical characteristics are included in the radionuclide sorption coefficients under ambient conditions. The sorption coefficient data on which the distributions are based are obtained in laboratory experiments in which crushed rock samples from the Yucca Mountain site are contacted with groundwaters (or simulated groundwaters) representative of the site, spiked with one or more of the radioelements (SNL 2007 [DIRS 177396], Sections A4 and

A5). The chemistry of pore waters and perched waters in the unsaturated zone along potential flowpaths to the accessible environment is discussed in *Yucca Mountain Site Description* (BSC 2004 [DIRS 169734]). In the insaturated zone, two distinct water types exist in the ambient system. One is perched water and the other is pore water. Perched water is generally more dilute than pore water. The J-13 and UE p#1 well waters were used in sorption experiments as end-member compositions intended to bracket the impact of water composition on sorption coefficients (SNL 2007 [DIRS 177396], Section A4). Some spatial trends in water composition through the TSw and CHn hydrogeologic units have been noted (BSC 2004 [DIRS 169734], Section 5.2.2.4.2). However, the uncertainty in these spatial variations (and the uncertainty with respect to the effects of the bounding water compositions on sorption (SNL 2007 [DIRS 177396], Sections A8.3, A8.4, and A8.9) have led to the treatment of natural variability in water composition as uncertainty. Sorption experiments have been carried out as a function of time, element concentration, atmospheric composition, particle size, and temperature. In some cases, the solids remaining from sorption experiments were contacted with unspiked groundwater in desorption experiments. The sorption and desorption experiments together provide information on the equilibration rates of the forward and backward sorption reactions. For elements that sorb primarily through surface complexation reactions, the experimental data are augmented with the results of modeling calculations using PHREEQC (PHREEQC V.2.3 [DIRS 155323], STN: 10068-2.3-00). The inputs for the modeling calculations include groundwater compositions, surface areas, binding constants for the elements of interest, and thermodynamic data for solution species. These modeling calculations provide a basis for interpolation and extrapolation of the experimentally derived sorption coefficient dataset. The effects of nonlinear sorption are approximated by capturing the effective K_d range (SNL 2007 [DIRS 177396], Section A8). In the case of a reactive or adsorbing radionuclide, several K_d values are used for different rock units in the unsaturated zone, as given in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Table 6-7). For a nonsorbing tracer, K_d is set to zero.

The effects of groundwater composition with respect to sorption coefficients are provided in terms of probability distributions for the sorption coefficient of each element of interest among the three major rock types (devitrified, zeolitic, and vitric) found in the unsaturated zone. The influence of expected variations in water chemistry, radionuclide concentrations, and variations in rock surface properties within one of the major rock types are incorporated into these probability distributions. These distributions are specified for each radionuclide–rock type combination (SNL 2007 [DIRS 177396], Section A8 and Appendix A[a]) and are sampled in the TSPA model to account for the effects of natural variations in pore-water chemistry and mineral surfaces on sorption. Correlations for sampling sorption coefficient probability distributions have been derived for the elements investigated (SNL 2007 [DIRS 177396], Appendix B[a]). To derive the correlations, a rating system was first developed to rate the impact of six different variables on the sorption coefficient for a given element in each of the three major rock types. The six variables are pH, Eh, water chemistry, rock composition, rock surface area, and radionuclide concentration. Water chemistry refers to the major ion concentrations and silica. Rock composition refers to both the mineralogical composition of the rocks and the chemical composition of the minerals (for example, zeolite compositions). The sorption coefficient uncertainty distributions, which include the effects of the chemical characteristics of groundwater, are used in the simulation of radionuclide transport in the TSPA model, as

described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.4).

FEP: 2.2.08.03.0A

FEP NAME:

Geochemical Interactions and Evolution in the SZ

FEP DESCRIPTION:

Groundwater chemistry and other characteristics, including temperature, pH, Eh, ionic strength, and major ionic concentrations, may change through time, as a result of the evolution of the disposal system or from mixing with other waters. Geochemical interactions may lead to dissolution and precipitation of minerals along the groundwater flow path, affecting groundwater flow, rock properties, and sorption of radionuclides. Effects on hydrologic flow properties of the rock, radionuclide solubilities, sorption processes, and colloidal transport are relevant. Kinetics of chemical reactions should be considered in the context of the time scale of concern.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Geochemical analysis indicates that current saturated zone groundwater under the repository and along the saturated zone transport path is paleoclimate recharge water (SNL 2007 [DIRS 177391], Section A7.1.2). These waters represent a mixture of waters from past flow systems having different climatic signatures than those indicative of current dry climatic conditions. Corrected saturated zone groundwater ages based on ^{14}C data range from late Pleistocene to Holocene epochs (SNL 2007 [DIRS 177391], Section A6.3.6.6.2). Corrections to the groundwater ^{14}C ages to account for geochemical interactions are small (SNL 2007 [DIRS 177391], Section A6.3.6.6.2), and thus indicative of minor chemical reactions between carbonate minerals such as calcite and groundwaters. However, values for $\delta^{13}C$ and ^{14}C are negatively correlated (SNL 2007 [DIRS 177391], Section A6.3.6.6.2 and Figure A6-45) and could be interpreted as a result of various levels of calcite dissolution by infiltrating waters having different ages (SNL 2007 [DIRS 177391], Section A6.3.6.6.2). Bulk chemical and isotopic composition of perched and saturated zone groundwaters indicates that there are some geochemical variations associated with spatial variations that may be related to mixing. However, the overall aqueous species concentrations of perched waters and groundwaters are similar (SNL 2007 [DIRS 177391], Section A6.3.6.3). Therefore, it is expected that mixing of paleowaters and recharged waters under current climatic conditions, noting that the latter are a product of local recharge, would not result in major changes in the bulk water chemistry. Sufficiently large residence times of these waters in contact with silica-rich rock would produce near-neutral to mildly alkaline pH, inducing partitioning of $CO_2(g)$ into the aqueous phase.

The ranges in radionuclide sorption coefficients (K_d) and effective colloidal retardation factors were derived based on variations in water chemistry, radionuclide concentrations, and variations in rock surface properties (SNL 2008 [DIRS 184806], Section A3; BSC 2004 [DIRS 170006], Section 1). The groundwater ionic strength is expected to remain low, so it would not affect colloid stability over time. Moreover, temporal variations in water chemistry are expected to be

reasonably well bounded by current spatial variations in geochemical conditions. Hence, the effects of anticipated changes in K_d and retardation factors are effectively bounded by employing the ranges of transport parameter values used in the saturated zone transport model. Therefore, it is anticipated that temporal changes in water geochemistry exert little effects on geochemical interaction in the saturated zone. Specific details pertaining to variability in redox conditions are discussed below.

Hydrothermal activity is considered to be of low consequence to regional saturated zone flow and flow paths in the Yucca Mountain vicinity (see excluded FEP 1.2.06.00.0A (Hydrothermal Activity)). Also, temporal geochemical changes due to an increase in geothermal (hydrothermal) activity are not expected based on the characterization of mineral alteration in the rock and/or geochemical data (see excluded FEP 1.2.06.00.0A (Hydrothermal Activity)). The kinetics of heterogeneous chemical reaction, such as dissolution and precipitation, are also expected to be of low consequence. Results indicate that the temperature will peak at the present-day water table approximately 6,000 years after waste emplacement with the maximum temperature equal to 73°C and an average of the maximum at each of the 560 locations modeled of 63°C (as extracted from the 560 *.*wt* files in DTN: LL0702PA013MST.068 [DIRS 180553] in subfolder: /SDT/SDT-01/SDT55). Even subject to a wetter climate in the future, the estimated maximum temperature at the elevated water table is 80°C (see discussion in excluded FEP 2.2.10.02.0A (Thermal Convection Cell Develops in SZ)). The rates of water–rock reactions are still low at or below this temperature. As described in excluded FEP 2.2.10.08.0A (Thermo Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)), there is little volcanic glass remaining below the water table where the most common alteration products of this phase are sorptive zeolites. Therefore, any effect on the remaining volcanic glass with time would be towards zeolite formation and/or recrystallization of preexisting secondary mineral phases without the constraints of rate limiting processes. It is then concluded that these processes are insufficient as to cause any significant effect on the amount of sorptive minerals present below the water table and do not significantly affect the saturated zone. It should be noted that models describing radionuclide transport from the EBS to the unsaturated zone and then to the saturated zone do not account for radionuclide solubility (see excluded FEP 2.2.10.08.0A (Thermo Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)).

For the SZ site-scale transport model (SNL 2008 [DIRS 184806], Figures F-1 and F-2), it is assumed that the groundwaters along the transport path are oxidizing from the unsaturated zone–saturated zone water table interface to the boundary of the accessible environment. However, there is evidence of localized reducing zones along the saturated zone transport pathway east of Yucca Mountain, which may result in the reduction of redox-sensitive radionuclides such as technetium and neptunium (BSC 2006 [DIRS 178672], Section 2.1.3). These radionuclides are less soluble at lower oxidation states (i.e., reducing environments) and could precipitate out of solution and accumulate in localized reduction zones. Radionuclides such as technetium and neptunium also have significantly higher values of sorption coefficients under reducing conditions (BSC 2006 [DIRS 178672], Section 2.3). A subsequent return to oxidizing conditions within the localized reduction zones would favor dissolution of these precipitates back into solution or remobilization of sorbed species. If such a scenario occurs, this would cause radionuclide concentrations in the saturated zone groundwater to increase to levels above those that were present prior to the influx of more oxidized groundwater.

It is not expected that the local reduction zones will be oxidized during the 10,000 years after repository closure or that they will increase in size. A large-scale change in oxidation state from that measured currently at Yucca Mountain is excluded on the basis of low consequence. The rationale for this conclusion is as follows:

1. Reducing conditions found in Boreholes USW H-1, USW H-4, UE-25b#1 (Ogard and Kerrisk 1984 [DIRS 100783], Section IV), and USW WT-17 (SNL 2008 [DIRS 184806], Section F2.2) indicate that reducing conditions in this area extend from the shallow saturated zone to the lower Tram Tuff (BSC 2006 [DIRS 178672], Section 2.1.2.1). The reducing agents for groundwater in these wells could be located in the groundwater itself or in the rock matrix. Because the reducing zones are local in extent, the aquifer matrix most likely supplies most of the reduction capacity. Generally, in volcanic rocks the reduction capacity is associated with solid sulfides (e.g., pyrite), biotite, and other ferrous iron-bearing minerals. Pyrite has been identified as a mineral component of the lower Tram Tuff (Castor et al. 1994 [DIRS 102495]; SNL 2007 [DIRS 177394], Appendix O) and is believed to have been entrained in the ash-flow eruptions that produced the Tram Tuff (BSC 2006 [DIRS 178672], Section 2.1.2.1). Within the Yucca Mountain vicinity, the Tram Tuff spans west of Bare Mountain, eastward to Jackass Flats, and southward to within five miles of Highway 95 (Carr et al. 1984 [DIRS 101522], Figure 11). Given that pyrite is a mineral component of the Tram Tuff within the Yucca Mountain vicinity, it promotes reducing conditions in groundwater that comes into contact with that unit (BSC 2006 [DIRS 178672], Section 2.1.2.1). Given the age, areal extent, and mineral content of these volcanic hydrogeologic units, it is inferred that there is sufficient pyrite in these hydrogeologic units such that reducing conditions will be limited to their present-day location and persist for at least 10,000 years after repository closure.

2. Resident groundwaters along the projected groundwater flow path were exposed to relatively long residence times in contact with volcanic rock (SNL 2007 [DIRS 177391], Section A6.3.6.6.2). This would result in pH at near-neutral to mildly alkaline levels and an oxidation state to be largely determined by water–rock interactions. Consequently, it is not expected that future groundwaters will further oxidize localized reducing zones within the next 10,000 years after repository closure.

3. There is no current mechanism known to support the concept that reducing conditions will become more extensive along the saturated zone flow path. The total reduction capacities in the tuff are a function of the concentration of the rock's in situ reducing agents and the extent of these reducing zones. To date, only localized reducing zones have been produced over the past several million years (BSC 2006 [DIRS 178672], Section 2.1.2). It is reasonable to presume that this reduction capacity will remain localized over the relatively short 10,000 years after repository closure. Therefore, a significant increase in the size of these local reducing zones is not expected. Also, any effect on the redox state of the groundwaters on these reducing zones as a result of microbial activity is excluded on the basis of low consequence (see excluded FEP 2.2.09.01.0A (Microbial Activity in the SZ)). The reason for this is the small amount or absence of organic carbon in the groundwaters.

Detailed discussions pertaining to related FEPs in groundwater chemistry as they affect transport and sorption are addressed by included FEPs 2.2.08.01.0A (Chemical Characteristics of Groundwater in the SZ), 2.2.08.06.0A (Complexation in the SZ), 2.2.08.09.0A (Sorption in SZ), and 2.2.08.10.0A (Colloid Transport in the SZ), and by excluded FEP 2.2.08.07.0A (Radionuclide Solubility Limits in the SZ). They are also addressed in the following reports: *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Appendix O), *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Appendix A), *Saturated Zone Colloid Transport* (BSC 2004 [DIRS 170006]), and *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Appendices A, B, D and D[a], and F). The geochemical interactions in the saturated zone as a result of the thermal pulse from the repository are discussed in detail in excluded FEP 2.2.10.08.0A (Thermo-Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)). That FEP was excluded on the basis of low consequence.

Based on the previous discussion, omission of FEP 2.2.08.03.0A (Geochemical Interactions and Evolution in the SZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.03.0B

FEP NAME:

Geochemical Interactions and Evolution in the UZ

FEP DESCRIPTION:

Groundwater chemistry and other characteristics, including temperature, pH, Eh, ionic strength, and major ionic concentrations, may change through time, as a result of the evolution of the disposal system or from mixing with other waters. Geochemical interactions may lead to dissolution and precipitation of minerals along the groundwater flow path, affecting groundwater flow, rock properties, and sorption of radionuclides. Effects on hydrologic flow properties of the rock, radionuclide solubilities, sorption processes, and colloidal transport are relevant. Kinetics of chemical reactions should be considered in the context of the time scale of concern.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP is closely related to excluded FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)).

The thermo-chemical interactions that will occur in the repository environment have been studied with respect to effects on the seepage water entering the waste emplacement drifts using the THC seepage model (SNL 2007 [DIRS 177404]). This model, which explicitly captures the effects of changes in temperature, pH, Eh, ionic strength (and other compositional variables), time dependency, precipitation or dissolution effects, and effects of resaturation, was used to examine near-field and drift seepage flow and chemistry (SNL 2007 [DIRS 177404], Section 6.2). Changes in fracture permeabilities resulting from mineral precipitation or dissolution were found to be on the order of the natural variation in these properties (DTN: LB0302DSCPTHCS.001 [DIRS 164744]; SNL 2007 [DIRS 177404], Section 6.5.5.3; BSC 2004 [DIRS 170038], Table 6-5), with most of the substantial effects limited to regions above and to the side of the drift within about a drift diameter (SNL 2007 [DIRS 177404], Figures 6.5-8 to 6.5-9). The predicted mineral precipitation reduces the permeability in the affected regions, and leads to a reduction in flow into the drift. The effects of mineral precipitation on fracture permeability as it relates to near-field and drift seepage chemistry were also evaluated with the THC seepage model. A discussion of potential THC processes that could result in modification of fracture permeability is provided in included FEP 2.2.03.02.0A (Rock Properties of Host Rock and Other Units). The effects of mixing of waters are not explicitly accounted for by the THC seepage model or the near-field chemistry model in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3). However, *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 7.1.2.2) shows a near-field chemistry modeling validation case where the PTn pore waters percolate through the TSw hydrogeologic unit. The overall results of this modeling at various feldspar dissolution rates indicate that the evolutionary pathways of the PTn

pore-water chemistries closely progress towards those of the TSw hydrogeologic unit. Therefore, it is not expected that mixing of PTn and TSw pore waters would generate water chemistries that are different from those defined by the compositional range of the TSw pore waters.

Geochemical alteration of the PTn nonwelded unit above the repository host rock due to heat from the repository should not significantly change the PTn hydrologic properties. The reason for this is because the current alteration state of the unit represents the cumulative effects from similar heating of longer duration. Simulations show that the peak temperature at the bottom of the PTn unit from repository heating will be 43°C, or approximately 25°C hotter than the prerepository in situ temperature (SNL 2008 [DIRS 179962], Figure 6.4.2-30). The cited figure also shows that the duration of repository heating at the base of the PTn unit is on the order of 10,000 years. Significant mineralogical changes in the PTn unit are not expected since a combination of higher temperatures and high water saturation levels would be necessary for widespread rock alteration to zeolite and clay phases (see excluded FEP 2.2.10.07.0A (Thermochemical Alteration of the Calico Hills Unit)). The PTn strata (comprising several nonwelded lithostratigraphic units) are located between the underlying Topopah Spring Tuff and the overlying Tiva Canyon Tuff (BSC 2004 [DIRS 170029], Section 6.4, Table 6-2). In the geologic past, the pyroclastic section that includes both the host rock and the PTn has been subject to temperature excursions of greater magnitude and duration than those predicted as a result of repository heating (SNL 2007 [DIRS 177412], Section 6.12.2.2.1, p. 6-187). The effects from past heating events are represented in the current highly variable state of alteration in the PTn unit (BSC 2004 [170031], Figures 6-9, 6-17, and 6-18; Levy et al. 1996 [DIRS 104157], p. 788, Table 1, Figure 2). Because the past heating was greater than what is predicted from the repository, the repository-induced effects on PTn properties will be minor and within the range of variability of existing natural alteration. Thermal conditions associated with the eruption of the Timber Mountain Group heated the Topopah Spring Tuff, which directly underlies the PTn unit, to 50°C to 100°C for up to several millions of years (SNL 2007 [DIRS 177412], Section 6.12.2.2.1, p. 6-187). Similar temperatures may have existed in the PTn unit because of its close stratigraphic proximity.

The representation of geochemistry in the THC seepage model includes the major solid phases (minerals and glass) encountered in hydrogeologic units at Yucca Mountain with a range of possible reaction product minerals, CO_2 gas, and the aqueous species necessary to include these solid phases and pore-water compositions within the model (SNL 2007 [DIRS 177404], Table 6.2-2). Compositional changes of seepage are calculated by the drift-scale THC seepage model (SNL 2007 [DIRS 177404], Section 6.5.5.4) for matrix/fracture pore waters and gas at gridblocks near the drift wall boundary. Variations in pH (SNL 2007 [DIRS 177404], Figures 6.5-16, 6.6-1, 6.6-7, 6.6-9, and 6.6-14), a key compositional variable for sorption of some radionuclides (SNL 2007 [DIRS 177396], Appendix A), roughly lie within the range of variability investigated for radionuclide sorption (SNL 2007 [DIRS 177396], Appendix A).

Results were investigated for the THC seepage model applied to the Tptpll unit considering a range of initial pore-water compositions. In this model, four different initial pore-water compositions were investigated (SNL 2007 [DIRS 177404], Table 6.2-1). Peak concentrations usually found at the time of rewetting reflect mostly the small values of the first, nonzero, liquid-saturation output. In any case, elevated concentrations are predicted only for small liquid

saturations that are not subject to significant fluid movement. The model predicts, upon rewetting, more rapid return to near-ambient conditions for aqueous calcium, sodium, and chlorine. The findings indicate that most of the significant compositional variations are limited to the low saturation conditions near the drift wall. In areas with high saturation, compositional variations have little impact relative to the processes considered in this FEP. The effects of variations in potential seepage water composition on in-drift water chemistry are addressed in included FEP 2.2.08.12.0A (Chemistry of Water Flowing into the Drift).

The effects of colloid formation are accounted for in the colloid source term (SNL 2007 [DIRS 177423], Section 6.5.2.3). Colloids are formed from the degradation of the HLW and SNF waste forms, EBS materials, and rock (SNL 2007 [DIRS 177423], Section 6.3.1). Radionuclides associated with colloids are modeled as either irreversibly or reversibly attached to colloids to encompass the broadest range of potential radionuclide-colloid interactions (SNL 2008 [DIRS 184748], Section 6.4.5). Elevated temperatures are expected to result in fewer colloids due to the decrease in colloid stability. This is due to the greater energy of colloid motion at higher temperatures, which allows colloids to overcome the threshold associated with coagulation (SNL 2007 [DIRS 177423], Section 6.3.2). Modeling of colloid transport is discussed in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 ([DIRS 184748], Sections 6.4.5, 6.5.12, and 6.5.13). The cumulative probability distribution for colloid concentrations as a function of ionic strength, based on available data, spans five orders of magnitude for water with ionic strength less than 0.05 M (SNL 2008 [DIRS 184748], Section 6.5.12, Table 6-21), indicating that variability in ionic strength below this limit will not have a strong effect on colloid transport because colloid concentrations are so variable. Colloid concentration for water with ionic strength greater than 0.05 M is set to 10^{-6}, lower than the values for water with lower ionic strength (SNL 2008 [DIRS 184748], Section 6.5.12, Table 6-21). Therefore, higher ionic strength waters would inhibit colloid transport, but such waters are expected to be present in small amounts that don't last long, as described above.

In addition to natural materials, introduced materials may take part in geochemical interactions. Cementitious material (shotcrete) is planned for use as part of the ground support for the turnout intersections of the main access drifts and for the turnouts and intersections of the exhaust drifts with the emplacement drifts (BSC 2007 [DIRS 183406], Section 7.3). The incorporation of cementitious materials in the repository poses two potential effects. The first is that the leaching of cementitious materials, particularly the shotcrete supporting the turnout intersections in the main access drifts and the intersections of the exhaust main drifts with the emplacement drifts, will affect repository performance by modifying the hydrologic properties of the surrounding rock and diverting the flow of water entering the drifts. The second concern is that an alkaline plume resulting from leaching of the cementitious material could enhance radionuclide transport to the accessible environment, either through the complexation of radionuclides or through the presence of pseudocolloids.

No cementitious material will be used in the emplacement drifts (BSC 2007 [DIRS 183406], Section 7.3). In nonemplacement drifts, all cementitious material (concrete invert and shotcrete used in shafts) will be used only for ground support (BSC 2007 [DIRS 183406], Section 7.3). The only significant cementitious materials remaining in the repository after closure will be shotcrete in the emplacement drift turnouts, exhaust intersections, and other non-emplacement openings. Grout used for rock bolt placement will be present in non-emplacement drifts and

turnout intersections. Excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS) addresses degradation of ground support material.

Transport enhancement by alkaline plumes will be negligible for long-term repository performance for two reasons. First, as discussed in excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS), there will be little opportunity for mixing of the alkaline plumes with the fluids in the EBS; hence, the plumes will have no effect on the generation of a mobile radionuclide source term. Second, high-pH plumes in the unsaturated zone are expected to be short-lived and rapidly neutralized. The unsaturated zone is open to gas circulation; particularly, ambient CO_2 will dissolve into the plume and neutralize the high-pH fluids. The rapid neutralization of cement leachates by CO_2 gas is indicated by experiment (DTN: LL030211523125.006 [DIRS 172021], file: *LiquidCarbonationEQ3-6Modeling.doc*). These findings are consistent with the analysis reported by Ziegler (2004 [DIRS 171694], Section D.4). Even in the northwestern end of the repository footprint, where the TSw-CHn contact is approximately 80 m below the repository horizon (source for the elevation of the top of the CHn: DTN: MO0610MWDHFM06.002 [DIRS 179352], file: *H06_18chvu_X.dat*; source for the repository outline and elevations: SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-01) where lateral flow may occur, the flow path from the emplaced cement to that contact is sufficient to neutralize the potential plumes. Additional details regarding the chemical effects of an alkaline plume are considered as part of excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS).

The potential porosity and permeability changes in the surrounding rock are discussed in excluded FEP 2.1.06.01.0A (Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS). Calcite precipitation will not lead to changes in host rock hydrologic properties that are sufficiently large or extensive enough to divert the dominantly vertical flow beneath the turnouts towards the emplacement drifts.

Based on the above discussion, omission of FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.04.0A

FEP NAME:

Re-Dissolution of Precipitates Directs More Corrosive Fluids to Waste Packages

FEP DESCRIPTION:

Re-dissolution of precipitates that have plugged pores as a result of evaporation of groundwater in the dry-out zone, may produce a pulse of fluid reaching the waste packages when gravity-driven flow resumes, which is more corrosive than the original fluid in the rock.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The process of redissolution of mineral precipitates is examined in the drift-scale thermal-hydrologic-chemical (THC) seepage model (SNL 2007 [DIRS 177404], Section 6.5.5.3). This model is used to evaluate the significance of coupled THC processes on the chemistry of seepage waters. In addition, a sensitivity study has been prepared (SNL 2007 [DIRS 177413]) that integrates features of the seepage model (SNL 2007 [DIRS 181244]; BSC 2005 [DIRS 172232]) with the drift-scale THC seepage model, to evaluate potential changes in seepage composition.

The results of these studies (primarily SNL 2007 [DIRS 177413], Section 6.6) show that:

- Precipitates form in the host rock during the thermal period, primarily consisting of silica and calcite, but also including halite, anhydrite, and minor amounts of sulfate, carbonate, and nitrate salts (SNL 2007 [DIRS 177404], Section 6.5.5.3).

- These precipitates redissolve when moisture returns to the dryout zone, with the most soluble species forming small amounts of concentrated brine when rewetting first occurs, at or before approximately 1,000 years after repository closure (SNL 2007 [DIRS 177404], Section 6.5.5.4).

- Seepage composition is dilute for conditions when seepage occurs, because relatively large local percolation flux is required to produce seepage, and the small amounts of brine that can be produced are insufficient to impact seepage chemistry (SNL 2007 [DIRS 177413], Section 6.1.2).

- After rewetting, seepage composition eventually returns to that of pore waters used for initial and boundary conditions (SNL 2007 [DIRS 177412], Section 6.3.2.4.5).

- THC processes affect seepage hydraulics, but the timing and magnitude of seepage are reasonably bounded by the abstraction used in TSPA (SNL 2007 [DIRS 181244]).

- The transient changes in the composition of seepage that occur immediately during or after rewetting of the dryout zone may involve re-dissolution of precipitated salts and temporary concentration of chloride and other soluble components relative to waters percolating through the rock around the dryout zone, but mostly involve dilution by condensation (SNL 2007 [DIRS 177413], Figure 6.6-7). For such transient changes to be significant, failure of the drip shield must occur during (or prior to) rewetting.

Drip Shield Performance during Rewetting – Seepage cannot contact the waste package if the drip shield performs its diversion function, so any transient flow of seepage that occurs during rewetting, and is concentrated in soluble salts, is not expected to contact the waste package. Drip shield corrosion will occur very slowly, and is not compositionally dependent (SNL 2007 [DIRS 180778], Section 8). The titanium alloy used in drip shield plates is not significantly affected by microbially influenced corrosion or localized corrosion (SNL 2007 [DIRS 180778], Section 8). Hence, the drip shield thickness will be substantially undegraded by corrosion during this early time period, and the drip shield will continue to perform its function.

Drip Shield Performance during Rewetting after an Early Failure Event – In the event of an early failure of a drip shield, the underlying waste package is assumed to fail by localized corrosion, so there is no additional dependence on seepage composition during rewetting (SNL 2008 [DIRS 183478], Section 6.4).

Drip Shield Performance during Rewetting after a Seismic Event – Vibratory ground motion effects are addressed in included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components). Consequences of damage to the drip shield are generally insignificant because: (1) advective flow through stress corrosion cracks on the drip shield is excluded (see excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield)), so the presence of stress corrosion cracks on the drip shield does not compromise its ability to divert seepage away from the waste package; (2) drip shield separation is not predicted to occur (SNL 2007 [DIRS 176828], Section 6.7.3); and (3) failure of the drip shield from waste package impacts is not predicted to occur (SNL 2007 [DIRS 176828], Section 6.8.5).

The direct effects of rockfall on drip shields are also excluded in FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components). The screening justification (SNL 2007 [DIRS 176828], Section 6.10) focuses on the potential impacts on the drip shields and waste packages from rockfalls involving large rock blocks in the nonlithophysal zones, which bound the effects from small rock blocks in the lithophysal zones.

The direct effects of fault displacement on the EBS components are included, as discussed for FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components). A conservative approximation is taken (neglecting the presence of the drip shield) to estimate damage to the waste package from fault displacement. Drip shield degradation from fault displacement occurs if the waste package is also damaged (SNL 2007 [DIRS 176828], Section 6.12.2, Item 27). This mitigates the effects from corrosion that might occur, for the unexpected circumstance of damage caused by fault displacement prior to rewetting of the near-field host rock (i.e., prior to approximately 1,000 to 3,000 years, depending on whether drift collapse has prolonged the boiling period in the EBS; SNL 2008 [DIRS 179962], Figure 6.4.2-28).

Drip Shield Performance during Rewetting after an Igneous Intrusion Event – An igneous intrusion in the form of a dike that may occur through the repository, as described in FEP 1.2.04.04.0A (Igneous Intrusion Interacts with EBS Components) is included in the TSPA and results in damage to the waste packages and mobilization of waste. This FEP leads to the assumption that drip shield and waste package are gone and therefore the impact of corrosive fluids on the waste package is irrelevant.

Summary – The above discussion shows that transient changes in seepage chemistry may occur during rewetting, although dilution is generally predicted by sensitivity analysis. These changes will have no significant effect on performance because the drip shields prevent seepage contact with waste packages, and performance of the drip shield does not depend on seepage composition.

Based on the preceding discussion, omission of FEP 2.2.08.04.0A (Re-Dissolution of Precipitates Directs More Corrosive Fluids to Waste Packages) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.05.0A

FEP NAME:

Diffusion in the UZ

FEP DESCRIPTION:

Molecular diffusion processes may affect radionuclide transport in the UZ. This includes osmotic processes in response to chemical gradients.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Although this FEP refers to diffusion in the unsaturated zone, it only addresses diffusion in faults and fractures in the unsaturated zone. Matrix diffusion in the unsaturated zone is described in included FEP 2.2.08.08.0B (Matrix Diffusion in the UZ).

The FEP description includes osmosis, which is a process that will not have a significant effect on radionuclide transport in the unsaturated zone compared to matrix diffusion. If groundwater present in a fault or fracture system in the unsaturated zone were to move across a mineral-based semi-permeable membrane into the rock matrix, the solutes present in the fracture or fault would be concentrated. Increased radionuclide concentrations could result in more matrix diffusion into the rock wall, a process that would tend to retard radionuclide transport in the unsaturated zone. Alternatively, if groundwater in the rock matrix were to move across a semi-permeable membrane into fractures or faults, the amount of water present in the fractures or faults would be increased, thus diluting the concentrations of radionuclides that are being transported to the water table, which may weaken matrix diffusion but not enough to impact transport times. In any case, a low volume of water may move across the boundary. Diffusion and osmosis into and from the fractures will eventually cancel each other. When radionuclides are present in fractures or faults, they can be transported by advection, dispersion, and diffusion. Transport by advection and dispersion are discussed in included FEP 2.2.07.15.0B (Advection and Dispersion in the UZ). Transport by diffusion, which is proportional to concentration gradient is not included in TSPA because under all scenarios, it is much less than transport by advection. The contribution of diffusion to total dispersion is negligible in comparison to that caused by advection related dispersion.

The free-water diffusion values for all radionuclides are defined in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748] Table 6.5.5-2). The largest value is for cesium and is 2.1×10^{-9} m^2/s. This can be compared with the corresponding value of the dispersion coefficient, which is the product of the flow velocity and the dispersivity. The fracture dispersivity has a fixed value of 10 m (SNL 2008 [DIRS 184748]). The flow velocity v depends upon the overall percolation flux q, the fraction of the flux which flows in fractures or faults (that is, not in the matrix) f, and the fracture porosity ϕ:

$$v = (q f)/\phi$$

Both q and f depend upon the flow field; that is, upon the climate (present-day, monsoon, or glacial-transition) and whatever percentile infiltration is imposed as a boundary condition. Porosity ϕ varies with the model layer, as shown in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Table 6-13). To minimize v, and therefore maximize the importance of diffusion relative to dispersion, q is taken from the slowest flow field, and f at the horizon where the greatest fraction of flow is through the matrix continuum. These are the lower bounds for present-day climate (probability distribution (pd10)), for which q = 3 mm/yr (SNL 2007 [DIRS 184614], Table 6.1-2) and f = 0.54 (SNL 2007 [DIRS 184614], Table 6.6-3), with f taken at the water table. For model layers below the repository, the greatest ϕ, giving the slowest v, is 0.025 (layer tswf; SNL 2008 [DIRS 184748], Table 6-13). Substituting these values, the minimum v = 65 mm/yr results in a minimum dispersion coefficient of 2.1×10^{-8} m^2/s. This minimum dispersion coefficient is still 10 times larger than the diffusion coefficient of 2.1×10^{-9} m^2/s for groundwater (Reimus et al. 2007 [DIRS 179246]). Because diffusion is at least one order of magnitude lower than the minimum dispersion, diffusion is excluded based on low consequence.

Free water diffusion represents an upper bound on radionuclide diffusion in faults and fractures (i.e., the transport of radionuclides by diffusion will be slower than the diffusional transport of water). Therefore, diffusional transport of radionuclides will be insignificant compared to transport by dispersion and advection.

Based on the previous discussion, omission of FEP 2.2.08.05.0A (Diffusion in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.06.0A

FEP NAME:

Complexation in the SZ

FEP DESCRIPTION:

Complexing agents such as carbonate, fluoride, and humic and fulvic acids present in natural groundwaters could affect radionuclide transport in the SZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Inorganic complexing agents are included in the saturated zone transport model (SNL 2008 [DIRS 184806], Appendix A) in that the surface-complexation models used to develop radionuclide K_d distributions include the effects of these complexing agents as well as the effects of competing cations in solution, such as calcium, magnesium, sodium, potassium, and aluminum. In the saturated zone, inorganic complexing agents, such as carbonates, are dominant, whereas organic complexing agents are not found in significant amounts (see excluded FEP 2.2.09.01.0A (Microbial Activity in the SZ)).

Complexing agents can affect solubility and speciation of radionuclides in groundwater, and as a consequence, affect their sorption onto the rock surface and colloids. The effects of complexing agents on radionuclide sorption on rock surfaces, radionuclide sorption on inorganic colloids, and effective radionuclide sorption on rock surfaces in the presence of inorganic colloids are accounted for in TSPA through the use of sorption coefficients, K_ds, in the equations describing transport through fractures and porous media (SNL 2008 [DIRS 184806], Sections 6.4.2.4 to 6.4.2.6, Equations 21, 22, 42, 43, 45, and 46). Uncertainty in the values of these K_ds is accounted for by defining appropriate ranges of values for the sorption coefficients, as described in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Appendix A) and implemented in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2.8, 6.5.2.11, 6.5.2.12, and Table 6-8). The sorption coefficient data on which these distributions are based were obtained in laboratory experiments in which crushed rock samples from the Yucca Mountain site were contacted with groundwaters (or simulated groundwaters) representative of the site (SNL 2008 [DIRS 184806], Appendix A), spiked with one or more of the elements of interest (SNL 2008 [DIRS 184806], Appendix A). The natural waters contained all the relevant inorganic complexants of interest in representative concentrations, and the synthetic groundwaters contained representative carbonate/bicarbonate concentrations. Carbonate ion is expected to be the dominant complexing agent in Yucca Mountain groundwaters.

Sorption experiments have been carried out as a function of time, element concentration, atmospheric composition, particle size, and temperature. In some cases, the solids remaining from sorption experiments were contacted with unspiked groundwater in desorption experiments.

The experimental data used to determine the sorption K_d distributions are discussed in Appendix A of *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806]). The sorption and desorption experiments together provide information on the equilibration rates of the forward and backward sorption reactions. For elements that sorb primarily through surface complexation reactions, the experimental data are augmented with the results of modeling calculations using PHREEQC (PHREEQC V2.3 [DIRS 157837], STN: 10068-2.3-01) with the thermodynamic input data file *PHREEQCDATA025.dat* (DTN: MO0604SPAPHR25.001 [DIRS 176868]). The inputs for the modeling calculations include groundwater compositions, surface areas, binding constants for the elements of interest, and thermodynamic data for solution species. These modeling calculations provide a basis for interpolation and extrapolation of the experimentally derived sorption coefficient dataset.

Uncertainty in sorption coefficients is quantified in terms of probability distributions for the sorption coefficient of each element of interest among the three major rock types (devitrified, zeolitic, and vitric) found in the saturated zone. The influence of expected variations in water chemistry, radionuclide concentrations, and variations in rock surface properties within one of the major rock types are incorporated into these probability distributions (see included FEP 2.2.08.09.0A (Sorption in the SZ)). These distributions are specified for each radionuclide–rock type combination (SNL 2008 [DIRS 184806], Appendix A), and are sampled in the TSPA model to account for the effects of natural variations in pore-water chemistry and mineral surfaces on sorption. Correlations for sampling sorption coefficient probability distributions have been derived for the elements investigated (SNL 2008 [DIRS 184806], Section A9). To derive the correlations, a rating system was first developed to rate the impact of six different variables on the sorption coefficient for a given element in each of the three major rock types. The six variables are pH, Eh, water chemistry, rock composition, rock surface area, and radionuclide concentration. Water chemistry refers to the major ion concentrations and silica. Rock composition refers to both the mineralogic composition of the rocks and the chemical composition of the minerals (e.g., zeolite compositions). The DTNs for the sorption K_ds and correlations are LA0702AM150304.001 [DIRS 184763] and LA0311AM831341.001 [DIRS 167015].

Although naturally occurring organic complexing agents are not found in significant amounts in the saturated zone, they could still potentially affect radionuclide retardation if they form strong complexes with radionuclides, and these complexes sorb very weakly. The potential effects of organic complexing agents on sorption were investigated by Triay et al. (1997 [DIRS 100422], Section IV.B). Their experiments tested the effects of organic materials (dihydroxyphenylalanine and Nordic Aquatic Fulvic Acid) on the sorption of plutonium and neptunium on tuff materials. The results of these tests showed very little effect of the organic materials for sorption of these radionuclides in tuffs.

FEP: 2.2.08.06.0B

FEP NAME:

Complexation in the UZ

FEP DESCRIPTION:

Complexing agents such as humic and fulvic acids present in natural groundwaters could affect radionuclide transport in the UZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Complexation of radionuclides by mobile complexing agents such as humic and fulvic acids is treated as part of colloid transport in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Sections 6.1.3 and 6.18). Complexation on immobile mineral surfaces is treated as part of sorption of dissolved radionuclides in that same report (SNL 2007 [DIRS 177396], Section A7). Therefore, the effects of complexation are implicitly included in the radionuclide sorption coefficients under ambient conditions. For TSPA, radionuclide transport is simulated by a particle-tracking model that includes the effects of complexation, as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.4).

The sorption coefficient data on which the distributions are based are obtained in laboratory experiments in which crushed rock samples from the Yucca Mountain site are contacted with groundwaters (or simulated groundwaters) representative of the site (SNL 2007 [DIRS 177396], Section A4), spiked with one or more of the elements of interest (SNL 2007 [DIRS 177396], Section A5). As such, the sorption experiments contain representative ligands responsible for complex formation (Triay et al. 1997 [DIRS 100422], pp. 85 and 133). Sorption experiments have been carried out as a function of time, element concentration, atmospheric composition, particle size, and temperature. In some cases, the solids remaining from sorption experiments were contacted with unspiked groundwater in desorption experiments. The sorption and desorption experiments together provide information on the equilibration rates of the forward and backward sorption reactions. For elements that sorb primarily through surface complexation reactions, the experimental data are augmented with the results of modeling calculations using PHREEQC (PHREEQC V2.3 [DIRS 157837], STN: 10068-2.3-01). The inputs for the modeling calculations include groundwater compositions, surface areas, binding constants for the elements of interest, and thermodynamic data for solution species. These modeling calculations provide a basis for interpolation and extrapolation of the experimentally derived sorption coefficient dataset. The effects of nonlinear sorption are approximated by capturing the effective K_d range (SNL 2007 [DIRS 177396], Section A8 and Appendix A[a]).

The effects of complexation with respect to sorption coefficients are provided in terms of probability distributions for the sorption coefficient of each element of interest among the three

major rock types (devitrified, zeolitic, and vitric) found in the unsaturated zone. The influence of expected variations in water chemistry, radionuclide concentrations, and variations in rock surface properties within one of the major rock types are incorporated into these probability distributions. These distributions are specified for each radionuclide–rock type combination (SNL 2007 [DIRS 177396], Section A8 and Appendix A[a]), and are sampled in the TSPA model to account for the effects of natural variations in pore-water chemistry and mineral surfaces on sorption. Correlations for sampling sorption coefficient probability distributions have been derived for the elements investigated (SNL 2007 [DIRS 177396], Appendix B[a]). To derive the correlations, a rating system was first developed to rate the impact of six different variables on the sorption coefficient for a given element in each of the three major rock types. The six variables are pH, Eh, water chemistry, rock composition, rock surface area, and radionuclide concentration. Water chemistry refers to the major ion concentrations and silica. Rock composition refers to the mineralogic composition of the rocks and the chemical composition of the minerals (e.g., zeolite compositions).

The effects of organics on sorption were investigated by Triay et al. (1997 [DIRS 100422], Section IV.B). Their experiments tested the effects of organic materials (dihydroxyphenylalanine and Nordic Aquatic Fulvic Acid) on the sorption of plutonium and neptunium on tuff materials. The results of these tests showed very little effect of the organic materials for sorption of these radionuclides in tuffs.

FEP: 2.2.08.07.0A

FEP NAME:

Radionuclide Solubility Limits in the SZ

FEP DESCRIPTION:

Solubility limits for radionuclides are different in saturated zone groundwater than in the water in the unsaturated zone or in the waste and EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Solubility determines the maximum concentration that a constituent can reach in the aqueous phase; therefore it is considered to be a bounding property. Once a particular radionuclide reaches its solubility limit, it will have the potential to precipitate or form a solid depending on kinetically related geochemical conditions in the local environment. The radionuclide constituent will then be at equilibrium between the solid and aqueous phase. The precipitate-forming solid phase will increase in mass until the concentration in the solution phase reaches the solubility limit. If the concentration in the aqueous phase decreases below the solubility limit, the solid phase will have the potential to dissolve into the aqueous phase depending on kinetically related geochemical conditions in the local environment.

Radionuclide solute concentrations entering the saturated zone from the unsaturated zone are not expected to exceed solubility limits because of the effects of dilution, dispersion, matrix diffusion, and sorption in the unsaturated zone (all of which will tend to decrease radionuclide concentrations below their concentrations at the source term, which are solubility-limited). Radionuclide concentrations will be further reduced in the saturated zone by the processes of dispersion, matrix diffusion, and sorption. Furthermore, throughout the saturated zone, the groundwater is primarily oxidizing, and is assumed to be such in the TSPA (SNL 2008 [DIRS 184806], Section 6.3). Redox-sensitive radionuclides introduced into the saturated zone from the unsaturated zone are more soluble in oxidizing waters than in reducing waters (SNL 2007 [DIRS 177418], Appendices V and VIII).

However, situated in the volcanic units (primarily the Tram Tuff), southeast of the repository footprint and within the first quarter of the predicted saturated zone flowpath length, there may exist a zone of reducing conditions (BSC 2006 [DIRS 178672], Figure 2.1-2). This zone cuts across the transport pathways from the repository that are predicted by the site-scale saturated zone flow model (SNL 2007 [DIRS 177391], Figure 6-17). If a solution containing a redox-sensitive constituent with lower solubility under reducing conditions passes through this reducing region, that constituent may precipitate out of solution, resulting in lower solution concentrations.

The effects of such a process are investigated in a sensitivity study reported in *Impacts of Solubility and Other Geochemical Processes on Radionuclide Retardation in the Natural System – Rev 01* (BSC 2006 [DIRS 178672]). In this study, the redox-sensitive radionuclide ^{99}Tc is introduced into oxidizing saturated zone groundwater and then transported through a thin reducing zone within the first quarter of the saturated zone flowpath length (BSC 2006 [DIRS 178672], Figure 2.6-1). When the technetium passes through the reducing zone, it is reduced from Tc(VII) to Tc(IV), and technetium precipitates may be formed if the solubility limit of one or more solid technetium phases is exceeded. This precipitation lowers the technetium concentrations in the groundwater. The aqueous technetium concentrations would be expected to remain at these lower levels downstream and well beyond the "exit point" of the reducing zone. Thus, the existence of the thin reducing zone would produce a significant delay in technetium peak concentrations at the compliance boundary (BSC 2006 [DIRS 178672], Section 3). The same result would be expected for other redox-sensitive radionuclides that have higher solubilities in oxidized groundwater than in reduced groundwater (e.g., nuclides of uranium, neptunium, plutonium), although the impact on dose is greatest for ^{99}Tc because of its high solubility and nonsorbing nature under oxidizing conditions. The study concludes that implementing solubility limits in the saturated zone, due to the presence of a zone of reducing conditions that may lie along the saturated zone transport path, could reduce concentrations of redox-sensitive constituents and significantly increase mean transport times to the accessible environment (BSC 2006 [DIRS 178672], Section 3).

The sensitivity study supports the supposition that if a solubility limit lower than that implemented in *Dissolved Concentration Limits of Radioactive Elements* (SNL 2007 [DIRS 177418], Section 6) were to be imposed in the saturated zone transport model, it could cause precipitates to form, dropping redox-sensitive radionuclide solutes out of the aqueous phase and reducing the maximum aqueous concentration capable of being transported to the accessible environment. No other changes in groundwater chemistry that may occur along flow paths in the saturated zone (e.g., pH, carbonate/bicarbonate concentration, ionic strength) are expected to be large enough (SNL 2007 [DIRS 177391], Sections A6.3.4.1, A6.3.5.1, and A6.3.4.4) to cause significant changes to radionuclide solubilities such that solubility limits would be exceeded in the saturated zone (SNL 2007 [DIRS 177418], Section 6). However, even if solubility limits were exceeded, this exceedance could only reduce radionuclide concentrations at the boundary of the accessible environment. The effect would be similar to, though presumably much lower in magnitude than, the effect of reducing conditions.

Potential precipitation of a radionuclide due to solubility limits in the saturated zone would increase the mean transport time and decrease the concentration of that radionuclide in the saturated zone relative to assuming no precipitation. Longer transport times in the saturated zone would allow radioactive decay to diminish the mass of radionuclides that are ultimately released to the accessible environment. Consequently, the process of precipitation due to solubility limits can only enhance the performance of the saturated zone with regard to its capability for retarding radionuclide migration. Thus, implementation of radionuclide solubility limits in the saturated zone can only be beneficial to repository performance. It follows that the exclusion of radionuclide solubility limits in the saturated zone is justified on the basis of low consequence because inclusion of these limits can only increase radionuclide travel times and decrease radionuclide releases to the accessible environment and radiation exposures to the RMEI.

Based on the previous discussion, omission of FEP 2.2.08.07.0A (Radionuclide Solubility Limits in the SZ) will not result in a significant adverse change to the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP NAME:

Radionuclide Solubility Limits in the UZ

FEP DESCRIPTION:

Solubility limits for radionuclides may be different in unsaturated zone groundwater than in the water in the waste and EBS.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The conditions that control radionuclide solubility are identified in *Dissolved Concentration Limits of Radioactive Elements* (SNL 2007 [DIRS 177418]) and include pH, fugacity of CO_2, concentration of fluoride ion, redox conditions, and temperature. These variables are not all independent: at higher temperature, CO_2 gas is less soluble. This reduces the solubility of carbonate complexes, which at high pH are the species that contribute the most to actinide solubilities. The result is that actinides are less soluble at higher temperatures (SNL 2007 [DIRS 177418], Section 6.3.3.3; but note that only solubility limits at 25°C are used for TSPA). Non-actinide radionuclides that may be released include carbon, cesium, iodine, strontium, and technetium. For the most part, the unsaturated zone will be under oxidizing conditions, which are more favorable to solubility and therefore mobility of radionuclides. In general, the conditions that control the solubility of actinides in the invert of the EBS will be different than in the unsaturated zone. This is because the drift and the invert will be hotter than the surrounding rock. The justification for exclusion is presented here in two parts. First, actinides will be less soluble in the invert than in the unsaturated zone below the invert. Therefore, transport away from the drift will be limited by the relatively low actinide solubility in the invert, compared to the unsaturated zone. Despite the greater potential for actinide solubility away from the invert in the unsaturated zone, there will be no source of actinides in the unsaturated zone to increase the concentration to the greater solubility limit. Therefore, the expected difference in actinide solubility limits between the invert and the unsaturated zone will have no adverse effect on the release of actinides to the accessible environment. Second, if radionuclide solubility in the unsaturated zone groundwater were to be less than the solubility in the invert, the addition of uncontaminated water to the "plume" of radionuclides leaving the EBS will decrease concentrations in the unsaturated zone groundwater. The radionuclide mass flux will remain the same even if solubilities in the unsaturated zone are lower than solubilities in the waste form/EBS because of the addition. The lower solubilities in the unsaturated zone are compensated for by a higher water volume in the unsaturated zone such that precipitation does not occur and the mass flux does not decrease.

Solubility limits could also affect the formation of certain kinds of true colloids, such as polymeric forms of plutonium oxide (SNL 2007 [DIRS 177423], Section 6.3.1). However, only small quantities of true colloids have been observed to form in experiments on waste form

degradation (SNL 2007 [DIRS 177423], Section 6.3.1). Furthermore, these colloids are expected to undergo transformation to pseudocolloids in the near- or far-field aquifer system (SNL 2007 [DIRS 177423], Section 6.3.1).

Based on the above discussion, omission of FEP 2.2.08.07.0B (Radionuclide Solubility Limits in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.07.0C

FEP NAME:

Radionuclide Solubility Limits in the Biosphere

FEP DESCRIPTION:

Solubility limits for radionuclides may be different in the biosphere pathways than in the water in the saturated zone.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

For the TSPA modeling cases involving radionuclide release to the groundwater, radionuclides are introduced into the biosphere with well water, either as dissolved species or in suspension attached to colloids. The conditions that dictate aqueous solubility levels in the saturated zone could be different from those prevailing in the surface soils of the biosphere. The degree of elemental solubility could potentially have an effect on the rate of removal of radionuclides from soils, thereby affecting the magnitude and duration of radionuclide accumulation in soil.

Radionuclide solute concentrations entering the saturated zone from the unsaturated zone are not expected to exceed solubility limits because of the effects of dilution, dispersion, matrix diffusion, and sorption in the unsaturated zone, all of which will tend to decrease radionuclide concentrations below their concentrations at the source, which are solubility-limited. Additional dilution is possible at the unsaturated zone–saturated zone interface, and radionuclide concentrations will be further reduced in the saturated zone by the processes of dispersion, matrix diffusion, and sorption. Furthermore, throughout the saturated zone, the groundwater is primarily oxidizing. Radionuclide constituents introduced into the saturated zone from the unsaturated zone are more soluble in oxidizing waters than in reducing waters (see excluded FEP 2.2.08.07.0A (Radionuclide Solubility Limits in the SZ)). The conditions in the biosphere are also expected to be predominantly oxidizing due to its proximity to the atmosphere. Therefore, it is not expected that the radionuclide concentrations in groundwater would exceed their solubility limits upon entering the biosphere. The concentration in the water may change when the water is used for irrigation, as discussed below. However, the conditions would still be oxidizing because the soils in the Yucca Mountain region have low organic matter content (SNL 2007 [DIRS 179993], Table 6.2-2), the agricultural soils are aerated by plowing, and the oxygen content of the irrigation water would be greater than that of the groundwater due to its contact with the atmosphere.

Precipitation of minerals is known to occur in the natural, not irrigated, soils in arid and semi-arid climates. This process results in a buildup of caliche layer, a hardened deposit of calcium carbonate and other minerals that forms when these minerals are leached from the upper soil layers and accumulate below as a result of water evaporation. If the volume of water in the soil significantly decreases due to evapotranspiration, the dissolved minerals will eventually

precipitate, regardless of their solubilities. This process will primarily occur in the natural systems in the arid and semi-arid climate when there is no excess water that would percolate below the region of soil where evaporation and plant uptake occur and prevent mineral buildup in the soil.

For the conditions where radionuclides are introduced into the biosphere from irrigation with contaminated groundwater, the solubility limits are not achieved (i.e., the rate of radionuclide removal from soil by leaching is proportional to the radionuclide concentration in the soil) (SNL 2007 [DIRS 177399], Sections 6.4.1.1 to 6.4.1.3). The biosphere model includes the overwatering parameter that represents the amount of irrigation water intentionally applied to soil to leach salts and the amount of precipitation that percolates below the root zone (BSC 2004 [DIRS 169673], Section 6.9). Because salts can impair root function and affect water uptake, salt buildup in soils in the plant root zone is undesirable. Overwatering is a common practice that prevents the soil buildup of salts from irrigation water, and there is evidence that it is practiced in Amargosa Valley (Stonestrom et al. 2003 [DIRS 165862]). In arid regions, the overwatering rate usually is determined by calculating the amount of water required to flush accumulated salts out of the surface soil to maintain long-term productivity (BSC 2004 [DIRS 169673], Section 6.9). The fraction of infiltrated water that must pass through the root zone to remove excess salts is a function of the salinity of the irrigation water and crop tolerance to salts. Soil salinity is measured by the electrical conductivity of the saturated soil solution. The crop salt tolerance is also expressed in terms of electrical conductivity.

Wells in the Amargosa and Yucca Mountain areas were drilled and monitored for salinity levels (among other variables) for the Nye County Early Warning Drilling Program (DTN: LA0206AM831234.001 [DIRS 160051]). Well number NC-EWDP-19D, located in the southwest corner of the Nevada Test Site, is the closest to the compliance location, as defined in 10 CFR 63.302 [DIRS 180319]. Average well water salinity, as reflected by the mean measurement of electrical conductivity, was 0.44 dS/m (BSC 2004 [DIRS 169673], Section 4.1.7). The electrical conductivity data from this source are corroborated by salinity measurements from 31 irrigation or domestic wells located in the town of Amargosa Valley or west of State Route 373 and south of Highway 95 in Amargosa Valley (BSC 2004 [DIRS 169673], Section 4.1.7). Average well water salinity for these 31 wells was 0.51 dS/m. Salinity tolerances for crops ranged from 1.0 to 2.8 dS/m for garden crops and alfalfa and from 6.0 to 8.0 dS/m for grains and grasses (Doorenbos and Pruit 1977 [DIRS 103062], Table 36, p. 78). Thus, to prevent garden crop and alfalfa yield reduction, the concentration of salts in the water can only increase by about a factor of 2 to 5. An average electrical conductivity for the water sampled from all the Nye County Early Warning Drilling Program wells that are included in DTN: LA0206AM831234.001 [DIRS 160051] is 0.76 dS/cm. If this value is used instead, the concentration in the soil water could increase only by a factor of 1 to 4. The tolerable concentration increase for alfalfa would be about 2 to 3 times. Alfalfa is the most common crop in Amargosa Valley and has the salt tolerance level of 2.0 dS/cm (Doorenbos and Pruitt 1977 [DIRS 103062], Table 36, p. 78).

Considering that the solubility limits in the groundwater would not be exceeded when the water enters the biosphere, it is also not expected that the limits would be exceeded in properly maintained agricultural soil. This is because agricultural practices in arid regions are specifically

designed to prevent precipitation of minerals in surface soil and, accordingly, the biosphere model excludes this process.

Those radionuclides that reach the biosphere irreversibly attached to colloidal particles will not take part in sorption exchange processes with soil and will, therefore, be transported through the soil system without any sorption buildup in soil. Because these radionuclides are not in solution, they are not available for plant uptake (via soil to plant transfer). However, in the biosphere model, radionuclide transfer from the soil to crops via root uptake is proportional to the radionuclide concentration in the surface soil (SNL 2007 [DIRS 177399], Section 6.4.3.1) (i.e., all radionuclides (solutes and colloids) in groundwater are assumed to be in solution and available for plant uptake). This is a conservative approach for cases where colloids are present because the activity associated with colloids is made available for plant uptake.

Based on the previous discussion, omission of FEP 2.2.08.07.0C (Radionuclide Solubility Limits in the Biosphere) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.08.0A

FEP NAME:

Matrix Diffusion in the SZ

FEP DESCRIPTION:

Matrix diffusion is the process by which radionuclides and other species transported in the SZ by advective flow in fractures or other pathways move into the matrix of the porous rock by diffusion. Matrix diffusion can be a very efficient retarding mechanism, especially for strongly sorbed radionuclides, due to the increase in rock surface accessible to sorption.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Matrix diffusion is the process by which radionuclides in fractures move into the matrix of the porous rock (SNL 2008 [DIRS 183750], Section 6.5.2.6). Diffusion into the rock matrix can occur from a subset of all fractures in the fractured volcanic units (i.e., flowing intervals), as described in *Probability Distribution for Flowing Interval Spacing* (BSC 2004 [DIRS 170014]). This process can be an effective retarding mechanism and is included in the conceptual model and equations describing radionuclide transport in volcanic rock in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Section 6.4.2.4.1, Equations (21a) and (21b)) and in the numerical implementation of the FEHM software code through the use of the diffusion coefficient and the random-walk particle-tracking method with a semi-analytical solution. The semi-analytical matrix diffusion equation obeys Fick's law and incorporates concentration gradients and the temporal and spatial changes in the gradient along the transport pathway.

Matrix diffusion is included in the SZ transport model abstraction (SNL 2008 [DIRS 183750], Section 6.3.1[a] and Table 6-8) through the parameter that represents the diffusion coefficient in volcanic units, which is sensitive to the volcanic matrix permeability and porosity (SNL 2008 [DIRS 183750], Section 6.5.2.6). This diffusion coefficient is specified with an uncertainty distribution so that uncertainty is captured in the characteristics of the breakthrough curves that are later propagated to TSPA. The uncertainty distribution for the diffusion coefficient in volcanic units is based on:

- Field and laboratory diffusion experiments performed in and on volcanic tuffs located within the Yucca Mountain vicinity (SNL 2008 [DIRS 183750], Section 6.5.2.6)
- A least-squares linear empirical equation fit to diffusion experiment results and measured values for matrix porosity and permeability (Reimus et al. 2002 [DIRS 163008], p. 2.25; 2007 [DIRS 179246], Figures 4 through 6).

The values of the effective matrix diffusion coefficient for diffusing radionuclides are stochastically sampled from this same cumulative distribution function. The process of matrix

diffusion is also a function of spacing between fractures with flowing groundwater, the fracture porosity, and matrix porosity (SNL 2008 [DIRS 184806], Section 6.4.2.4.1). The parameters for flowing interval spacing and flowing interval and average fracture porosity in volcanic units are represented by uncertainty distributions in the SZ flow and transport abstraction model (SNL 2008 [DIRS 183750], Sections 6.5.2.3[a] and 6.5.2.5).

Given the inhomogeneous nature of the alluvium, flow could preferentially occur through high permeability regions, and diffusion could potentially occur into the low permeability regions of the alluvium. Data are available from single-hole and cross-hole tracer tests conducted at the Alluvial Testing Complex and Site 22 (SNL 2007 [DIRS 177394], Sections 6.5.3 and 6.5.4). Based on these available data, the approach of not taking credit for matrix diffusion into low-permeability regions within the alluvium or for matrix diffusion of colloids in either the volcanic units or the alluvium does not underestimate dose to the RMEI because these effects would be small and would only retard transport.

FEP: 2.2.08.08.0B

FEP NAME:

Matrix Diffusion in the UZ

FEP DESCRIPTION:

Matrix diffusion is the process by which radionuclides and other species transported in the UZ by advective flow in fractures or other pathways move into the matrix of the porous rock by diffusion. This includes osmotic processes in response to chemical gradients. Matrix diffusion can be a very efficient retarding mechanism, especially for strongly sorbed radionuclides, due to the increase in rock surface accessible to sorption.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Migration of radionuclides from water flowing in fractures into the surrounding rock matrix by diffusion could expose radionuclides to sorbing sites in the matrix. The diffusion into the matrix and its subsequent sorption into the matrix material will make these radionuclides unavailable for transport in the water flowing in the fracture for some times. Migration of radionuclides from fast flow fracture into surrounding slow flow matrix blocks by diffusion could play an important role in delaying the transport of radionuclides in fractures. Matrix diffusion is identified in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Section 6.2.2) as a process to be included in transport modeling. The role of matrix diffusion is included through the development of the particle tracking approach as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.3). Transfer function curves (DTN: LA0311BR831229.001 [DIRS 166924]) that are generated are fed directly to the TSPA model. These curves are used by FEHM in simulating the effect of matrix diffusion on radionuclide transport in TSPA model simulations as described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.3 and Appendix C). This particle tracking approach was used to simulate matrix diffusion of dissolved radionuclides. This treatment of matrix diffusion includes the effects of partial saturation of the matrix, radionuclide sorption in the matrix, and finite spacing of fractures. Diffusion in the unsaturated zone is treated separately in excluded FEP 2.2.08.05.0A (Diffusion in the UZ).

Osmosis would tend to cause water from fractures to flow into the matrix, if the matrix presents a suitable barrier to the migration of dissolved salts, but not a barrier to water migration. Osmosis is a process that is not expected to have a significant effect on radionuclide transport in the unsaturated zone compared to matrix diffusion (see excluded FEP 2.2.08.05.0A (Diffusion in the UZ)).

Matrix diffusion of colloids was assumed not to occur because its effects would be small because of the larger size of colloids compared to solutes and because diffusion coefficients of colloids

are significantly lower than values for solutes (SNL 2008 [DIRS 184748], Section 6.4.5). The potential for matrix diffusion of dissolved radionuclides is described by a matrix diffusion coefficient. The matrix diffusion coefficient can be presented as the product of the tortuosity and the free-water diffusion coefficient. The tortuosity is correlated to matrix water content, matrix effective permeability, and free-water diffusion coefficient through the relationship developed by Reimus et al. (2007 [DIRS 179246]). The free-water diffusion coefficients and the distribution of tortuosity are outputs from *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.5 and Table 6-6; DTN: LA0407BR831371.001 [DIRS 170806]). The TSPA model uses these outputs in multiple realization simulations to randomly generate matrix diffusion coefficients (DTN: LA0407BR831371.001 [DIRS 170806]). Related to this FEP is included FEP 2.1.09.08.0A (Diffusion of Dissolved Radionuclides in EBS).

FEP: 2.2.08.09.0A

FEP NAME:

Sorption in the SZ

FEP DESCRIPTION:

Sorption of dissolved and colloidal radionuclides in the SZ can occur on the surfaces of both fractures and matrix in rock or soil along the transport path. Sorption may be reversible or irreversible, and it may occur as a linear or nonlinear process. Sorption kinetics and the availability of sites for sorption should be considered. Sorption is a function of the radioelement type, mineral type, and groundwater composition.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Sorption of dissolved radionuclides onto rock surfaces in the saturated zone can occur both in the volcanic rocks and the alluvium, as confirmed by field-scale tracer testing (SNL 2007 [DIRS 177394], Sections 6.3, 6.5.5, and G5.4.3). Radionuclides can be transported as a dissolved species, as well as a species attached to mobile colloids. Both of these mechanisms of transport are implemented in the TSPA model. Radionuclides can sorb onto the colloidal materials in two modes, either reversibly or irreversibly (SNL 2008 [DIRS 184806], Sections 6.4.2.6, 7.1.2.5, and 7.1.2.9). Uncertainties in radioelement sorption distributions are used in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Table 6-8) and propagated to TSPA by way of their effects on the breakthrough curves.

Reversible Sorption of Dissolved Radioelements onto Rock Surfaces: The process of reversible sorption in the saturated zone is modeled using the sorption coefficient (K_d) approach in volcanic rocks (SNL 2008 [DIRS 184806], Section 6.4.2.4.1) and in alluvium (SNL 2008 [DIRS 184806], Section 6.4.2.5). In the volcanic rocks, sorption in the matrix is included in the model, but sorption onto fracture surfaces is not included in the model. Recognizing that sorption is a function of the radioelement type, mineral type, and groundwater composition, and that these vary over the transport domain of interest, probability distribution functions reflect uncertainty and variability in values of the sorption coefficients, and K_ds of various radioelements have been developed independently for volcanic formations and alluvium over the range of groundwater compositions expected to occur in the saturated zone (SNL 2008 [DIRS 184806], Sections A2, A3, A7, and Table C-14[a]). These probability distribution functions have been developed for use in stochastic simulations for the radioelements americium, cesium, neptunium, protactinium, plutonium, radium, selenium, strontium, thorium, tin, and uranium (SNL 2008 [DIRS 183750], Sections 6.5.2.8, 6.5.3.1, and Tables 6-8 and 6-7[a]).

Sorption coefficient distributions have been developed in the SZ transport report (SNL 2008 [DIRS 184806], Table 5-1 and Appendix A) assuming oxidizing conditions along the entire flowpaths to the accessible environment, not taking into account the reducing conditions that

potentially occur to the east of the Yucca Mountain (BSC 2005 [DIRS 174958], Figure 2.1-2). This introduces a bias towards lower values for the K_d distributions for neptunium and technetium used in the SZ transport model. Further, the SZ transport model treats the sorption as a reversible process. As discussed in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Table 6.6-1a, item 1), this introduces a bias towards lower values for the K_d distributions for uranium and neptunium used in the SZ transport model. The K_d approach used in the SZ transport model is based on treating the sorption as a linear, equilibrium process (SNL 2008 [DIRS 184806], Section 6.3). As discussed in *Site-Scale Saturated Zone Transport* (SNL 2008 [DIRS 184806], Table 6.6-1b, rows 1 and 2), the potential effects of nonlinear and nonequilibrium sorption are accounted for in the model by biasing the K_d distributions towards low values. This is because available data show that the rate of desorption of uranium and neptunium from the rock surfaces is slower than the rate of absorption. Sorption reactions that are not fully reversible result in rates of transport that are slower than would be the case for fully reversible reactions. Therefore, using unadjusted sorption coefficients would result in diminished total radionuclide mass breakthrough from the saturated zone, compared to the breakthrough based on the actual values used.

In the volcanic units, for radionuclides that are not transported by colloid-facilitated mechanisms (neptunium, radium, selenium, strontium, and uranium), sorption between the aqueous phase and the solid phase (parent rock) is modeled in the FEHM flow and transport code using sampled parameters (SNL 2008 [DIRS 183750], Section 6.5.2.8, Tables 6-8 and 6-7[a]); sorption for the same radionuclides in the alluvium is also modeled through sampled parameters (SNL 2008 [DIRS 183750], Section 6.5.2.8, Tables 6-8 and 6-7[a]).

Reversible Sorption of Radioelements onto Colloids: Equilibrium sorption between aqueous and solid phases and a colloidal phase is modeled (SNL 2008 [DIRS 184806], Section 6.4.2.6) for four radionuclide classes represented by partitioning of the radionuclides americium, thorium, protactinium, cesium, plutonium, and tin (SNL 2008 [DIRS 183750], Table 6-9[a]). Partitioning between the colloidal and aqueous phase is the same in both the volcanic units and the alluvium. Partitioning between the aqueous and solid phase (parent rock) for each species differs between the volcanic and alluvial units.

Irreversible Sorption of Radioelements onto Colloids: Only plutonium and americium are assumed to irreversibly sorb onto colloids. In the volcanic units, advectively transported colloids with irreversibly attached plutonium and americium (BSC 2004 [DIRS 170006], Section 6.4) undergo reversible filtration that results from a combination of physical processes and electrochemical interactions with media surfaces; this reversible filtration is modeled through the sampled colloid retardation factor (SNL 2008 [DIRS 183750], Section 6.5.2.11). These same colloids also undergo reversible filtration in the alluvium, which is modeled via a retardation factor sampled from a separate distribution (SNL 2008 [DIRS 183750], Section 6.5.2.11). The use of retardation factors to model filtration processes assumes that forward and reverse filtration rates are linear and fast relative to transport travel times and that there is no irreversible colloid filtration.

FEP NAME:

Sorption in the UZ

FEP DESCRIPTION:

Sorption of dissolved and colloidal radionuclides in the UZ can occur on the surfaces of both fractures and matrix in rock or soil along the transport path. Sorption may be reversible or irreversible, and it may occur as a linear or nonlinear process. Sorption kinetics and the availability of sites for sorption should be considered. Sorption is a function of the radioelement type, mineral type, and groundwater composition.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Sorption is identified in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Section 6.2.3) as a process to be included in transport modeling. It is included in the TSPA model for mountain-scale UZ radionuclide transport as a linear equilibrium sorption (K_d) model in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Section 6.1). K_d values and their basis in experimental data are presented in the same report (SNL 2007 [DIRS 177396], Appendix A[a]). In TSPA simulations, sorption coefficients are sampled and provided to FEHM.

The model implemented in FEHM can account for sorption in both the matrix continuum and the fracture continuum. While dissolved radionuclide sorption may occur in fractures, it is assumed that no sorption of dissolved radionuclides occurs on fracture surfaces (SNL 2008 [DIRS 184748], Section 6.5.8). This assumption will not result in underestimating radionuclide transport rates. Thus, a fracture surface retardation factor of one is set for use in TSPA model simulations (SNL 2008 [DIRS 184748], Section 6.5.8). A retardation factor of one assumes there is no radionuclide sorption onto fracture surfaces. Sorption characteristics of the rock minerals are assumed to be static in time. Sorption K_ds have been derived for the following eleven radioelements: americium, cesium, neptunium, protactinium, plutonium, radium, strontium, thorium, tin, selenium, and uranium as dissolved radionuclides; other dissolved radioelements treated by TSPA (for example, technetium) are modeled as nonsorbing.

The sorption coefficient data on which the distributions are based are obtained in laboratory experiments in which crushed rock samples from the Yucca Mountain site are contacted with groundwaters (or simulated groundwaters) representative of the site, spiked with one or more of the elements of interest (SNL 2007 [DIRS 177396], Sections A4 and A5). Sorption experiments have been carried out as a function of time, element concentration, atmospheric composition, particle size, and temperature. In some cases, the solids remaining from sorption experiments were contacted with unspiked groundwater in desorption experiments. The sorption and desorption experiments together provide information on the equilibration rates of the forward

and backward sorption reactions. For elements that sorb primarily through surface complexation reactions, the experimental data are augmented with the results of modeling calculations using PHREEQC (PHREEQC V2.3 [DIRS 157837], STN: 10068-2.3-01) with the thermodynamic input data file *PHREEQCDATA025.dat* (DTN: MO0604SPAPHR25.001 [DIRS 176868]). The inputs for the modeling calculations include groundwater compositions, surface areas, binding constants for the radioelements, and thermodynamic data for solution species. These modeling calculations provide a basis for interpolation and extrapolation of the experimentally derived sorption coefficient dataset. The effects of nonlinear sorption are approximated by the effective K_d range (SNL 2007 [DIRS 177396], Section A8, and Appendix A[a]).

Sorption coefficients are provided in terms of probability distributions for the sorption coefficient of each radioelement among the three major rock types (devitrified, zeolitic, and vitric) found in the unsaturated zone. The influence of expected variations in water chemistry, radionuclide concentrations, and variations in rock surface properties within one of the major rock types are incorporated into these probability distributions. These distributions are specified for each radionuclide–rock type combination (SNL 2007 [DIRS 177396], Section A8 and Appendix A[a]) and are sampled in the TSPA to account for the effects of natural variations in pore-water chemistry and mineral surfaces on sorption. Correlations for sampling sorption coefficient probability distributions have been derived for the elements investigated (SNL 2007 [DIRS 177396], Appendix B[a]). To derive the correlations, a rating system was first developed to rate the impact of six different variables on the sorption coefficient for a given element in each of the three major rock types. The six variables are pH, Eh, water chemistry, rock composition, rock surface area, and radionuclide concentration. Water chemistry refers to the major ion concentrations and silica. Rock composition refers to both the mineralogic composition of the rocks and the chemical composition of the minerals (for example, zeolite compositions).

Sorption in the unsaturated zone is treated as a linear reversible infinite capacity process in the radionuclide transport abstraction model (SNL 2008 [DIRS 184748], Section 6.5.4 in AD01). In the matrix, sorption is incorporated in the generation of transfer function curves and expressed as part of the defined dimensionless parameters (SNL 2008 [DIRS 184748], Section 6.4.3). For colloid facilitated radionuclide transport, radionuclide sorption onto colloids and its effect on transport are simulated through the colloid K_c factor (SNL 2008 [DIRS 184748], Section 6.4.5). The K_c factor is the product of the radionuclide sorption coefficient onto colloids and the colloid concentration (SNL 2008 [DIRS 184748], Section 6.5.12 in AD01). Radionuclide sorption coefficients that were used in the simulation of radionuclide transport in the unsaturated zone are documented in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.4 in AD01). Colloid concentration and radionuclide sorption coefficients onto colloids are documented in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Section 6.3) and used in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.5.12 in AD01). Sorption on colloids and the effects of colloid transport are addressed in *Radionuclide Transport Models under Ambient Conditions* (SNL 2007 [DIRS 177396], Sections 6.1.3 and 6.2.3), with simulation results presented in Section 6.18 of that report.

FEP NAME:

Colloidal Transport in the SZ

FEP DESCRIPTION:

Radionuclides may be transported in groundwater in the SZ as colloidal species. Types of colloids include true colloids, pseudo colloids, and microbial colloids.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The colloid-facilitated transport of radionuclides is explicitly included in the SZ transport abstraction model and the SZ one-dimensional transport model (SNL 2008 [DIRS 183750], Sections 6.5.2.11 and 6.5.2.12). Colloids are subject to advection in the alluvium and fractures of tuff units and are assumed not to diffuse into the fractured rock matrix (SNL 2008 [DIRS 184806], Section 6.4.2.6 and Appendix B). Colloid transport in the saturated zone has been investigated at the field scale by tracer testing using carboxylate-modified latex microspheres in tracer tests in both the saturated volcanics and alluvium, as described in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394], Sections 6.3 and 6.5).

Radionuclide transport in association with colloids is simulated in the TSPA to occur by two modes: (1) as solutes reversibly sorbed onto colloids, and (2) as solutes irreversibly attached to colloids or as true colloids (SNL 2008 [DIRS 183750], Sections 6.5.2.11 and 6.5.2.12). Natural or anthropogenic colloids with solutes reversibly sorbed or irreversibly attached onto them are called pseudocolloids. Reversible sorption of radionuclides may occur onto any colloidal material present in the groundwater. Measurements of natural colloid concentrations in groundwater of the saturated zone do not discriminate between mineral and microbial colloids, although available data on total organic carbon concentrations in saturated zone groundwaters (DTN: GS931100121347.007 [DIRS 149611], Table S96375_009); DTN: GS010308312322.003 [DIRS 154734], Table S01053_003) indicate that natural microbial colloid concentrations are insignificant in the saturated zone. The parameter distributions that are used to describe uncertainty related to reversible sorption onto colloids are based on field observations and laboratory experiments performed on colloids under geochemical conditions found in the vicinity of Yucca Mountain (BSC 2004 [DIRS 170006], Section 7). The key parameters for reversibly sorbed radionuclide transport in association with colloids are sorption coefficients onto colloids for americium, plutonium, cesium, and tin; colloid retardation factor in the volcanics; colloid retardation factor in the alluvium; and groundwater concentration of colloids as discussed in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Tables 6-8 and 6-7[a]). These parameters are randomly sampled from probability distributions described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Tables 6-8 and 6-7[a]) to propagate uncertainties through to the results of the performance assessment.

Colloids with irreversibly attached radionuclides originate from the degradation of the glass waste form in the repository (SNL 2007 [DIRS 177423], Section 6.3.1), and are subject to retardation in the saturated zone both in the fractured tuff and the alluvium. However, a small fraction of colloids with irreversibly attached radionuclides are transported through the saturated zone with no retardation due to the kinetic nature of colloid attachment to the aquifer materials (BSC 2004 [DIRS 170006], Section 6.6). This small fraction is a result of inherent heterogeneity in natural colloid populations, which results in heterogeneous colloid transport properties, including a small fraction of colloids that transport unretarded over long time and distance scales because they have extremely low filtration rates. The parameters related to the retardation of colloids with irreversibly attached radionuclides are colloid retardation factors for fractured tuff and alluvium (SNL 2008 [DIRS 183750], Tables 6-8 and 6-7[a]). These parameters are randomly sampled from probability distributions described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Tables 6-8 and 6-7[a]) to propagate uncertainties associated with transport of radionuclides that are irreversibly sorbed to colloids through to the results of the performance assessment.

FEP NAME:

Colloidal Transport in the UZ

FEP DESCRIPTION:

Radionuclides may be transported in groundwater in the UZ as colloidal species. Types of colloids include true colloids, pseudo colloids, and microbial colloids.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Colloidal transport of radionuclides is identified in *Conceptual Model and Numerical Approaches for UZ Flow and Transport* (BSC 2004 [DIRS 170035], Section 6.2.4) as a process to be included in transport modeling. The influence of colloid transport on radionuclide migration through the unsaturated zone is included and discussed in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.5). Parameters that can impact colloid transport in the unsaturated zone include colloid size (DTN: LL000122051021.116 [DIRS 142973]), colloid concentration (DTN: MO0701PAGROUND.000 [DIRS 179310]), radionuclide sorption coefficients onto colloid (DTN: MO0701PASORPTN.000 [DIRS 180391]) for plutonium, americium, thorium, protactium, and cesium; (DTN: MO0701PAKDSUNP.000 [DIRS 180392]) for tin; and colloid retardation factors (DTN: LA0303HV831352.002 [DIRS 163558]). The colloid concentration data and sorption-onto-colloid data are documented in *Waste Form and In-Drift Colloids-Associated Radionuclide Concentrations: Abstraction and Summary* (SNL 2007 [DIRS 177423], Sections 6.3.11 and 6.3.12). Colloid retardation factors are documented in *Saturated Zone Colloid Transport* (BSC 2004 [DIRS 170006], Section 6.4.3). These data are used in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Sections 6.5.9 to 6.5.13).

Colloid transport processes include advection and dispersion. In addition, colloids undergo a process by which certain size colloids are mechanically excluded from entering the matrix from the fractures (SNL 2008 [DIRS 184748], Section 6.5.9). Colloids can also be permanently removed from the system by a size-based filtration at matrix unit boundaries. The colloid retardation factor in the fracture continuum, R_{coll} (a function of physical and electrochemical processes collectively termed attachment), is evaluated on the basis of field experiments at the C-Well Complex using microspheres as analogues for natural colloids as well as laboratory experiments evaluating the transport of both microspheres and inorganic colloids (SNL 2008 [DIRS 184748], Section 6.5.13). Field experiments have also shown that a small percentage of colloidal particles are transported through the groundwater system essentially unretarded (BSC 2004 [DIRS 170006], Section 6.6). The fractions of unretarded colloids have been developed based on field data (BSC 2004 [DIRS 170006]). Included FEP 2.2.08.09.0B (Sorption in the UZ) addresses sorption of colloids in the unsaturated zone. Colloid matrix

diffusion is assumed not to occur because of the relatively larger size of colloids campared to solute, and therefore its effect would be small and would have little effect on dose. Included FEP 2.2.08.08.0B Matrix Diffusion in the UZ) discusses matrix diffusion in the unsaturated zone.

FEP: 2.2.08.11.0A

FEP NAME:

Groundwater Discharge to Surface Within the Reference Biosphere

FEP DESCRIPTION:

Radionuclides transported in groundwater as solutes or solid materials (colloids) from the far-field may discharge at specific "entry" points that are within the reference biosphere. Natural surface discharge points, including those resulting from water table or capillary rise, may be surface water bodies (rivers, lakes), springs, wetlands, holding ponds, or unsaturated soils.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Currently, groundwater discharge from the regional groundwater flow system in the area of Yucca Mountain occurs at Franklin Lake Playa (also known as Alkali Flat) and Ash Meadows (D'Agnese et al. 1997 [DIRS 100131], pp. 40 to 48); both are located over 10 km beyond the boundary of the accessible environment. There is evidence of paleospring discharge points within northern Amargosa Desert that could become reactivated during wetter climatic conditions. These are the paleospring deposits located in Crater Flat, Crater Flat Wash, Amargosa Valley Diatomite, Indian Pass, Scranton Well, Mesquite Wash, and the Amargosa River Snail Site (Paces et al. 1997 [DIRS 109148], Figure 18). The Stranton Wells, Mesquite Wash, and Amargosa River Snail Site paleospring deposits lie at the far terminus of Fortymile Wash and downstream from the projected flow path (from the repository to the 18-km boundary). The other paleospring deposits are separated from Fortymile Wash by faults and ridges and are not along the projected saturated zone transport path. Therefore, they would not contain contaminants originating from the repository if reactivated under wetter climatic conditions. 10 CFR 63.102(i) [DIRS 180319] defines the reference biosphere as "the environment inhabited by the [RMEI], along with associated human exposure pathways and parameters." Because these latter paleospring deposits do not contain repository contaminants and are not part of human exposure pathways, they would not be part of the reference biosphere.

Paleosprings along the far terminus of Fortymile Wash are not expected to be activated within 10,000 years after repository closure, based on geochemical evidence of previous groundwater discharge at these locations. With the exception of the Amargosa River Snail Site, geochemical dating indicates the last episode of paleospring activity for the majority of paleosprings occurred between 14,000 to 20,000 years ago (Paces et al. 1997 [DIRS 109148], Figure 18). Scranton Wells was active 40,000 to 60,000 years ago, Mesquite Wash active 30,000 years ago, and the Amargosa River Snail Site between 9,000 to 12,000 years ago (Paces et al. 1997 [DIRS 109148], Figure 18). There is some uncertainty regarding the activity that occurred 9,000 to 12,000 years ago at the Amargosa River Snail Site. Surface "lag" samples taken from this site and collected for dating indicate that plant petrifications may have tapped a subsided water source (a one-time discharge point that has been lowered below the ground surface). Thus, surface discharge may

have ceased much earlier than indicated from geochemical dating. Nevertheless, if the saturated zone plume potentially discharges at the historic discharge points located south of Fortymile Wash, it would contain lower radionuclide concentrations than at the 18-km boundary, because such discharge locations are over 10 km beyond the accessible environment boundary. Longer path lengths from the repository facilitate the processes of sorption and dispersion, which would lower the plume's radionuclide concentration levels as the path length increases. Additionally, a longer path length coupled with more sorption and dispersion equates to longer transport times, thus allowing more time for radioactive decay. More time for decay reduces the radionuclide activities in groundwater withdrawn from the community wells. Because of the distant location of these paleosprings relative to the accessible environment boundary (and thus the location of the hypothetical community that includes the RMEI), it is not expected that the exposures that could be potentially received from the discharges of groundwater to the surface at these distant locations would affect the average dose to the RMEI.

Flow and transport modeling was performed on the saturated zone site-scale model domain to assess water table elevations reflective of glacial-transition climatic conditions (SNL 2008 [DIRS 184806], Appendix E). For these simulations, the water table was allowed to rise under the repository by 50 m (SNL 2007 [DIRS 177391], Section 6.6.4.2). The higher water table estimated for use in these simulations does not indicate spring formation within the 18-km boundary, but does show a shallow water table within 5 m of the surface. The shallow water table corresponds to the three paleospring deposits located along Highway 95 and at the southern end of Crater Flat (SNL 2007 [DIRS 177391], Figure 6-21). Even if the water table were to rise to form springs, the Windy Wash fault and the Stagecoach fault (SNL 2007 [DIRS 177391], Figure 6-12) serve as barriers between Crater Flat and Fortymile Wash. It is in the Fortymile Wash where flow paths from the repository to the 18-km boundary converge. Consequently, if springs were to develop in the shallow water table area at the southern end of Crater Flat, radionuclides released from the repository are not expected to be constituents of the spring waters.

In summary, current natural groundwater discharge points along the saturated zone flow paths are greater than 10 km downstream from the 18-km boundary, and radionuclide concentrations at natural groundwater discharge locations would not be greater than concentrations at the 18-km boundary due to increased dispersion and sorption. Future discharge points, if they occur at all, would be located several kilometers downstream from the 18-km boundary, but would not contain contaminants originating from the repository because of the physical barriers, such as faults and ridges, which separate them from the projected path of radionuclide transport from the repository.

The biosphere model for the groundwater exposure scenario includes all exposure pathways expected to contribute to the annual dose to the RMEI (SNL 2007 [DIRS 177399], Section 6.3), as required by proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]). Exposure is calculated for the radionuclide concentration in groundwater at the boundary of the accessible environment. Although not expected, if spring reactivation were to occur, the potential pathways from exposure to water flowing from such springs within the reference biosphere or other groundwater discharge points would be consumption of water, external exposure from contaminated soil around springs, and water immersion. These pathways are considered in the biosphere model because groundwater entering the biosphere from a spring or other discharge

point is assumed to be used in the same way as groundwater from a well. Because radionuclide concentrations at natural groundwater discharge locations would not be greater than concentrations at the 18-km boundary, radiological effects of exposure to groundwater discharged to surface are bounded by the radiological effects from exposure to groundwater withdrawn from wells at the compliance location. Therefore, the groundwater discharge to surface within the reference biosphere, if it occurred at all, would not need to be modeled separately. The groundwater release to the surface outside the reference biosphere (excluded FEP 2.3.11.04.0A (Groundwater Discharge to the Surface Outside the Reference Biosphere)) does not affect the dose to the RMEI and is, therefore, excluded.

Based on the previous discussion, omission of FEP 2.2.08.11.0A (Groundwater Discharge to Surface within the Reference Biosphere) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.08.12.0A

FEP NAME:

Chemistry of Water Flowing into the Drift

FEP DESCRIPTION:

Inflowing water chemistry may be used in analysis or modeling that requires initial water chemistry in the drift. Chemistry of water flowing into the drift is affected by initial water chemistry in the rock, mineral and gas composition in the rock, and thermal-hydrological-chemical processes in the rock.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The near-field chemistry (NFC) process model in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 6.3.2) predicts potential seepage water compositions at the drift wall, and was designed specifically to investigate the effects of thermal-hydrologic-chemical processes in the host rock, including the effects of initial water chemistry, and mineral and gas compositions in the rock (SNL 2007 [DIRS 177412], Sections 6.3.2 and 6.6). The near-field chemistry model evaluates water–rock interactions as the pore water percolates through the rock above the repository, using a repository depth and TSw unit thickness consistent with the repository geographic and geologic location within Yucca Mountain (SNL 2007 [DIRS 179466], Parameter Numbers 01-01 and 01-03). Therefore, these effects are accounted for in the potential seepage compositions predicted by the NFC model, which are in turn used as initial conditions for evaluating in-drift water chemistries in the seepage dilution/evaporation abstraction model (SNL 2007 [DIRS 177412], Sections 6.3.3 and 6.9). The seepage dilution/evaporation model provides lookup tables of in-drift water chemistry for TSPA calculations.

The NFC model does not simulate seepage into the drifts, but rather evaluates water compositions delivered to the evaporation front in the rock or at the drift wall. It is expected that these water compositions closely represent in-drift seepage chemistry. The evaluation of seepage flow rates into the drifts is discussed in included FEP 2.2.07.20.0A (Flow Diversion around Repository Drifts).

In the P&CE report (SNL 2007 [DIRS 177412], Section 6.6), available TSw pore-water analyses are screened for analysis quality (e.g., anion-cation charge balance) and for evidence of being affected by microbial processes during core storage. After eliminating those pore-water analyses with a poor charge balance or which showed evidence of having been modified by post-collection microbial activity, 34 TSw waters remained (SNL 2007 [DIRS 177412], Section 6.6.4). These were further evaluated to identify the number of waters required to adequately represent the observed compositional variability within the group. A statistical analysis of these water compositions and their evaporated equivalents, using the method of

principal components (SNL 2007 [DIRS 177412], Section 6.6.5), showed that they clustered into four compositional clusters or groups. After grouping the waters, a representative water composition was chosen for each group on the basis of statistical proximity to the cluster centroid. The NFC model outputs that are used by the seepage dilution/evaporation model are based on four initial pore-water compositions, corresponding to the four representative waters.

The statistical analysis and the observed similarities in evaporative evolution provide support that the four representative waters adequately cover the observed range in water compositions. While pore-water samples are not available from all possible locations in the repository, the available data are assumed to be representative of all water chemistries actually present in the repository units (SNL 2007 [DIRS 177412], Section 5.2.2). This assumption is supported by the chemical similarity of the four TSw lithostratigraphic units that host the repository (the Tptpll, Tptpul, Tptpmn, and Tptpln). The units are compositionally similar with respect to major oxides, trace elements, and normative mineral compositions (Peterman and Cloke 2002 [DIRS 162576], Erratum, Tables 4 and 5). The tight clustering also indicates that the effect of localized mineral heterogeneity on large-scale rock compositions, due to the presence of minerals which precipitated from the vapor phase during cooling of the tuff and low–temperature minerals, such as calcite and opal, is insignificant. Because the rocks are homogeneous, reaction with these rocks should result in similar pore-water evolution and large variations in the concentrations of nonconservative aqueous species in the TSw are not expected (SNL 2007 [DIRS 177412], Section 5.2.2).

The set of 34 pore waters represents samples from all four of the repository host units. They represent several different stratigraphic depths and degrees of water–rock interaction within the TSw, increasing the confidence that any new pore-water analysis would fall within that range. In addition, because the 34 TSw pore waters cluster into distinct groups, the potential that any new water will form a new, unrepresented group is reduced.

Uncertainty in the initial pore-water compositions is captured in the NFC and seepage dilution evaporation models and propagated to TSPA by use of the four water compositions, representing the four pore-water groups. Uncertainty in the nitrate-to-chloride ratio, an important parameter for evaluating localized corrosion of the waste package outer surface (SNL 2007 [DIRS 178519], Section 6.4.4), is treated specially. Following random selection of the starting water and determination of the in-drift water chemistry using the seepage dilution/evaporation model lookup tables and the nitrate-to-chloride ratio is sampled from a discrete distribution of all pore-water analyses that fall within that pore-water group. The resulting value is applied to predicted in-drift water chemistry (SNL 2007 [DIRS 177412], Section 6.12.3). Thus, the nitrate-to-chloride ratios for all 34 pore waters that passed the screening analysis, instead of just the four representative waters, are propagated to TSPA calculations.

To summarize, the near field chemistry model incorporates the effects of water–rock interactions and thermal-hydrologic-chemical processes. Uncertainty in the initial water chemistry is incorporated by using four starting waters in the P&CE models, representing the four chemically distinct groups of TSw pore-water compositions. Uncertainty in the nitrate-to-chloride ratio is propagated through use of the values for all 34 water analyses in the four groups. These pore waters are assumed to capture the range of actual pore-water compositions in the rock because they were collected throughout the entire stratigraphic interval of the TSw representing the

repository host horizon, and because of the compositional homogeneity of the TSw across that interval.

Included

TSPA DISPOSITION:

Eight different initial water compositions were used to represent the chemistry of the water flowing into the waste package in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506] Section 6.6.2[a]). The compositions included representative waters from four representative groundwater types from Yucca Mountain, mean J-13 well water, and three waters from basalt aquifers.

To account for igneous intrusion events, three groundwater samples from large fractured basalt reservoirs were selected for sensitivity analyses that examined pH and ionic strength of water that has reacted with cooled basalt (SNL 2007 [DIRS 180506], Section 4.1.2[a]). These sensitivity studies in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.6.2[a]) were used to estimate solution development during reactions between basalt-equilibrated water and the in-package materials and determined that in-package chemistry is insensitive to seepage water composition and subsequent reaction with basalt. Therefore, the in-package chemistry abstraction is used in TSPA to simulate the waste form chemical conditions following an igneous intrusion event.

The in-package chemistry model is used to predict pH, ionic strength, total carbonate, chloride, and fluoride in the waste form cells. Therefore, the variability of the incoming water composition is included in the in-package chemistry model and in the abstractions passed to the TSPA in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506]). The TSPA then feeds these results to the solubility, colloid, commercial SNF, and HLW glass submodels. The effects of the inflowing water chemistry are captured within the in-package chemistry model parameters: pH, ionic strength, total carbonate, chloride, and fluoride.

The TSPA parameters for pH and ionic strength have been described in *In-Package Chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 8.2[a] and Table 6-21[a]), and the details for TSPA implementation of these abstractions are also provided (SNL 2007 [DIRS 180506], Section 6.10.9[a]). Uncertainties in the values of pH and ionic strength are quantified and propagated in TSPA, as described in *In-Package chemistry Abstraction* (SNL 2007 [DIRS 180506], Section 6.10.8[a]).

The dissolved concentration report considers the chemistry of the water potentially entering a waste package (SNL 2007 [DIRS 177418], Section 6.4). Examination of 25 pore-water compositions indicates that these pore waters are similar to the composition of the base-case water (J-13). The ratios of the average pore-water values to the base-case values of nine components (Na^+, K^+, Ca^{2+}, Mg^{2+}, SiO_2(aq), Cl^-, F^-, NO_3^-, and SO_4^{2-}) range from 0.83 (for SiO_2(aq)) to 8.51 (for Ca^{2+}), and the ratios of the maximum values of those nine components to the base-case values range from 1.07 to 18.46. Various sensitivities covering the range up to 1,000 times the base-case concentrations of Na^+, K^+, Ca^{2+}, Mg^{2+}, SiO_2(aq), Cl^-, F^-, NO_3^-, and SO_4^{2-} were performed to examine the effect that elevated concentrations of these components have on dissolved limits (SNL 2007 [DIRS 177418], Section 6.4.2.5). For the species that have an impact on solubility limits, an uncertainty term was developed (SNL 2007 [DIRS 177418], Sections 6.3.3.2 and 6.4.3.6) to account for the variation of the concentration of that species in the incoming water and its possible concentration within waste packages.

FEP: 2.2.09.01.0A

FEP NAME:

Microbial Activity in the SZ

FEP DESCRIPTION:

Microbial activity in the SZ may affect radionuclide mobility in rock and soil through colloidal processes, by influencing the availability of complexing agents, or by influencing groundwater chemistry.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Microbial activity can potentially change groundwater pH and Eh and introduce additional complexing agents, which could affect radionuclide K_d distributions in the saturated zone. Microbial activity can also potentially result in biotransformations and biocolloid-facilitated transport of radionuclides. Excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS), and *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 7) address these processes very thoroughly for the EBS, and it is concluded that microbial activity can be excluded in the EBS. The justifications for excluding the effects of microbial-produced complexing agents, biotransformation, and biocolloid transport in the EBS also apply in the saturated zone given that they are based on information obtained primarily from unsaturated zone and saturated zone rocks and saturated zone waters. These justifications are:

- Although microorganisms may release chemicals that complex with radionuclides, the concentrations of complexing agents are expected to be small, and their binding sites are expected to be dominated by iron ions, which these agents are designed to complex (BSC 2004 [DIRS 169991], Section 6.5.2).

- Reductive biotransformation reactions (the only kind that need be considered since redox-sensitive radionuclides are all assumed to be in oxidized states because of the oxidizing conditions at Yucca Mountain) will only decrease the solubility and increase the sorption of key redox-sensitive radionuclides, so their inclusion can only benefit performance (BSC 2004 [DIRS 169991], Section 6.5.3).

- Even if microbial cells can transport through rock fractures in the unsaturated and saturated zones, their impact on radionuclide transport is expected to be well bounded by the impact of inorganic groundwater colloids. Growing microbes have a propensity to attach to surfaces to remain in their favorable growth environment (BSC 2004 [DIRS 169991], Section 6.5.4), so they tend to be less mobile than inorganic colloids. Oligitrophic (i.e., starved) microbes can have dimensions as small as 0.2 to 0.3 μm (BSC 2004 [DIRS 169991], Section 6.5.4), which classifies them as biocolloids.

However, under oligitrophic conditions, cell concentrations will tend to be low; a concentration of ~7×10^6 cells/mL was observed in experiments conducted with Yucca Mountain tuff samples immersed in J-13 well water without the addition of a carbon source (DTN: LL040801512251.115 [DIRS 171476], Table S04340_001). This concentration translates to a mass concentration of ~0.1 mg/L if the cells have the dimensions stated above and are approximately the density of water. The range of saturated zone colloid mass concentrations used in TSPA is 0.001 to 200 mg/L (SNL 2008 [DIRS 183750], Figure 6-26), so the inclusion of cell mass concentrations would have an insignificant impact on these bounds, particularly on the upper end of the range where the effect on radionuclide transport and dose is greatest.

The remaining concern associated with microbial activity in the saturated zone is the effect on inorganic water chemistry, which can adversely affect radionuclide K_d values. The principal concerns are changes to pH and, more importantly, changes to bicarbonate/carbonate concentrations. The actinides (uranium, neptunium, plutonium, and americium) all have higher solubilities and lower K_d values as bicarbonate/carbonate concentrations increase.

In the saturated zone, heterotrophic microbial activity, which uses organic carbon as the sole energy source, is expected to be limited because geochemical analyses of groundwater samples taken from saturated zone wells within the Yucca Mountain vicinity indicate that there is little organic carbon in these waters (DTN: GS931100121347.007 [DIRS 149611], Table S96375_009; DTN: GS010308312322.003 [DIRS 154734], Table S01053_003; DTN: GS040108312322.001 [DIRS 179422], Table S04188_001; DTN: GS040808312322.006 [DIRS 179434], Table S04399_004). The maximum reported organic carbon concentration in pumped groundwater samples from the vicinity of Yucca Mountain (with the exception of samples from NC-EWDP-1DX, zone 2, which is located far to the west of any predicted groundwater flow pathways and was believed to be contaminanted by organic drilling fluids) is about 7.5 mg/L (DTN: GS040808312322.006 [DIRS 179434], Table S04399_004). Using the analysis approach in *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 6.5.1), if 7.5 mg/L of organic carbon (assumed to be carbon, not CH_2O, as is often reported) were converted to HCO_3^- (bicarbonate), ~38 mg/L of HCO_3^- would be generated. Measured carbonate/bicarbonate concentrations in saturated zone groundwaters range from ~70 mg/L to several hundred mg/L (DTN: GS040808312322.006 [DIRS 179434], Table S04399_004), and the high-end concentration used to derive saturated zone radionuclide K_d distributions (UE-25p#1 water) is ~700 mg/L HCO_3^- (SNL 2008 [DIRS 184806], Table I-1). Thus, an increase of 38 mg/L of HCO_3^- is small compared to the range of uncertainty in carbonate/bicarbonate concentrations considered for radionuclide K_d values, and the impact of microbial activity on saturated zone water chemistry (pH and ΣCO_2) can be considered negligible. Furthermore, because the development of radionuclide K_d distributions was based on ranges of observed saturated zone pHs and bicarbonate/carbonate concentrations (SNL 2008 [DIRS 184806], Section A3), which reflect the influence of any naturally occurring processes on water chemistry, the K_d distributions used in TSPA should inherently reflect the influence of any naturally occurring microbial activity.

Based on the preceding discussion, omission of FEP 2.2.09.01.0A (Microbial Activity in the SZ) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is

excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.09.01.0B

FEP NAME:

Microbial Activity in the UZ

FEP DESCRIPTION:

Microbial activity in the UZ may affect radionuclide mobility in rock and soil through colloidal processes, by influencing the availability of complexing agents, or by influencing groundwater chemistry. Changes in microbial activity could be caused by the response of the soil zone to changes in climate.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Microbial activity can potentially change groundwater pH and Eh and introduce additional complexing agents, which could affect radionuclide K_d distributions in the unsaturated zone. Microbial activity can also potentially result in biotransformations and biocolloid-facilitated transport of radionuclides. Excluded FEP 2.1.10.01.0A (Microbial Activity in the EBS) and *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 7) address these processes very thoroughly for the EBS, and it is concluded that microbial activity can be excluded in the EBS. The justifications for excluding the effects of microbial-produced complexing agents, biotransformation, and biocolloid transport in the EBS also apply in the unsaturated zone given that they are based on information obtained primarily from unsaturated zone and saturated zone rocks and saturated zone waters. These justifications are:

- Although microorganisms may release chemicals that complex with radionuclides, the concentrations of complexing agents are expected to be small, and their binding sites are expected to be dominated by iron ions, which these agents are designed to complex (BSC 2004 [DIRS 169991], Section 6.5.2).

- Reductive biotransformation reactions (the only kind that need be considered since redox-sensitive radionuclides are all assumed to be in oxidized states because of the oxidizing conditions at Yucca Mountain) will only decrease the solubility and increase the sorption of key redox-sensitive radionuclides, so their inclusion can only benefit performance (BSC 2004 [DIRS 169991], Section 6.5.3).

- Even if microbial cells can transport through rock fractures in the unsaturated and saturated zones, their impact on radionuclide transport is expected to be well bounded by the impact of inorganic groundwater colloids. Growing microbes have a propensity to attach to surfaces to remain in their favorable growth environment (BSC 2004 [DIRS 169991], Section 6.5.4), so they tend to be less mobile than inorganic colloids. Oligitrophic (i.e., starved) microbes can have dimensions as small as 0.2 to 0.3 μm

(BSC 2004 [DIRS 169991], Section 6.5.4), which classifies them as biocolloids. However, under oligitrophic conditions, cell concentrations will tend to be low; a concentration of ~7 × 10^6 cells/mL was observed in experiments conducted with Yucca Mountain tuff samples immersed in J-13 well water without the addition of a carbon source (DTN: LL040801512251.115 [DIRS 171476], Table S04340_001). This concentration translates to a mass concentration of ~0.1 mg/L if the cells have the dimensions stated above and are approximately the density of water. The range of unsaturated zone colloid mass concentrations used in TSPA is 0.001 to 200 mg/L (SNL 2008 [DIRS 184748], Table 6-21), so the inclusion of cell mass concentrations would have an insignificant effect on these bounds, particularly on the upper end of the range where the effect on radionuclide transport and dose is greatest.

The effects of changes in soil during future climates on microbial activity may be evaluated by considering the expected changes in soil depth and vegetation. Soil erosion and deposition are not expected to significantly affect soil depth over the next 10,000 years (see excluded FEPs 1.2.07.01.0A (Erosion/Denudation) and 1.2.07.02.0A (Deposition)). A significant change in microbial activity in the subsurface is not expected if the thin soils that exist over the repository footprint (SNL 2008 [DIRS 182145], Figure 6.5.2.4-1[a] and Tables 6.5.2.4-1[a] and 6.5.2.4-2[a]) do not develop into a thicker soil profile.

The remaining concern associated with microbial activity in the unsaturated zone is the effect on inorganic water chemistry, which can adversely affect radionuclide K_d values. The principal concerns are changes to pH and, more importantly, changes to bicarbonate/carbonate concentrations. The actinides (uranium, neptunium, plutonium, and americium) all have higher solubilities and lower K_d values as bicarbonate/carbonate concentrations increase.

In the saturated zone near Yucca Mountain, heterotrophic microbial activity, which uses organic carbon as the sole energy source, is expected to be limited because geochemical analyses of groundwater samples taken from saturated zone wells within the Yucca Mountain vicinity indicate that there is little organic carbon in these waters (DTNs: GS931100121347.007 [DIRS 149611], Table S96375_009; GS010308312322.003 [DIRS 154734], Table S01053_003; GS040108312322.001 [DIRS 179422], Table S04188_001; and GS040808312322.006 [DIRS 179434], Table S04399_004). Given that the source of saturated zone waters beneath the repository is primarily waters infiltrating from the unsaturated zone (SNL 2007 [DIRS 177391], Section A6.3.6.2), it is reasonable to expect that deeper unsaturated zone waters (at the repository level and below) will have similar organic carbon concentrations as saturated zone waters. The maximum reported organic carbon concentration in pumped groundwater samples from the vicinity of Yucca Mountain (with the exception of samples from NC-EWDP-1DX, zone 2, which is located far to the west of any predicted groundwater flow pathways and was believed to be contaminanted by organic drilling fluids) is about 7.5 mg/L (DTN: GS040808312322.006 [DIRS 179434], Table S04399_004). Using the analysis approach in *Evaluation of Potential Impacts of Microbial Activity on Drift Chemistry* (BSC 2004 [DIRS 169991], Section 6.5.1), if 7.5 mg/L of organic carbon (assumed to be carbon, not CH_2O, as is often reported) were converted to HCO_3^- (bicarbonate), ~38 mg/L of HCO_3^- would be generated. The lower and upper bound bicarbonate/carbonate concentrations used to derive unsaturated zone radionuclide K_d distributions are based on water chemistries from wells J-13 and UE-25p#1, with the latter well water providing an effective upper bound of ~700 mg/L HCO_3^- (SNL 2008 [DIRS 184806],

Table I-1). Thus, an increase of 38 mg/L of HCO_3^- is small compared to the range of uncertainty in carbonate/bicarbonate concentrations considered for radionuclide K_d values, and the impact of microbial activity on unsaturated zone water chemistry (pH and ΣCO_2) can be considered negligible. Furthermore, because the development of radionuclide K_d distributions was based on ranges of observed unsaturated zone pHs and bicarbonate/carbonate concentrations (SNL 2007 [DIRS 177396], Section A4), which reflect the influence of any naturally occurring processes on water chemistry, the K_d distributions used in TSPA should inherently reflect the influence of any naturally occurring microbial activity.

Based on the preceding discussion, omission of FEP 2.2.09.01.0B (Microbial Activity in the UZ) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide relases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.01.0A

FEP NAME:

Repository-Induced Thermal Effects on Flow in the UZ

FEP DESCRIPTION:

Thermal effects in the geosphere could affect the long-term performance of the disposal system, including effects on groundwater flow (e.g., density-driven flow), mechanical properties, and chemical effects in the UZ.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses thermal effects on flow in the unsaturated zone with respect to water arrival at the repository and flow from the repository to the water table. Note that the effects of thermal-hydrologic processes on drift seepage and seepage water chemistry are addressed in included FEPs 2.2.07.10.0A (Condensation Zone Forms Around Drifts), 2.2.07.11.0A (Resaturation of Geosphere Dry-Out Zone), 2.2.08.12.0A (Chemistry of Water Flowing into the Drift), 2.2.10.10.0A (Two-Phase Buoyant Flow/Heat Pipes), and 2.2.10.12.0A (Geosphere Dry-Out Due to Waste Heat).

Heat from each emplacement drift dries out the rock surrounding the drift, and the resulting "vaporization barrier" diverts water around the drift. This thermal effect on flow is of limited temporal and spatial extent. Thermal-hydrologic modeling at the drift scale has been performed using a two-dimensional cross-sectional dual-permeability model in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]). Simulations by the TH seepage model (BSC 2005 [DIRS 172232], Figures 6.2.2.1-3 through 6.2.2.1-6) show that during the heating period vaporization of percolating water near hot emplacement drifts forms a dry-out zone around the drifts. A condensation cap forms above the dry-out zone where the rock is cooler. As a result of this vaporization and condensation, downward-percolating water above the drift is diverted laterally. A variety of simulations for base cases and sensitivity cases presented in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Sections 6.2.2 and 6.2.3) show that the flow-field disturbance can extend to distances on the order of 10 m above the drift center. Above that elevation the vertical percolation flux is the same as imposed at the top boundary (e.g., BSC 2005 [DIRS 172232], Figure 6.2.2.1-7). Additional two-dimensional thermal-hydrologic simulation results in *Drift Scale THM Model* (BSC 2004 [DIRS 169864, Figures 6.5.5-3(b), 6.5.5-4(b), and 6.5.5-5(b); DTN: LB0306DRSCLTHM.002 [DIRS 174490]) also show redistribution of percolating water around heated drifts.

Numerical simulations of flow at 100 and 500 years after emplacement show reduced fracture saturation and diversion of percolating water inside the dryout zone (BSC 2005 [DIRS 172232], Section 6.2.2.1). Because of the flow diversion, the dryout is more extensive and longer lasting

beneath the drift; this is called the "drift shadow" effect. Note that there is no water flux through the fractures inside the dryout region, because fracture saturation is zero. After resaturation in 1,000 to 2,000 years, saturations below the drift remain smaller than above, because of the "shadow zone" created by the diversion of flow around the drift (BSC 2005 [DIRS 172232], Section 6.2.2.1; DTN: LB0306DRSCLTHM.002 [DIRS 174490]; BSC 2004 [DIRS 169864, Figures 6.5.5-3(b), 6.5.5-4(b), and 6.5.5-5(b)). The thermal-hydrologic dryout and associated coupled processes will lead to an environment where radionuclide transport in the vicinity of the drift is less likely (BSC 2005 [DIRS 172232], Section 6.2.2.1.1; DTN: LB0306DRSCLTHM.002 [DIRS 174490]; BSC 2004 [DIRS 169864], Figures 6.5.5-3(b), 6.5.5-4(b), and 6.5.5-5(b)).

Two-dimensional thermal-hydrologic simulations in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Figures 6.5.13-1(a) to 6.5.13-6(a)) show the flow redistribution, with vertical percolation flux reduced beneath the drifts and increased around each drift. The limited extent of flow redistribution found in the mountain-scale modeling is consistent with drift-scale results discussed above (DTN: LB0306DRSCLTHM.002 [DIRS 174490]; BSC 2004 [DIRS 169864], Figures 6.5.5-3(b), 6.5.5-4(b), and 6.5.5-5(b)). Results from thermal-hydrologic modeling (BSC 2004 [DIRS 174101], Figures 6.2-10a and b, 6.3.1-18) show that the flow changes resulting from thermal-hydrologic processes are much smaller than those that result from climate change modeled to occur at 600 and 2,000 years after repository closure. The range of variation in flux resulting from climate change is similar in magnitude to the variation in flux resulting from infiltration and unsaturated zone flow uncertainty for the first 10,000 years (SNL 2007 [DIRS 184614], Tables 6.1-2 and 6.8-1). Therefore, the effects of thermal-hydrologic processes are much smaller than the range of variations resulting from existing uncertainties that are included in the flow and transport models (included FEP 1.3.01.00.0A (Climate Change)).

The effects of repository heat and the associated dryout on shallow infiltration at the surface of Yucca Mountain were investigated in *Final Report: Plant and Soil Related Processes Along a Natural Thermal Gradient at Yucca Mountain, Nevada* (CRWMS M&O 1999 [DIRS 105031]). The primary issue for thermal effects at the ground surface is the change in temperature and its associated effect on vegetation. Based on the detailed analysis of soil temperature changes documented in *Impact of Radioactive Waste Heat on Soil Temperatures* (CRWMS M&O 1999 [DIRS 103618], Figure 30), the temperature rise in the repository will have a negligible effect on vegetation, and hence on surface infiltration and groundwater flow in the unsaturated zone.

For thermal effects on chemical processes, see excluded FEPs 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ), 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)), 2.2.10.07.0A (Thermo-Chemical Alteration of the Calico Hills Unit), and 2.2.10.09.0A (Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre). For thermal effects on mechanical processes, see excluded FEPs 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository), 2.2.10.04.0B (Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository), and 2.2.10.05.0A (Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository).

Based on the preceding discussion, omission of FEP 2.2.10.01.0A (Repository-Induced Thermal Effects on Flow in the UZ) will not result in a significant adverse change in the magnitude or

time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.02.0A

FEP NAME:

Thermal Convection Cell Develops in SZ

FEP DESCRIPTION:

Thermal effects due to waste emplacement result in convective flow in the saturated zone beneath the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

To evaluate thermal effects in the saturated zone due to waste emplacement, two mechanisms that could potentially induce convective flow of groundwater are examined. The first mechanism evaluates the potential for convective flow cells to occur as a result of increasing temperatures from the repository. The second mechanism examines the potential for flow to occur due to mounding of the water table resulting from increased temperatures and decreased density of groundwater in the saturated zone below the repository. Either of these mechanisms could lead to greater migration rates of radionuclides in the saturated zone, and the convective outflow of groundwater would be additive to the ambient groundwater movement.

The three-dimensional multiscale thermohydrologic model (SNL 2008 [DIRS 184433]) estimates the temperature at the water table and within the saturated zone as a function of time following emplacement of the waste. Results indicate that temperature will peak at the present-day water table approximately 6,000 years after waste emplacement, with the maximum temperature equal to 73°C and an average of the maximum at each of the 560 locations modeled of 63°C (as extracted from the 560 **.wt* files in DTN: LL0702PA013MST.068 [DIRS 180553] in subfolder /SDT/SDT-01/SDT55). This represents an approximate, average 30°C increase in comparison with the ambient temperature of 30°C to 34°C observed at the water table in the general area of the repository (DTN: LB991201233129.001 [DIRS 146894], file: *INCON_thm_s32.dat*). *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]) used an initial water-table temperature range of 26.7°C to 32.7°C with an average (and median) of 30°C (DTN: LL0702PA013MST.068 [DIRS 180553], file: *Twt.dat*). Although ambient groundwater flow will convect heat away from the area below the repository, it is assumed that the groundwater near the water table is stagnant and that none of the heat is swept downgradient by flow in the saturated zone. Consequently, this model overestimates the values of temperature at and below the water table.

Development of thermal convection cells in porous media is physically driven by an underlying heat source. In the case of the saturated zone at Yucca Mountain, the repository heat source is located above the saturated zone, in the unsaturated zone. Increased temperature in the saturated zone near the water table would decrease the potential for the development of classical thermally

driven convection cells by decreasing the magnitude of the ambient geothermal gradient in the upper part of the saturated zone.

The theoretical potential for the initiation of thermal convection currents in a horizontal porous medium heated from below is given by the modified Rayleigh number N_{RA} (e.g., Domenico and Schwartz 1990 [DIRS 100569], pp. 344 to 345):

$$N_{RA} = \frac{g\rho_o\left(c_w\rho_w\right)Hk\alpha_f\Delta T}{\mu\kappa_e}, \qquad \text{(Eq. 2.2.10.02.0A-1)}$$

where g is the acceleration of gravity, ρ_o is the reference density of water, c_w is the specific heat of water, ρ_w is the temperature-dependent density of water, H is the aquifer thickness, k is the intrinsic permeability, α_f is the coefficient of thermal expansion for water, ΔT is the difference in temperature between the bottom and top of the aquifer, μ is the viscosity of water, and κ_e is the effective thermal conductivity. The lower the Rayleigh number, the lower the likelihood of thermal convection. An increase in the temperature at the water table by repository-induced heating would decrease the value of ΔT in this expression, yielding decreased N_{RA} and a corresponding decrease in the potential for thermal convection compared to the potential for convection under ambient temperature conditions. Under ambient conditions, there is little or no evidence for vertical mixing in the saturated zone beneath Yucca Mountain due to any mechanism including heating from below (SNL 2007 [DIRS 177391], Appendices A and B); hence, it is reasonable to conclude that the Rayleigh number is below the critical value for the onset of convection and will remain below this critical value with additional repository-induced heating.

Mounding of the water table may occur due to the repository heating of the groundwater in the saturated zone. In addition to the ambient flow beneath the water table surface, a local rise in the water table would create a potential for lateral flow at or near the water table. The water-table gradient due to mounding will tend to increase the velocity of radionuclide transport in the saturated zone between the heated region beneath the repository and the downgradient edge of the heated region. The analysis presented below estimates an upper bound on the mound height by considering hydrostatic (no flow) conditions. Groundwater flow away from the water table mound would tend to dissipate the heat from the repository, and therefore lower the mound.

Consider a saturated column of permeable rock with the top at the water table (z = 0 m) and the bottom at a depth at which the temperature is relatively unchanged by the repository (z_d = 1,000 m, which is the maximum depth simulated in the MSTHM). The pressure at the bottom of the column is given by:

$$p_w = \int_0^{z_d} \rho(z) g dz, \qquad \text{(Eq. 2.2.10.02.0A-2)}$$

where $\rho(z)$ is the spatially dependent water density. Assuming a linear thermal gradient and linear relationship between the temperature and density, this equation becomes:

$$p_w = \frac{1}{2} z_d \left[\rho(0) + \rho(z_d) \right] g. \qquad \text{(Eq. 2.2.10.02.0A-3)}$$

Note that $\left[\rho(0)+\rho(z_d)\right]g/2$ represents an average water density within the column. The relationship between the water density and temperature is generally not linear; however, within the temperature range of interest (30°C to 74°C (Dean 1992 [DIRS 100722], Table 5.14)) it is nearly linear with best-fit equation:

$$\rho = 1010.5 - 0.46T. \qquad \text{(Eq. 2.2.10.02.0A-4)}$$

The temperature at the depth of 1,000 m (T_d) can be estimated as:

$$T_d = T_{wt}^0 + \frac{\mathrm{d}T}{\mathrm{d}z} \cdot 1000 \text{ m}, \qquad \text{(Eq. 2.2.10.02.0A-5)}$$

where T_{wt}^0 is the ambient temperature at the water table (30°C) and dT/dz = 25°C/km is the approximate ambient average thermal gradient (DTN: MO0102DQRBTEMP.001 [DIRS 154733], Figures 4, 5, 6, 7, 8, and 10). The resulting temperature at a depth of 1,000 m is 55°C. Consequently, the pressure at the bottom of the unheated vertical column can be written as:

$$p_w = \frac{1}{2} z_d \left[\rho\left(T = 30^\circ C\right) + \rho\left(T = 55^\circ C\right) \right] g. \qquad \text{(Eq. 2.2.10.02.0A-6)}$$

Based on MSTHM results, temperatures at the water table under the repository typically increase by 30°C at 6,000 years after repository closure. Assuming the temperature everywhere within the 1,000-m profile to be approximately 55°C is a reasonable and conservative approximation, given that the temperature at depth is 55°C and that the average temperature at the water table increases from 30°C to 60°C during the first 6,000 years of heating. This temperature is also maximized because the MSTHM does not take credit for any advective transport of heat away from the system due to flow in the saturated zone (in the MSTHM, the water table behaves only as a conducting medium).

The water pressure at the bottom of the 1,000-m vertical column under the repository is assumed constant, but the height of the column (z_{new}) will increase to reflect the increase in temperature and decrease in density. The increase can be found by equating the pressures under the repository with those of the ambient condition (the hydrostatic assumption):

$$p_w = \frac{1}{2} z_d \left[\rho\left(T = 30^\circ \mathrm{C}\right) + \rho\left(T = 55^\circ \mathrm{C}\right) \right] g = z_{new} \rho\left(T = 55^\circ \mathrm{C}\right) g. \qquad \text{(Eq. 2.2.10.02.0A-7)}$$

Rearranging the preceding equation, the following relationship is obtained:

$$z_{new} = \frac{z_d \left[\rho\left(T = 30^\circ \mathrm{C}\right) + \rho\left(T = 55^\circ \mathrm{C}\right) \right]}{2\rho\left(T = 55^\circ C\right)}. \qquad \text{(Eq. 2.2.10.02.0A-8)}$$

The following data from Dean (1992 [DIRS 100722], Table 5.14) were used as input in the formula for z_{new}:

$$\rho(T = 30°C) = 995.65 \text{ kg/m}^3,$$

$$\rho(T = 55°C) = 985.70 \text{ kg/m}^3 \text{ (linear interpolation).}$$

Using the equation for z_{new} results in a column height of 1,005 m. Consequently, the maximum water table mounding resulting from peak temperature at the water table surface is 5 m. To evaluate the effect of this potential increase in the water table above the heated repository, the associated change in the hydraulic gradient between the repository and the 18-km compliance boundary is estimated. The 18-km compliance boundary is at Nevada State Plane Northing 213,078 m (minimum Northing coordinate from DTN: MO0712DELNPCCA.001 ([DIRS 184172], file: *controlled.txt*). This Northing position is at approximately 4058250 m N in the UTM coordinate system. The potentiometric surface within the inferred flowpath, which is in the Lower Fortymile Wash Alluvium, is somewhere between UTM Easting 548017 and 551553 m. These easting coordinates were interpolated from the SZ site-scale flow model data set (DTN: SN0612T0510106.004 [DIRS 178956], file: *lower_fortymile_wash.zonn*). The average water table at Northing coordinate 4058250 between the Easting coordinate limits given above is about 711 m above mean sea level (DTN: SN0612T0510106.004 [DIRS 178956], file: *wt.dat*). The average water table over the repository, eighteen kilometers north of this location, and between UTM Easting 547800 and 548375 m, is about 732 m. Without heating, there is a change in potentiometric surface of 21 m yielding a hydraulic gradient of 1.2×10^{-3}. Adding the 5 m due to heating above the repository results in a hydraulic gradient of 1.5×10^{-3}, or an increase of approximately 24%. This additional increase in the hydraulic gradient resulting from the mounding of the water table is small relative to the uncertainty range for GWSPD multiplier, which goes as high as a factor of 8.93 (log-10-transformed value of 0.951) (SNL 2008 [DIRS 183750], Table 6.7[a]) and is linearly proportional to the hydraulic gradient times the hydraulic conductivity (permeability).

Subject to a wetter climate in the future, the water table below the repository is expected to rise by 120 m (SNL 2008 [DIRS 184748], Section 6.4.8) to an elevation of 850 m above sea level. Eighteen kilometers south and within the expected flowpaths, the water table is expected to be 739 m above sea level (DTN: SN0702T0510106.006 [DIRS 179575], file: *future_wt.dat*), which equates to a hydraulic gradient of 6.3×10^{-3}. The temperature in the nearby Calico Hills Formation reaches a maximum temperature of about 80°C, which is a reasonable approximation for the maximum temperature at the elevated water table (SNL 2008 [DIRS 179962], Figure 6.4.2-31; DTN: MO0707TH2D3DDC.000 [DIRS 182472], file: *p10-t_elws.dat*). Conservatively assuming a water-column mean temperature of 70°C (and corresponding density of 977.75 kg/m^3) yields Δz_{new} = 10 m and a new hydraulic gradient of 6.8×10^{-3}. This is a 9% relative increase still well within the maximum GWSPD multiplier of 8.93.

The potential for convective flow to occur in the saturated zone is decreased as a result of increasing temperatures from the repository heat source above. An increase in the temperature at the water table would decrease the value of the ΔT term in the Rayleigh expression, resulting in a smaller value for N_{RA} and a decrease in the potential for thermal convection. Mounding of the water table that may occur due to the repository serving as a heat source to the groundwater in

the saturated zone yields up to a 24% increase in the existing hydraulic gradient, which is small relative to the uncertainty range for GWSPD, as described above. Even subject to an elevated water table in a wetter climate, the increase is still much less than the maximum GWSPD multiplier.

Based on the previous discussion, omission of FEP 2.2.10.02.0A (Thermal Convection Cell Develops in SZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.03.0A

FEP NAME:

Natural Geothermal Effects on Flow in the SZ

FEP DESCRIPTION:

The existing geothermal gradient, and spatial or temporal variability in that gradient, may affect groundwater flow in the saturated zones.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Natural geothermal effects, as they influence fluid properties, are included in the SZ site-scale flow model. Groundwater flow is simulated in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]) using conservation of mass and momentum equations in the numerical code FEHM. The fluid–rock momentum equation (simplified to Darcy's equation) is, in part, a function of permeability, density, viscosity, and temperature (SNL 2007 [DIRS 177391], Section 6.4.1). For temperatures that range between 20°C to 100°C, the density of water changes by only a few percent. In contrast, the variation in water viscosity changes by a factor of 3.3 over the same temperature range. Consequently, natural geothermal effects on groundwater flow are more effectively captured by spatially varying viscosity rather than density. *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.4.3.10) assigns a specified temperature to each node, which varies with depth and is based on variable temperature measurements reported by Sass et al. (1988 [DIRS 100644]), using an average geothermal gradient. Temporal variations in the natural geothermal gradient are expected to be minor, as explained with regard to hydrothermal activity (see excluded FEP 1.2.06.00.0A (Hydrothermal Activity)). Specifically, studies of two-phase fluid inclusions in the unsaturated zone at Yucca Mountain using petrography, microthermometry, and uranium-lead dating indicate that temperatures have remained close to the current ambient values over the past 2 to 5 million years (Wilson et al. 2003 [DIRS 163589], Section 8). These findings show that significant or widespread alteration of the natural geothermal gradient has not occurred in the unsaturated zone in the recent geologic past, and imply that significant change to the geothermal gradient has likewise been absent from the saturated zone.

Permeability and viscosity are also assigned to each node. Temperatures are used to calculate nodal viscosities. Using both spatially varying viscosity and calibrated permeabilities, lumped fluid/rock property parameters can be calculated. Estimated hydraulic conductivity at each node is calibrated to hydraulic head measurements, while nodal viscosities and temperatures remain fixed (SNL 2007 [DIRS 177391], Section 6.4.3.10). Hydraulic heads are, in part, manifestations of multiple processes within the system, including geothermal effects. By calibrating permeabilities to hydraulic heads while maintaining temporally constant, spatially varying temperatures and viscosities, geothermal effects on flow are implicitly captured. The site-scale SZ transport model (SNL 2008 [DIRS 184806]) incorporates these effects by using the calibrated SZ site-scale flow

model as its basis. Furthermore, the uncertainty that temperature may have on matrix diffusion is implicitly captured in the range for effective diffusion coefficients adopted in the SZ flow and transport abstraction model (SNL 2008 [DIRS 183750], Section 6.5.2.6 and Table 7-1[b]). Because the natural geothermal gradient directly impacts the saturated zone flow field and groundwater specific discharge, its impact on TSPA is propagated through uncertainty in the groundwater specific discharge multiplier (SNL 2008 [DIRS 183750], Table 6-8).

Natural Geothermal Effects on Flow in the UZ

FEP DESCRIPTION:

The existing geothermal gradient, and spatial or temporal variability in that gradient, may affect groundwater flow in the UZ.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Natural geothermal effects, observed as the natural temperature profile in the unsaturated zone, are included in the unsaturated zone model calibration. The temperature profile is primarily determined by the ground surface temperature, the water table temperature, water flux through the unsaturated zone, and the thermal conductivity from layer to layer (SNL 2007 [DIRS 184614], Section 6.3). The influence of water flux on temperature is utilized to calibrate the probabilities for different surface water flux boundary conditions for the unsaturated zone flow model. The calibration is based on the Generalized Likelihood Uncertainty Estimation methodology utilizing temperature observations and model predictions, as well as chloride observations and model predictions (SNL 2007 [DIRS 184614], Section 6.8). The probabilities for surface water flux are applied as flow weighting factors for unsaturated zone flow fields in TSPA, which are used for present-day, monsoon, glacial-transition, and post-10,000-year climates (SNL 2007 [DIRS 184614], Table 6.8-1).

The UZ flow fields, which are calibrated to the existing geothermal gradient, also provide percolation-flux boundary conditions in *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 5.1.2). Therefore, the effects of natural geothermal gradients are included in the multi-scale thermohydrologic model through the use of the calibrated flow fields. Subsequent effects caused by repository heating included in the TSPA model are discussed in that report (SNL 2008 [DIRS 184433], Sections 6.3 and 6.3[a]). The natural geothermal gradient in the unsaturated zone is explicitly included in boundary conditions for the thermal seepage model in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232], Section 6.5.2).

FEP: 2.2.10.04.0A

FEP NAME:

Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository

FEP DESCRIPTION:

Heat from the waste causes thermal expansion of the surrounding rock, generating changes in the stress field that may change the properties (both hydrologic and mechanical) of fractures in the rock. Cooling following the peak thermal period will also change the stress field, further affecting fracture properties near the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Changes to rock thermo-mechanical stresses due to heating by emplaced waste may alter rock hydro-mechanical characteristics (e.g., permeability, moisture retention) of the fractures near the repository. For this justification, the region near the repository is defined as the region below the Paintbrush non-welded unit (PTn) and above the water table. Changes to material properties at greater distances extending upward to the land surface and downward to the water table are presented in excluded FEP 2.2.10.05.0A (Thermo-mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository). In addition, the thermal effects on sorption, solubility, and precipitation/dissolution are discussed in excluded FEP 2.2.10.06.0A (Thermal-chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)). Thermally induced stress changes in the near-field are discussed in excluded FEP 2.2.01.02.0A (Thermally-Induced Stress Changes in the Near-Field), where they are determined to have a minimal impact on rockfall and the hydrologic performance of emplacement drifts.

The effects of thermo-mechanical loading on fractures within the vicinity of the repository drifts due to waste emplacement are evaluated in *Drift Scale THM Model* (BSC 2004 [DIRS 169864]). The results of the coupled drift-scale thermal-hydrological-mechanical (THM) model (BSC 2004 [DIRS 169864], Sections 6.5 and 6.6) indicate that time-dependent THM processes will last for more than 10,000 years. The thermo-mechanical processes have a small or moderate impact on the drift-scale behavior, including a negligible impact on the temperature evolution and small impact on the percolation flux as demonstrated by the comparison of thermal-hydrological (TH) and THM simulation results (BSC 2004 [DIRS 169864], Section 6.5.2, Figures 6.5.5-3, 6.5.5-4, 6.5.5-5, 6.6.2-1, 6.6.2-2, and 6.6.2-3). The THM simulation results were obtained by adopting parameters that emphasize the effect of THM coupling on hydrologic properties and the flow field. This included a bounding estimate of a thermal expansion coefficient (that emphasizes thermal stress) and a bounding estimate of a stress-versus-permeability function that emphasizes THM-induced permeability change. As fracture apertures are modified by the thermo-mechanical impact on the stress field, the permeability may be significantly altered because permeability varies as approximately the cube of the aperture (BSC 2004

[DIRS 169864], Equation 6.4-4). These parameter sets are sufficient for bounding the possible impact of the THM processes on permeability and percolation flux.

Overall, model results indicate that the impact of stress-induced changes in hydrological properties on the flow field is small as characterized by a slightly smaller extent of the dryout zone and a shorter time for resaturation of the rock to the drift wall for the THM case (BSC 2004 [DIRS 169864], Figure 6.5.5-4 and Section 8.1). In the long term, at around 10,000 years, vertical permeability is reduced just above the emplacement drift. The impact of this reduction in permeability is small, but tends to prevent vertical flux from reaching the drift wall at the drift crown (BSC 2004 [DIRS 169864], Figure 6.5.5-5). These changes in hydrological properties are not important because the impacts to the flow system are small. Impacts to the hydrologic property changes are not as important as impacts to the amount of seepage into the drifts. To assess the impact of hydrologic property changes, simulations were conducted to assess the impact to seepage at the repository horizon.

The THM simulations discussed in *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.4.1) indicate that temperature-induced stress changes give rise to changes in the vertical fracture permeability in the vicinity of waste emplacement drifts, particularly in the Tptpmn unit (Topopah Spring Tuff middle nonlithophysal zone) (SNL 2007 [DIRS 181244], Section 6.5.1.4). However, these permeability changes do not result in significant changes to the vertical percolation flux as noted in the paragraph above. In particular, the seepage rates calculated for a permeability field including THM permeability changes were similar to, but 10% less than, those calculated for a permeability field representative of the initial post-excavation conditions (SNL 2007 [DIRS 181244], Section 6.4.4.1.1). These simulations examine effects during the heating and cooling phases out to 10,000 years. It is concluded that an ambient seepage model with consideration of anisotropic THM property changes is only slightly different from the model with only TH considerations. Therefore, the thermo-mechanical impacts to fractures near the repository are insignificant.

Based on the previous discussion, omission of FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures near Repository) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.04.0B

FEP NAME:

Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository

FEP DESCRIPTION:

Heat from the waste causes thermal expansion of the surrounding rock, generating changes to the stress field that may change the properties (both hydrologic and mechanical) in and along faults. Cooling following the peak thermal period will also change the stress field, further affecting fault properties near the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Changes to rock thermo-mechanical stresses due to heating by emplaced waste may alter rock hydro-mechanical characteristics of faults (e.g., permeability) and may alter mechanical characteristics such as shear slip potential. Rock alteration above and below the repository from thermo-mechanical stresses caused by repository heat have been shown to have an insignificant impact on percolation through the unsaturated zone as demonstrated by the comparison of thermal-hydrological and THM simulation results (see excluded FEP 2.2.10.05.0A (Thermo-mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository) and BSC 2004 [DIRS 169864], Section 6.5.2, Figures 6.5.5-3, 6.5.5-4, 6.5.5-5, 6.6.2-1, 6.6.2-2, and 6.6.2-3). As discussed in excluded FEP 2.2.01.02.0A (Thermally-Induced Stress Changes in the Near-field), thermally induced stress changes in the near-field have been shown to have a minimal effect on rockfall. Thermo-mechanical stress effects in the near-field are discussed in excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository) and *Drift Scale THM Model* (BSC 2004 [DIRS 169864], Sections 6.5 and 6.6). These stress-related impacts are determined to have a minimal impact on the hydrologic performance of emplacement drifts. In addition, thermo-chemical effects on sorption, solubility, and precipitation/dissolution have been shown to be insignificant as discussed in excluded FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)). Stress changes in the cooling period are considered in excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository) and are also shown to be insignificant.

Faults are treated as large fractures when assessing the impact of changes to thermo-mechanical stresses on faults. The primary differences between faults and fractures with respect to flow, transport, drift seepage, and coupled processes, are that faults may have greater permeability and continuity than fractures. Thermo-mechanical effects on fault-fractures are expected to be qualitatively similar to rock-mass fractures where thermal-hydrological-mechanical (THM) processes lead to reductions in vertical permeabilities (see excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository) and SNL 2007 [DIRS 181244], Sections 6.4.4.1 and 6.5.1.4). As the faults are typically oriented vertical or near

vertical, the expected hydrologic impact of increased thermo-mechanical stresses due to heating on faults would be to decrease the vertical permeability of the faults as a result of rock expansion as a result of rock expansion.

The thermo-mechanical-induced stresses have no long-term effect on fracture properties that would affect long-term unsaturated zone flow and transport, as noted in excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository) and SNL (2007 [DIRS 181244], Section 6.4.4.1.1). Thus, the thermo-mechanical stresses will have less of an impact on the block-bounding faults (Solitario Canyon Fault and Bow Ridge Fault), which will be further away from the heat source of the repository block. A block-bounding fault's response to the same thermo-mechanical-induced stresses imposed on fractures will be mitigated due to its size and distance from the heat source.

Based on the previous discussion, omission of FEP 2.2.10.04.0B (Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.05.0A

FEP NAME:

Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository

FEP DESCRIPTION:

Thermal-mechanical compression at the repository may produce tension fracturing in the Paintbrush non-welded tuff and other units above the repository. These fractures may alter unsaturated zone flow between the surface and the repository. Extreme fracturing may propagate to the surface, affecting infiltration. Thermal fracturing in rocks below the repository may affect flow and radionuclide transport to the saturated zone.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Changes to rock thermo-mechanical stresses due to heating by emplaced waste may alter rock hydro-mechanical characteristics (e.g., permeability). This FEP addresses rock fracturing above and below the repository as a result of thermo-mechanical stresses due to heating of the rock by emplaced wastes and examines the potential impacts on vertical permeability in the unsaturated zone. Other FEPs related to this one are excluded FEP 2.2.01.02.0A (Thermally-Induced Stress Changes in the Near-Field) and excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository), which discuss thermo-mechanical stress effects in the near-field. These stress-related impacts are determined to have a minimal impact on rockfall and the hydrologic performance of emplacement drifts. Stress changes in the cooling period are considered in excluded FEP 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository). Thermo-chemical alteration of the Calico Hills unit is addressed in excluded FEP 2.2.10.07.0A (Thermo-Chemical Alteration of the Calico Hills Unit).

The mountain-scale THM model (BSC 2005 [DIRS 174101], Section 6.5) assesses the magnitude and distribution of changes in hydrological properties and analyzes the potential impacts on the mountain-scale percolation flux through the repository horizon for a time period up to 10,000 years that includes both heating and cooling conditions. Calculations show that the vertical permeability changes much more than the horizontal permeability because the horizontal fractures remain open during the entire heating cycle and during cooling to 10,000 years. Thus, this discussion will focus on the changes to the vertical fractures. Results indicate that a maximum THM-induced change in hydrological properties occurs at about 1,000 years after emplacement of waste when the average temperature in the mountain is maximal. Near the ground surface, a zone of tensile stresses is caused by the redistribution of horizontal compressive stresses from the relatively cool regions near the ground surface towards hot regions near the repository horizon (BSC 2005 [DIRS 174101], Section 6.5.11). Compressive stresses transition to tensile stresses between about 260 and 330 m above the repository (BSC 2005 [DIRS 174101], Figure 6.5.11-1b).

At distances of about 190 to 230 m above the emplacement drifts, and again from 270 m above the emplacement drifts to the land surface, zones of tensile stresses with potential fracturing and shear slip were simulated in the THM model (BSC 2005 [DIRS 174101], Section 6.5.14). These zones may potentially represent strata where vertical permeability will be enhanced because fractures will tend to open under tension. The PTn unit, located between the land surface and the repository horizon, is expected to experience a smaller change in horizontal stress (BSC 2005 [DIRS 174101], Figures 6.1-2 and 6.5.11-1), but falls within a near-surface zone that may experience fracturing and shear slip that could result in permanent permeability changes (BSC 2005 [DIRS 174101], Section 6.5.14). Using estimates of input THM properties that would result in upper-bound changes in permeability and percolation rates, changes in permeability by elastic closure or opening of preexisting fractures are within a factor of 0.3 to 5, whereas calculated changes in capillary pressure range between a factor of 0.7 to 1.2 (BSC 2005 [DIRS 174101], Section 6.5.12). To assess the impact of the tensile zones, more extreme changes in vertical permeability and capillary pressure were assumed based on a wider range of observed values to assess the widest range of values possible. The vertical permeability of the tensile zones was increased by three orders of magnitude (representing an upper bound estimate of the increase in permeability expected during shear) and the capillary pressure was reduced by a factor of 10 to correct for the permeability change (BSC 2005 [DIRS 174101], Equation 6.5.5-6, Section 6.5.14). The simulated vertical percolation flux at 10,000 years across the repository horizon was no different, indicating that the potential increase in permeability above the repository horizon as a result of the thermo-mechanical-induced stresses does not impact the percolation flux at the repository level (BSC 2005 [DIRS 174101], Section 6.5.14, Figure 6.5.14-3).

The impact of thermo-mechanical stresses on units below the repository were also presented in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Section 6.5). Beneath the repository horizon, thermo-mechanical impacts from repository heat will increase horizontal stresses (BSC 2005 [DIRS 174101], Figure 6.5.11-1), which lead to small decreases in vertical permeability relative to pre-emplacement values (0.7 to 0.9) (BSC 2005 [DIRS 174101], Figure 6.5.12-1). In the analysis of thermo-chemical alteration of the Calico Hills unit beneath the repository (excluded FEP 2.2.10.07.0A (Thermo-chemical Alteration of the Calico Hills Unit)), even larger increases or decreases in vertical fracture permeability, caused by chemical interactions, were shown to have an insignificant impact on the rate of radionuclide migration. Thus, the small changes in permeability of the Calico Hills unit due to thermo-mechanical stresses can also be excluded on the basis of low consequence.

The effects of seismic-induced mechanical disturbance of fractures along radionuclide transport pathways are discussed in excluded FEP 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures). The conclusion reached in the screening justification of that FEP is that the effects of changes to fracture aperture or spacing on radionuclide transport are expected to be negligible over a wide range of permeability variation. The conclusions reached in that FEP are also applicable here because the analysis is based on a general sensitivity study of how fracture properties affect unsaturated zone flow and radionuclide transport.

Overall effects of thermal stresses on fluid flow due to repository heating above, around, and below the repository are evaluated in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Section 6.5.13; DTN: LB0310MTSCLTHM.002

[DIRS 170718]). This analysis indicates that in the zones near and below the repository, the thermally induced stress changes do not impact the water flux at the repository level. Thus, it is appropriate to exclude thermal effects on mechanical coupling because fluid flow is unaffected by thermally induced stresses.

In the saturated zone, the impact of thermally induced stresses on the characteristics of fractures will also be small. Calculations (SNL 2008 [DIRS 184433], Figure 6.2-14[a]) were made assuming a fixed temperature boundary condition 1,000 m below the water table. The results of the calculation demonstrate that the average temperature change at the water table peaks at approximately 33°C above the initial temperature about 6,000 years after waste emplacement (as extracted from the 560 **.wt* files in DTN: LL0702PA013MST.068 [DIRS 180553], subfolder: /SDT.SDT-01/SDT55). This magnitude of temperature increase is not enough to produce thermo-mechanical stresses at the water table sufficient to produce compression stresses that would significantly affect fracture permeability in the saturated zone.

Based on the previous discussion, omission of FEP 2.2.10.05.0A (Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.06.0A

FEP NAME:

Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)

FEP DESCRIPTION:

Thermal effects may affect radionuclide transport directly, by causing changes in radionuclide speciation and solubility in the UZ, or indirectly, by causing changes in the host rock mineralogy that affect the flow path. Relevant processes include volume effects associated with silica phase changes, precipitation and dissolution of fracture-filling minerals (including silica and calcite), and alteration of zeolites and other minerals to clays.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

This FEP addresses thermal effects on water–rock interactions in the unsaturated zone. These effects could exert changes on heterogeneous chemical reactions such as mineral dissolution and precipitation. Such effects could also be manifested in changes on rock transport properties (e.g., fracture permeability) and modification of the chemistry of percolating waters. They could affect the sorption properties of radionuclides on tuff. The FEP description also raises some issues addressed in excluded FEPs 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ), 2.2.08.07.0B (Radionuclide Solubility Limits in the UZ), 2.2.10.07.0A (Thermo-Chemical Alteration of the Calico Hills Unit), 2.2.10.09.0A (Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre), and 2.2.01.05.0A (Radionuclide Transport in the Excavation Disturbed Zone), and in included FEP 2.2.08.12.0A (Chemistry of Water Flowing into the Drift). The effects of colloid formation are accounted for in the colloid source term (SNL 2007 [DIRS 177423], Section 6.5.2.3), and are discussed in excluded FEP 2.2.08.03.0B (Geochemical Interactions and Evolution in the UZ).

Measurements at various temperatures of K_d for sorption of barium (a proxy for radium), cesium, strontium, and neptunium on Yucca Mountain tuff are reported, respectively, in DTNs: LA0010JC831341.001 [DIRS 162476], LA0010JC831341.002 [DIRS 153321], LA0010JC831341.003 [DIRS 153322], and LA0010JC831341.007 [DIRS 153319]. Plots of these data showing that K_d values for these elements are either unaffected by temperature or increase slightly with temperature are presented in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Figure I-1). These data were combined with additional measurements of these elements, plus plutonium, americium, uranium, and europium and cerium (proxies for trivalent actinides), and analyzed in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Appendix I) to estimate the enthalpy of sorption, ΔH_r (see also Equations I-6 to I-13b). ΔH_r greater than zero indicates that sorption increases with increasing temperature. The results of that analysis are shown in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Figure I-5,

Table I-12). For cesium, barium, cerium, europium, plutonium, and americium, the values of ΔH_r were not statistically different from zero; that is, no dependence of K_d upon temperature could be inferred. For uranium, strontium, and neptunium, the ΔH_r values were somewhat greater than zero within their overall range. Given the overall weak dependency of sorption K_d values on temperature, the effect of temperature on radionuclide transport is, therefore, excluded on the basis of low consequence because it has no adverse effects on performance.

The thermal-chemical interactions that will occur in the repository environment have been studied with respect to effects on the seepage water entering the waste emplacement drifts in *Drift-Scale THC Seepage Model* (SNL 2007 [DIRS 177404]). This model captures the effects of changes in temperature, pH, ionic strength (and other compositional variables), time dependency, precipitation or dissolution effects, and effects of resaturation (SNL 2007 [DIRS 177404], Section 6.2). Changes in fracture permeabilities resulting from mineral precipitation or dissolution were found to be on the order of the natural variation in these properties (SNL 2007 [DIRS 177404], Section 6.5.5.3; BSC 2004 [DIRS 170038], Table 6-5), with most of the substantial effects spatially limited to localized regions above and to the side of the drift within about a drift diameter (SNL 2007 [DIRS 177404], Figure 6.5-8). The predicted mineral precipitation decreases permeability in the affected regions and leads to a diversion of flow into unaltered rocks further from the drift.

The geochemical model includes the major solid phases (minerals and glass) encountered in geologic units at Yucca Mountain, together with a range of possible reaction product minerals, CO_2 gas, and the aqueous species necessary to include these solid phases and the pore-water composition within the THC model (SNL 2007 [DIRS 177404], Table 6.2-2). Compositional changes of seepage are calculated by the drift-scale THC seepage model (SNL 2007 [DIRS 177404], Section 6.5.5.4) for matrix/fractures pore waters and gas at gridblocks nearby the drift wall boundary. Variations in pH (SNL 2007 [DIRS 177404], Figures 6.5-16, 6.6-1, 6.6-5, 6.6-7, 6.6-9, and 6.6-14), a key compositional variable for sorption of some radionuclides (SNL 2007 [DIRS 177396], Appendix A), roughly lie within the range of variability investigated for radionuclide sorption (SNL 2007 [DIRS 177396], Appendix A).

Results were also investigated for the Tptpll by considering a range of initial pore-water compositions. In this analysis, four different initial pore-water compositions were investigated (SNL 2007 [DIRS 177404], Table 6.2-1). Peak concentrations of aqueous species at the time of rewetting reflect mostly the small values of the first nonzero liquid-saturation output. Elevated concentrations are predicted only for small liquid saturations that are not subject to significant fluid movement. Overall, silica (and calcite) deposition at the boiling front is one of the main processes responsible for the long-term decrease in permeability (2007 [DIRS 177404], Section 6.5.5.3). Short-term effects on the decrease of fracture permeability are mainly restricted to the peak thermal period where salts precipitate as a result of dryout at the boiling front. As previously stated, fluid mobility during the thermal period is expected to be low since liquid saturations are also low.

The modeling results indicate that, at the drift wall, most of the significant compositional variations resulting from thermal-chemical processes are limited to low-saturation conditions over time periods that are short (approximately 1,400 years maximum) relative to a 10,000-year time period (SNL 2007 [DIRS 177404], Section 6.5.5.4). Included FEP 2.2.08.12.0A

(Chemistry of Water Flowing into the Drift) describes the chemistry of water percolating into the drift using the NFC model (SNL 2007 [DIRS 177412], Section 6.3.2). This model is used to predict the chemistry of potential seepage waters flowing into the repository drifts, and it is similar to the drift-scale THC model but differs conceptually in its implementation. The NFC model focuses more on the treatment of fluid–rock interactions as the water percolates through the TSw towards the evaporation front bounding the drift. Comparison of the two models in the validation presented in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Section 7.1.3) shows that, overall, they provide similar results, capturing the major bounding mechanism responsible for changes in seepage chemistry. These analyses suggest that the effects of these changes upon water chemistry in the unsaturated zone are minimal in the long-term.

Based on the previous discussion, omission of FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.07.0A

FEP NAME:

Thermo-Chemical Alteration of the Calico Hills Unit

FEP DESCRIPTION:

Fracture pathways in the Calico Hills may be altered by the thermal and chemical properties of the water flowing out of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The Calico Hills nonwelded unit (CHn) is composed of the Calico Hills vitric (CHv) and Calico Hills zeolitic (CHz) units. The CHn unit is situated below the repository horizon and is characterized by complex hydrologic properties for both fracture and matrix (SNL 2007 [DIRS 184614], Section 6.1.1; SNL 2007 [DIRS 177396], Section 6.1.1). Thermo-chemical alteration of fracture pathways in the Calico Hills unit might affect unsaturated zone flow and transport (1) by mineral dissolution and precipitation, which would change the fracture porosity and permeability of the fracture network (SNL 2007 [DIRS 177396], Section 6.1.1), (2) by changing the fraction of active fractures in the active fracture model (Liu et al. 1998 [DIRS 105729]), or (3) by changing the sorptive properties of minerals present on the fracture wall surfaces through mineral dissolution and precipitation, which would change the overall sorptive capacity, represented by K_d (SNL 2007 [DIRS 177396]). As discussed in the following paragraphs, sensitivity studies to examine these effects have shown that none of them significantly increases transport to the accessible environment or the dose to the RMEI.

Sensitivity of tracer transport to fracture porosity was studied by calculating breakthrough curves using (1) the base-case calibrated fracture porosity for each unit, and (2) fracture porosity reduced by a factor of ten everywhere (BSC 2004 [DIRS 169861], Section 6.8.2.2). *UZ Flow Models and Submodels* (BSC 2004 [DIRS 169861], Figure 6.8-4) shows that, with reduced fracture porosity, the fractional mass breakthrough of the tracer arriving at the water table is larger than the one obtained using the calibrated fracture porosity only during the first 50 years. However, in both cases, less than 15% of the released mass arrives during this period. After 100 years, both simulation cases give similar results: almost 50% of the tracer mass arrives at the groundwater table at about 3,400 years, and the two breakthrough curves are not distinguishable. Increasing the fracture porosity was not considered in that sensitivity study because it would retard tracer breakthrough and would, therefore, not be conservative. Comparison of the cases studied shows that transport is not sensitive to fracture porosity.

Sensitivity of tracer transport to the permeability of the fracture network in the Calico Hills unit was studied in *UZ Flow Models and Submodels* (BSC 2001 [DIRS 158726], Sections 6.2.2, 6.2.3, 6.2.5, and 6.7.3, Figures 6-54 to 6-56). Radionuclide breakthrough curves were evaluated for alternative perched water models presented in *UZ Flow Models and Submodels* (BSC 2001

[DIRS 158726], Section 6.7.3). Perched water conceptual models #1 and #2 are named the "flow-through" perched water model and "by-passing" perched water model, respectively (BSC 2001 [DIRS 158726], Section 6.2.2). For model #1, fracture permeability in some layers of the Calico Hills unit is set ten times as great as matrix permeability (BSC 2001 [DIRS 158726], Section 6.2.3, Table 6-6); this property set produces the known perched water. For model #2, fracture permeability is set equal to matrix permeability in all zeolitic units, effectively removing the fractures; this represents the case of fracture sealing. Comparisons for transport simulations between the repository and the water table for the two perched water models (and one other model not discussed here) were performed using sorbing and nonsorbing radionuclides (BSC 2001 [DIRS 158726], Section 6.7.2). The transport results for perched water models #1 and #2 have only minor differences (BSC 2001 [DIRS 158726], Figures 6-54 to 6-56). Transport is, therefore, not sensitive to fracture permeability in the zeolitic Calico Hills unit.

Based on evidence of past alteration, potential thermo-chemical alteration of the Calico Hills unit (CHn) falls into two categories: (1) zeolitization of vitric CHv tuff and (2) recrystallization of zeolitized CHz tuff. Vitric tuff exists mostly above the present water table and former high stands of the water table, suggesting that full saturation and slightly elevated temperatures are conducive to pervasive zeolitic alteration (Levy 1991 [DIRS 100053], Bish and Aronson 1993 [DIRS 100006]). Temperatures around 60°C to 65°C (Bish and Aronson, 1993 [DIRS 100006], Figure 6) and an elevated water table are the factors that would promote zeolitization of the vitric CHv unit. Recrystallization of clinoptilolite, the dominant zeolite in the CHz, to other zeolites may not occur at temperatures below about 100°C (Bish and Aronson, 1993 [DIRS 100006]. The top of the CHn unit will experience temperatures above ambient, exceeding ~60°C beginning at ~400 years and a peak of ~80°C at ~1,100 years during the thermal period (SNL 2008 [DIRS 179962], Figure 6.4.2-31). It is expected that, during the thermal pulse period, the hydraulic conductivity of the CHn will increase as a result of decreasing water viscosity thus promoting flow and drainage. This would lower the water content of the vitric CHv unit. For all these reasons, further alteration of this unit through fluid–rock interaction is not expected since the unit will not be fully saturated and average temperatures will not exceed 100°C. Therefore, significant changes in fracture and matrix permeability as a result of rock alteration during the thermal pulse period and beyond are not expected and are, thus, considered of low consequence in affecting radionuclide transport.

This conclusion differs from that of the mountain-scale thermal-hydrologic-chemical model presented in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Section 6.4). The mountain-scale THC model concludes that significant mineralogic changes—glass alteration and changes in the abundance and mineralogy of the zeolite mineral assemblage—will occur in the Calico Hills unit during the thermal pulse. However, the mountain-scale model implements an older version of the THC seepage model, which differs from the current model. Specifically, dissolution/precipitation rates for several silicate minerals and for rhyolitic glass are 2 to 4 orders of magnitude lower in the current revision of the THC seepage model (SNL 2007 [DIRS 177404], Appendix H) than in the mountain-scale THC model (BSC 2005 [DIRS 174101], Section 4.1.12]). The slower rates implemented in the current THC seepage model are more consistent with field-based measurements of mineral dissolution (the older model used laboratory-derived rates) and with the site-specific observations of the degree of alteration at Yucca Mountain (SNL 2007

[DIRS 177404], Appendix H). If the mountain-scale model were implemented with the updated mineral dissolution/precipitation rates, considerably less alteration of the Calico Hills unit would be expected. Because a previous parameter set was used, and because the results with respect to alteration of the Calico Hills unit are inconsistent with the extended thermal history of that unit, the mountain-scale results do not represent the expected degree of alteration within that unit, and are not considered here.

Additional sensitivity studies concerning the effects of fracture permeability in the Calico Hills unit on radionuclide transport were discussed in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Figures 6-29 and 6-30). Two sensitivity cases were investigated for aqueous ^{99}Tc, ^{237}Np, and ^{242}Pu, and colloidal ^{242}Pu. In one case, the fracture permeabilities were increased throughout the model domain by one standard deviation and in the other case, the fracture permeabilities were decreased by one standard deviation. The results of these sensitivity analyses indicate that the effect of changing the permeability of the fracture continuum on the normalized cumulative breakthrough curves for the investigated actinides is small.

In the active fracture model conceptualization (Liu et al. 1998 [DIRS 105729], pp. 2,638 to 2,641), only a portion of fracture networks is active (hydraulically conductive) under unsaturated conditions. Numerically, this active portion is defined as a function of water saturation S and the active fracture parameter γ (Liu et al. 1998 [DIRS 105729], pp. 2,638 to 2,641). By definition, γ ranges between 0 and 1, with $\gamma = 0$ or $S = 1$ (corresponding to a saturated condition), signifying that all fractures are active, while $\gamma = 1$, signifying the smallest active fracture portion for a given saturation. Reducing γ increases the fraction of active fractures and allows more fracture–matrix interaction. Sensitivity of flow and transport to the active fracture parameter γ was studied by calculating flow fields and breakthrough curves for three cases: "base case" using the calibrated γ for each unit, "TSw" with γ reduced by half in the TSw units above and below the repository, including the repository layer, and "UnderRepo" with γ reduced by half in the TSw units below the repository, including the repository layer, and in all units below the TSw (DTN: LB0304RDTRNSNS.001 [DIRS 165992]; BSC 2004 [DIRS 169861], Table 6.8-1). The flow field was not sensitive to these changes in γ. Fracture fluxes at the repository layer and at the water table varied less than 2.5% from the base case (BSC 2004 [DIRS 169861], Table 6.8-2).

In the study of transport sensitivity to γ, the breakthrough curve for case "TSw" showed delayed tracer breakthrough at the water table compared to the base case. When a tracer is released as a pulse from the repository gridblocks, it travels faster in the fractures than in the matrix, causing a temporary concentration gradient between the fracture and matrix. Decreasing γ allows more tracer to diffuse into the matrix, where its transport is delayed (no sorption was modeled). In the base case, 20% of the total input mass arrives at the water table at (approximately) 150 years, and 50% of the total mass arrives at the water table at (approximately) 3,400 years. For case "TSw," there is 20% mass arrival at 1,900 years and 50% at (approximately) 7,100 years (BSC 2004 [DIRS 169861], Figure 6.8-3). The breakthrough curve for case "UnderRepo" was indistinguishable from that for case "TSw" (BSC 2004 [DIRS 169861], Figure 6.8-3). This indicates that increasing the fracture–matrix interaction in the Calico Hills unit does not further

delay tracer breakthrough; that is, fracture–matrix interaction in the TSw unit is more important in delaying transport than fracture-matrix interaction in the Calico Hills unit.

Additional sensitivity studies concerning the effects of the active-fracture parameter γ on radionuclide transport were conducted in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Figures 6-33 to 6-36). Five sensitivity cases were investigated for aqueous ^{99}Tc, ^{237}Np, and ^{242}Pu. The active fracture parameter γ in the TSw unit was set to values of 0.6, 0.5, 0.4, 0.3, and 0.2, with the base-case values for hydrogeologic units in and below the repository for the TSw unit (tsw33 through tsw38) ranging from 0.569 to 0.6 (SNL 2008 [DIRS 184748], Section 6.6.4 and Table 6-11). This uncertainty range for γ is discussed in *Conceptual Model and Numerical Approaches for Unsaturated Zone Flow and Transport* (BSC 2004 [DIRS 170035], Sections 7.4.1 and 7.4.2). The results show that transport is sensitive to γ only for the TSw unit; changes in γ for hydrogeologic units below the TSw unit had almost no effect on transport behavior (SNL 2008 [DIRS 184748], Figure 6-36).

Sensitivity of transport to K_d values was studied in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Section 6.9.1.5; DTN: LB0310MR0060R1.010 [DIRS 174489]), which simulated transport of ^{237}Np for a base case and three alternative cases. For the base case, nonzero K_d values (SNL 2007 [DIRS 177396], Table 6-3) were used for TSw, CHv, and CHz units. In the alternative cases, K_d values for TSw, CHv, or CHz units were set to zero, leaving the others unchanged. Breakthrough curves for a mean present-day infiltration scenario (4.43 mm/yr; SNL 2007 [DIRS 177396], Table 6-5) are shown in *Radionuclide Transport Models Under Ambient Conditions* (SNL 2007 [DIRS 177396], Figure 6-37). Eliminating sorption in the TSw unit caused a portion of ^{237}Np to arrive at the water table significantly earlier, but eliminating sorption in the CHz or CHv units had little effect on the breakthrough curve.

These sensitivity studies show that alteration of fracture pathways in the Calico Hills unit would not significantly change the rate of radionuclide transport.

Based on the previous discussion, omission of FEP 2.2.10.07.0A (Thermo-Chemical Alteration of the Calico Hills Unit) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.08.0A

FEP NAME:

Thermo-Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)

FEP DESCRIPTION:

Thermal effects may affect radionuclide transport directly by causing changes in radionuclide speciation and solubility in the SZ, or, indirectly, by causing changes to host rock mineralogy that affect the flow path. Relevant processes include volume effects associated with silica phase changes, precipitation and dissolution of fracture filling minerals (including silica and calcite), and alteration of zeolites and other minerals to clays.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Waste emplacement and subsequent heating of the rocks around the repository may increase the temperature of the groundwater at the water table and in the saturated zone below the repository footprint. An estimate of the potential temperature increase is predicted with the three-dimensional multiscale thermohydrologic model (SNL 2008 [DIRS 184433]). Average of the maximum water table temperatures at each of the 560 locations modeled is approximately 63°C at around 6,000 years after waste emplacement (as extracted from the 560 **.wt* files in DTN: LL0702PA013MST.068 [DIRS 180553], subfolder: /SDT/SDT-01/SDT55). This represents an approximate 33°C increase in comparison with the ambient temperature of 30°C to 34°C specified at the water table beneath the repository (Fridrich et al. 1994 [DIRS 100575], Figure 8). Available data show little statistical variation in the sorption coefficient values up to 80°C (DTN: LA0407AM831341.002 [DIRS 170621], file*: LA0407AM831341_002_S04296_001.TXT*, and DTN: LA0407AM831341.003 [DIRS 170626], file: *LA0407AM831341_003_S04297_001.TXT*). As long as temperatures at the water table do not consistently exceed the upper-bounding estimate of about 80°C, the thermal impact on host-rock mineralogy and water chemistry will not affect the saturated zone because these temperatures ranges were used when collecting sorption data.

Furthermore, CO_2 becomes less soluble at elevated temperatures. Small changes in CO_2 concentration may notably affect pH. These correlated constituents are the primary components that affect mineral/water interactions (SNL 2007 [DIRS 177404], Section 6.2.1.2). Therefore, as temperatures increase, CO_2 would exsolve from solution, and cause pH to rise with concomitant calcite precipitate in pores and fractures. Calcite precipitation in pores and along fractures would decrease permeability. Once temperatures start to drop, CO_2 dissolution will increase, and pH will decrease. This is because the temperature drop causes calcite that had precipitated in pores and fractures at elevated temperatures to dissolve. As a result, concomitant permeabilities would return to those in effect under ambient conditions. Thus, the net result of an increase in saturated

zone groundwater temperatures, induced by the expected heating from emplaced wastes, and a subsequent decrease in groundwater temperatures during repository cooling would be neutral with respect to saturated zone barrier capability. Regardless of the timing of the calcite precipitation, it serves to decrease permeability. This, in turn, decreases flux. As upstream gradients increase, flow will be forced through the units with decreased permeability or it will find alternate pathways. In any case, flow through the affected (heated) area is decreased, and with respect to precipitation/dissolution effects, thermo-chemical alteration in the saturated zone can beconsidered negligible.

At Yucca Mountain, the most sorptive zeolites (the mineral clinoptilolite) formed only from alteration of volcanic glass. However, there is almost no volcanic glass remaining below the water table that could alter to zeolites. If temperatures below the water table increase, the most likely mineralogic reaction would be recrystallization of clinoptilolite to the less sorptive zeolite analcime. Regardless, Bish and Aronson (1993 [DIRS 100006]) conclude that repository heating will be insufficient to cause clinoptilolite below the water table to recrystallize to less sorptive minerals.

Groundwater flow enters the saturated zone site-scale flow system primarily as underflow at the lateral boundaries of the model domain (lateral flows account for 90% of the flow through the system), with distributed recharge (infiltration or percolation) primarily in the northern part of the model domain and focused recharge along the Fortymile Wash channel (SNL 2007 [DIRS 177391], Section 6.4.3.9). Recharge through the footprint of the unsaturated zone model domain to the SZ flow model constitutes a small fraction of the entire groundwater budget of the site-scale flow system (10%); relative to the total water budget in the saturated zone flow domain, the distributed recharge from the UZ flow model to the saturated zone is only about 13% of total recharge (SNL 2007 [DIRS 177391], Section 6.4.3.9). Therefore, thermally induced changes in water chemistry would be diluted given the relatively small volume of unsaturated zone water that contributes to the total volume of water that passes through the saturated zone flow system (13% of 10%, which is about 1% of the total water budget flowing through the 30×45-km^2 saturated zone model domain).

In the case of no mixing, the analysis presented in excluded FEP 2.2.10.06.0A (Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)) is relevant. This analysis considers the effects of THC processes on radionuclide transport in terms of radionuclide solubility, colloid stability, water composition, mineral precipitation and dissolution, and temperature. The results of this analysis indicate that the effects of THC processes on radionuclide transport between the repository and the water table are negligible. Therefore, the effects of THC processes on water composition entering the saturated zone from the unsaturated zone will also have a negligible effect on radionuclide transport in the saturated zone.

Radionuclides introduced in the unsaturated zone from the EBS are unconstrained; that is, the solubility is not reduced as radionuclides go from the higher temperature repository conditions to the unsaturated zone. Furthermore, neither does *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750]) implement a solubility limit for each transported radionuclide, so radionuclide concentration introduced into the saturated zone from the

unsaturated zone is also unconstrained. Therefore, saturated zone temperature variability will not alter the influx of radionuclides from the unsaturated zone to the saturated zone.

Excluded FEP 2.2.10.07.0A (Thermo-chemical Alteration of the Calico Hills Unit) evaluates the thermal-chemical effects on alteration in the Calico Hills unit (CHn) in the unsaturated zone below the repository. That analysis indicates that thermal-chemical effects are limited to the near-field environment and are of such short duration that they will not have a significant effect on unsaturated zone radionuclide transport or radionuclide release to the accessible environment. Because thermal-chemical effects can be excluded in the near-field, by deduction, thermal-chemical alteration will have less of an impact further away in the saturated zone. Therefore, thermal-chemical effects can also be excluded in the saturated zone.

Based on the previous discussion, omission of FEP 2.2.10.08.0A (Thermo-Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.09.0A

FEP NAME:

Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre

FEP DESCRIPTION:

Heating the Topopah Spring basal vitrophyre with available water may cause alteration of the glasses to clays and zeolites. Possible effects include volume increases that plug fractures, changes in flow paths, creation of perched water zones, and an increase in the sorptive properties of the unit.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The Topopah Spring Tuff basal vitrophyre is densely welded glassy tuff extending downward from the base of the lower nonlithophysal zone of the Topopah Spring Tuff into the crystal-poor vitric zone. The total thickness varies from about 3 to 30 m. Due to heat generated by radioactive decay, the rate of volcanic glass alteration to clays and zeolites will increase, potentially resulting in local changes to the hydrologic or sorptive properties of the unit. However, this effect is expected to be small, because the current degree of alteration represents exposure to elevated temperatures for extended periods of time—millions of years—since deposition. The thermal history of the Topopah Spring Tuff exposed in the Exploratory Studies Facility has been well characterized by fluid inclusion and isotopic (oxygen isotope and uranium-thorium series) studies of fracture minerals within the unit (BSC 2004 [DIRS 170004], Section 6.14.2.3.1). The highest temperatures (>80°C) occurred at times greater than or equal to 10 Ma, and temperatures cooled gradually to near-modern ambient temperatures over the next six or more million years where they have remained for the past 2 to 4 million years (BSC 2004 [DIRS 170004], Figure 6-199).

While no data are available prior to 10 Ma, Whelan et al. (2006 [DIRS 179305], Figure 8) present a thermal model that is consistent with the available data and suggest that the tuff cooled rapidly after eruption (12.8 Ma), but was reheated to temperatures of approximately 95°C by magmatic heat related to Timber Mountain group volcanism at 11.6 Ma. The thermal model predicts that temperatures above 80°C persisted until about 10 Ma, and then dropped gradually over the next several million years, consistent with the thermal history of the unit based on the measured data.

The overall thermal history of the tuff is corroborated by Evans et al. (2005 [DIRS 178836], p. 1,103), who performed (uranium-thorium)/helium dating of fluorite in the Topopah Spring Tuff. Two-phase fluid inclusions in fluorite were found to have trapping temperatures of 65°C to 80°C (Evans et al. 2005 [DIRS 178836], p. 1,100), which lies below the He closure temperature of 90°C. This implies that the fluorite was closed to He diffusion since deposition and that the average (uranium-thorium)/helium age of 9.7 Ma found for fluorite is the depositional age.

However, uncertainties regarding partial helium loss below the closure temperature suggest that the (uranium-thorium)/helium age may represent the time since the last period of heating, or the "cooling" age." Wilson et al. (2003 [DIRS 163589], p. 1,171) also provide corroborating information; they determined ages (uranium-lead dating) and temperatures (fluid inclusion homogenization temperatures) of calcite/silica mineral formation in the unsaturated zone at Yucca Mountain. They found that mineral deposition temperatures above 50°C persisted until about 6.3 Ma, and temperatures between 35°C to 45°C until about 5.3 Ma.

Thus, the Topopah Spring Tuff at the level of the Exploratory Studies Facility (where the fracture mineral samples were collected), and by implication, the underlying basal vitrophyre, was exposed to temperatures of approximately 80°C to 95°C for at least a million years, and temperatures above 50°C for several million years.

Much of the observed alteration in the basal vitrophyre occurred at 40°C to 100°C (Levy andO'Neil1989 [DIRS 133364], p. 322), apparently soon after eruption of the tuff (Levy and Valentine 1993 [DIRS 106681], p. 146). However, given the thermal history of the tuff, the relatively rapid rate of alteration associated with the initial cooling and devitrification of the tuff was not maintained in the long term; elevated temperatures later in the tuff history has lesser effect. The degree of alteration of the vitrophyre at the base of the unit reflects the total, extended thermal history of the tuff, with elevated temperatures lasting millions of years. During the period of repository thermal heating, the drift wall boiling duration will be at most 1,500 years (SNL 2008 [DIRS 184433], Figure 6.3-78[a], and drift wall temperatures drop below 50°C in less than 20,000 years (for most waste package locations, much less) (SNL 2008 [DIRS 184433], Figure 6.3-76[a]). These values offer bounds on conditions in the more distal Topopah Spring Tuff basal vitrophyre. Hence, the postclosure thermal pulse will be very brief relative to the extended thermal history of the tuff and will result in only minor changes in the abundance of secondary minerals in the vitrophyre. Therefore, thermally induced alteration of the basal vitrophyre will be limited and is not anticipated to significantly affect the sorptive or hydrologic properties of the unit.

This conclusion differs from that of the mountain-scale THC model presented in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Section 6.4). The mountain-scale THC model concludes that significant glass alteration—up to nearly 20% in the first 7,000 years after closure—will occur in the basal vitrophyre of the Topopah Spring Tuff. However, the mountain-scale model implements an older version of the THC seepage model, which differs from the current model. Specifically, dissolution/precipitation rates for several silicate minerals and for rhyolitic glass are 2 to 4 orders of magnitude lower in the current revision of the THC seepage model (SNL 2007 [DIRS 177404], Appendix H) than in the mountain-scale THC model. The slower rates implemented in the current THC seepage model are more consistent with field-based measurements of mineral dissolution (the older model used laboratory-derived rates) and with the site-specific observations of the degree of alteration at Yucca Mountain (SNL 2007 [DIRS 177404], Appendix H). If the mountain-scale model were implemented with the updated mineral and glass dissolution/precipitation rates, considerably less alteration of the basal vitrophyre would be expected. Because a previous parameter set was used, and because the results with respect to alteration of the basal vitrophyre are inconsistent with the extended thermal history of that unit, the mountain-scale THC model results do not represent the expected degree of alteration within that unit, and are not considered here.

Based on the previous discussion, omission of FEP 2.2.10.09.0A (Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.10.0A

FEP NAME:

Two-Phase Buoyant Flow/Heat Pipes

FEP DESCRIPTION:

Heat from waste can generate two phase buoyant flow. The vapor phase (water vapor) could escape from the mountain. A heat pipe consists of a system for transferring energy between a hot and a cold region (source and sink respectively) using the heat of vaporization and movement of the vapor as the transfer mechanism. Two phase circulation continues until the heat source is too weak to provide the thermal gradients required to drive it. Alteration of the rock adjacent to the drift may include dissolution that maintains the permeability necessary to support the circulation (as inferred for some geothermal systems).

SCREENING DECISION:

Included

TSPA DISPOSITION:

The coupled processes causing heat-pipe behavior are simulated with the TH seepage model described in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]) that provides input to *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244], Section 6.4.3). Using this model, the impact of heat-pipe behavior on seepage is assessed for several simulation cases in which percolation fluxes and rock properties are varied (BSC 2005 [DIRS 172232], Section 6.2.1.6). Thus, the TH seepage-modeling results include the effect of heat pipes and the resulting uncertainties in the conditions under which seepage occurs and in the volume of seepage. The TH seepage model results are used to develop an appropriate thermal-seepage methodology in the seepage abstraction (SNL 2007 [DIRS 181244], Section 6.5.2).

The effect of heat pipes on predicted in-drift thermal-hydrologic conditions is taken into account in the drift-scale submodels of *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433], Section 6.2.1). The MSTHM provides in-drift temperature and relative humidity values, which are used by the TSPA to extract in-drift water chemistry from lookup tables provided by the seepage dilution-evaporation abstraction, described in *Engineered Barrier System: Physical and Chemical Environment* (SNL 2007 [DIRS 177412], Sections 6.9 and 6.15.1).

Drift-Scale THC Seepage Model (SNL 2007 [DIRS 177404]) evaluates the effects of thermal-hydrologic-chemical coupled processes, including heat pipe behavior, on the composition of potential seepage waters. The development of a heat pipe results in evaporation and condensation above the drift, affecting potential seepage water compositions; however, these effects are largely confined to the boiling period, when seepage is not possible. After boiling ceases, heat pipe induced dilution-evaporation of potential seepage water compositions becomes negligible (SNL 2007 [DIRS 177404], Figure 6.5-13). The THC seepage model results provide the technical basis for the methodology used in the near-field chemistry model (SNL 2007

[DIRS 177412], Section 6.3.2) The near-field chemistry model provides initial seepage water compositions to the in-drift seepage dilution-evaporation model, and does not explicitly evaluate the effects of heat pipes.

FEP: 2.2.10.11.0A

FEP NAME:

Natural Air Flow in the UZ

FEP DESCRIPTION:

Natural convective air circulation has been observed at a borehole at the top of the mountain. Repository heat may increase this flow.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Natural air flow in the unsaturated zone may impact thermal hydrological processes in the host rock units and water vapor removal from the unsaturated zone during ambient conditions (not perturbed by repository heating). Gas flow in the host rock units may be radially directed toward or away from the emplacement drifts, or axially within emplacement drifts and connected openings. Radial gas flow in the host rock for thermally perturbed conditions is incorporated in models for thermal-hydrological response of the host rock (SNL 2008 [DIRS 184433], Section 6.1), thermal seepage (BSC 2005 [DIRS 172232], Section 6.2.2.1.1), and thermal-hydrological-chemical processes (SNL 2007 [DIRS 177404], Section 6.4.1). Potential effects from axial gas flow in the emplacement drifts on condensation (SNL 2007 [DIRS 181648], Section 6.3) and CO_2 fugacity (SNL 2007 [DIRS 177412], Section 6.15.1) are included in TSPA, while effects on the evolution of temperature and humidity in the emplacement areas are of limited magnitude and duration and are excluded (SNL 2008 [DIRS 184433], Section 7.8[a]).

Various aspects of gas-phase flow under thermally perturbed conditions are discussed in included FEPs 2.1.08.11.0A (Repository Resaturation due to Waste Cooling), 2.1.11.09.0A (Thermal Effects on Flow in the EBS), 2.2.07.10.0A (Condensation Zone Forms Around Drifts), 2.2.07.11.0A (Resaturation of Geosphere Dry-Out Zone), 2.2.10.10.0A (Two-Phase Buoyant Flow/Heat Pipes), and 2.2.10.12.0A (Geosphere Dry-Out Due to Waste Heat). The effects of natural air flow, or barometric pumping, on both thermal-hydrologic processes and water vapor removal are discussed below.

Barometric pumping is considered in the MSTHM (SNL 2008 [DIRS 184433]) and the in-drift convection and condensation model (SNL 2007 [DIRS 181648]). Although the effect is not explicitly included in either model as implemented in TSPA, both models have investigated ranges of three-dimensional axial transport behavior that cover the potential effects from barometric pumping. The following discusssion starts with the condensation model to develop the conceptual basis for describing the potential effects, followed by a discussion of three-dimensional validation test cases used in the multiscale thermohydrologic model which more clearly show the potential effects on the in-drift environment. The discussion then addresses the potential for moisture removal from the unsaturated zone by natural air flow.

Axial transport of water vapor in the emplacement drifts controls the potential for condensation. The in-drift convection and condensation model (SNL 2007 [DIRS 181648], Section 6.2) uses a three-dimensional thermal convection (dry air) simulation for a drift segment containing 14 waste packages to evaluate gas transport by convective mixing. Axial transport is represented using a one-dimensional dispersion approach, and the three-dimensional convection model produced a range of values for the effective dispersion coefficient for use in the one-dimensional model. The values can be conveniently expressed as multiples of the gaseous binary diffusion coefficient for water in air. A range of the diffusion coefficient multipliers from approximately 200 to 4,700 is developed, normalizing the values in Tables 6.2.7-2 and 6.2.7-3 by 2.13×10^{-5} m^2/s (SNL 2007 [DIRS 181648], Section 6.2.7), representing repository-center and -edge conditions, respectively. Barometric pumping could produce transport equivalent to extending the upper end of this range. However, the in-drift convection and condensation model shows that a value of 4,700 already causes condensation to occur predominantly in the unheated regions at the ends of the drifts, a result that would not change with greater dispersive transport.

A set of three-dimensional thermal-hydrological simulations was performed to further evaluate the effects from axial transport (SNL 2008 [DIRS 184433], Section 6.3.18[a]). This work was performed as a parametric sensitivity study, varying the axial dispersion factor well beyond the previous range (up to 10,000). The results are analyzed in *In-Drift Natural Convection and Condensation* (SNL 2007 ([DIRS 181648], Section 6.2) confirming that condensation within the emplacement area is not predicted for higher values of the dispersion factor. Using an intermediate value of 1,000, the validation test cases for the multiscale model demonstrate that axial transport lowers the relative humidity in the emplacement regions and delays the return of humidity by hundreds of years as the waste packages cool (SNL 2008 [DIRS 184433], Section 7.8[a]). These effects are not significant to the application of the multiscale model, which represents many thousands of years of repository thermal evolution.

Increased axial gas transport, as potentially induced by natural air flow, tends to dry out the near-field host rock in heated regions and deposit the resulting condensate at cooler or unheated regions of the drifts. Over the range of dispersion factor values investigated, the effect is limited in magnitude by other factors, such as the percolation flux (e.g., compare the gas-phase fluxes versus time for PWR waste packages in cases 1 and 4 of DTN: MO0703PAEVSIIC.000 [DIRS 181990], file: *Stage 2 Analysis.xls*). These results show that gas-phase transport of moisture from the rock is weakly related to the dispersion factor (and, therefore, natural air flow) because it is limited by availability of moisture as percolation and by the mass-transfer resistance within the host rock.

The effects of natural air flow due to barometric pumping and the associated removal of water through vapor transport under isothermal conditions have also been investigated. Estimates of the rate of water removal from Yucca Mountain through this mechanism range from 0.001 mm/yr to 0.3 mm/yr (Martinez and Nilson 1994 [DIRS 174095], p. 106; Tsang and Pruess 1990 [DIRS 172018], p. iii). These estimated rates are negligible in comparison with the estimates for average infiltration at Yucca Mountain, which range from 3 to 73 mm/yr (SNL 2007 [DIRS 184614], Table 6.1-2). During repository heating, enhanced flow of heated air will not increase the amount of water vapor removal from the mountain because water would condense upon reaching the cooler units above the repository.

In summary, barometric pumping may increase gas-phase axial transport of moisture in the emplacement drifts during the thermal period, with greater condensation occurring in cooler or unheated regions and lower relative humidity occurring in the heated regions. However, the potential effects are within the range of effects represented in the condensation model based on modeling of other processes, and are minor compared with the thermal-hydrological responses represented by the multiscale model. Also, the effects of natural air flow on moisture movement in the unsaturated zone are found to be small compared with the range of infiltration flux estimated for Yucca Mountain.

Based on the previous discussion, omission of FEP 2.2.10.11.0A (Natural Air Flow in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.12.0A

FEP NAME:

Geosphere Dry-Out Due to Waste Heat

FEP DESCRIPTION:

Repository heat evaporates water from the UZ rocks near the drifts as the temperature exceeds the vaporization temperature. This zone of reduced water content (reduced saturation) migrates outward during the heating phase (about the first 1000 years) and then migrates back to the waste packages as heat diffuses throughout the mountain and the radioactive sources decay. This FEP addresses the effects of dry-out within the rocks.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Multiscale Thermohydrologic Model (SNL 2008 [DIRS 184433], Section 6.3[a]) provides histories for thermal-hydrologic conditions at key locations within the drifts. The multiscale model simulates dryout of the rock around the drift, and therefore includes its effect on in-drift thermal-hydrologic parameters used in performance assessment, such as temperature and relative humidity at the drift wall, drip shield, and waste package surface; the duration of drift wall boiling; and the temperature and liquid saturation in the invert. Following closure, dryout occurs in an expanding region in the rock around each drift where the rock temperatures exceed the boiling point of water; dryout is associated with higher temperatures and lower relative humidities within the emplacement drifts. Rewetting of the host rock occurs as the waste heat output decays and the rock temperature cools back toward the boiling point. The rate of rewetting at a particular location depends on the local temperature and percolation flux. Uncertainty associated with the timing and extent of dryout is propagated to TSPA calculations through the use of different rock thermal conductivities and a suite of percolation flux values (SNL 2008 [DIRS 184433], Sections 6.3.15[a] and 6.3.16[a]). Other sources of uncertainty that could affect the development and extent of the dryout zone, including rock hydrologic properties, ventilation heat removal efficiency, and the effects of axial vapor transport, were evaluated using sensitivity analyses and found to have an insignificant effect on multiscale model outputs (SNL 2008 [DIRS 184433], Sections 6.3.11[a], 6.3.12, and 6.3.18[a]).

The coupled processes of vaporization, dryout, and resaturation are simulated with the TH seepage model in *Drift-Scale Coupled Processes (DST and TH Seepage) Models* (BSC 2005 [DIRS 172232]). The TH seepage model assesses the impact of such coupled processes on seepage into the drift using several simulation cases (BSC 2005 [DIRS 172232], Section 6.2.4.2). Thus, the TH seepage model results (DTN: LB0301DSCPTHSM.002 [DIRS 163689]) include these effects. *Abstraction of Drift Seepage* (SNL 2007 [DIRS 181244]) utilizes these modeling results to develop an appropriate seepage abstraction methodology for use in the TSPA. An important feature of the seepage abstraction is that seepage does not occur when the drift wall

temperature exceeds 100°C, a bounding approximation that is consistent with the TH seepage conceptual model results (SNL 2007 [DIRS 181244], Section 6.5.2).

Uncertainty associated with the effect of the dryout zone on seepage was evaluated using sensitivity analyses varying the percolation flux, different fracture flow conceptual models, alternative thermal loads, and transient versus steady state flow conditions (BSC 2005 [DIRS 172232], Section 6.2.4.2). The results of these calculations support the conclusion that seepage will not occur until the drift wall cools below 100°C and the dryout zone no longer exists.

The coupled processes of vaporization, dryout, and resaturation are also simulated with the THC seepage model (SNL 2007 [DIRS 177404], Sections 6.2.1 and 6.5.5.1). These simulations are used to corroborate the near-field chemistry model (SNL 2007 [DIRS 177412], Section 7.1.3), which provides the composition of potential seepage waters. In the near-field chemistry model, the effect of dryout is implemented by adjusting the length of the flow pathway considered for water–rock interactions; however, the seepage compositions that are predicted during the boiling period are not used, because the abstraction of drift seepage does not predict seepage when the drift-wall temperature exceeds the boiling point.

Finally, the effects of dryout on larger-scale flow processes in the unsaturated zone are discussed in FEP 2.2.10.01.0A (Repository-Induced Thermal Effects on Flow in the UZ), which is excluded on the basis of low consequence.

Repository-Induced Thermal Effects on Flow in the SZ

FEP DESCRIPTION:

Thermal effects in the geosphere could affect the long-term performance of the disposal system, including effects on groundwater flow (e.g., density-driven flow), mechanical properties, and chemical effects in the SZ.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Numerical modeling of the mountain-scale effects of thermal loading on the host rock due to waste emplacement is evaluated in *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101], Section 6.5), and results indicate that the host rock temperatures at the drift wall are about 100°C approximately 1,000 years after waste emplacement (BSC 2005 [DIRS 174101], Figure 6.5.10-2). These elevated temperatures produce a long-term heat pulse that originates at the repository and propagates outwards. A review of *Multiscale Thermohydrologic Model* (SNL 2008 [DIRS 184433]) indicates that temperature at the water table will peak at approximately 6,000 years after repository closure, with the maximum temperature equal to 73°C and an average of the maximum at each of the 560 locations modeled of 63°C (as extracted from the 560 *.*wt* files in DTN: LL0702PA013MST.068 [DIRS 180553], subfolder /SDT/SDT-01/SDT55). This represents an approximate 33°C increase in comparison with the ambient temperature of 30°C to 34°C specified at the water table beneath the repository (Fridrich et al. 1994 [DIRS 100575], Figure 8). Furthermore, saturated zone ambient temperatures increase with depth, with some temperatures as high as 45°C (depths of up to 1,000 m measured in well UE 25p#1; DTN: MO0102DQRBTEMP.001 [DIRS 154733]). Any changes in mechanical or chemical properties of the saturated zone due to repository heating are comparable to those due to ambient variability in temperature.

Heating of the water table from above will have the effect of decreasing fluid viscosity and density. For a given formation permeability, a decrease in kinematic viscosity (dynamic viscosity divided by density) will result in a corresponding increase in specific discharge. For example, if the specific discharge is 0.30 m/yr at 30°C, it will be 0.51 m/yr at 60°C due to the decrease in kinematic viscosity with temperature (Lide 2006 [DIRS 178081], p. 6-2). The peak temperature at the water table is uncertain and will depend, in part, on water-table elevation. However, even if the saturated zone temperature was to reach the theoretical upper bound of 96°C (vaporization point), the specific discharge would be 0.78 m/yr, a factor of 2.6 increase. This is still well within the factor of 8.93 (log-10-transformed value of 0.951) that is the upper limit of the uncertainty distribution for the specific discharge multiplier in the flow and transport model abstraction (SNL 2008 [DIRS 183750], Table 6-7[a]). Hence, repository-induced thermal effects on flow in the saturated zone are excluded due to low consequence because any such

effects are well within the uncertainty bounds provided by the flow and transport abstraction modeling.

Increased temperatures in the unsaturated zone can cause some changes in groundwater chemistry; however, recharge from the unsaturated zone to the SZ flow model domain constitutes a small fraction of the entire groundwater budget of the site-scale flow system (SNL 2007 [DIRS 177391], Section 6.4.3.9). Relative to the total water budget in the saturated zone flow domain, the distributed recharge (infiltration) to the saturated zone is approximately 10% of total flow through the model (SNL 2007 [DIRS 177391], Section 6.4.3.9), most of which is through the lateral boundaries. Therefore, thermally induced changes in saturated zone water chemistry would be diluted, given the relatively small volume of unsaturated zone water that is contributing to total volume of water that passes through the saturated zone flow system. Sorption is a temperature-dependent process, and an increase in groundwater temperatures could increase the sorption coefficient of cations and decrease the sorption of anions, but overall for temperatures below 80°C, corrections would be small (SNL 2007 [DIRS 177396], Appendix I). In the saturated zone models, radionuclide partitioning coefficients are based on ambient saturated zone temperatures and are not temperature dependent. Overall, including the effects of elevated saturated zone groundwater temperatures would introduce much less variability than is already included in the range of distribution coefficients used to model sorption.

This FEP is linked to excluded FEP 2.2.10.02.0A (Thermal Convection Cell Develops in SZ), which describes the low-consequence effects of temperature-induced density changes in the saturated zone groundwater and the resultant low-consequence effects of density-driven convection in the saturated zone.

The low-consequence effects of repository-induced thermal-mechanical stresses on the saturated zone rock characteristics are discussed in excluded FEPs 2.2.10.05.0A (Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below the Repository), 2.2.10.04.0B (Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository), and 2.2.10.04.0A (Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository).

Based on the previous discussion, omission of FEP 2.2.10.13.0A (Repository-Induced Thermal Effects on Flow in the SZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.10.14.0A

FEP NAME:

Mineralogic Dehydration Reactions

FEP DESCRIPTION:

Mineralogic dehydration reactions release water affecting hydrologic conditions. Dehydration of zeolites below the repository may lead to large-scale volume changes affecting flow and/or drift stability.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The most common hydrous minerals and noncrystalline phases at Yucca Mountain are zeolites (predominantly clinoptilolite and mordenite), clays (predominantly smectite and illite), and volcanic glass (CRWMS M&O 2000 [DIRS 138960], Sections 1.4, 6.3.2, and 6.3.3). These phases are present both above and below the planned repository horizon (CRWMS M&O 2000 [DIRS 138960], Figures 12, 13, 20, 21, 22, and 23). The units of the repository horizon contain small quantities of zeolites (less than 0.10 wt %) and clay (less than 2.8 wt %) (DTN: LB0101DSTTHCR1.002 [DIRS 161277], file: *ecrb_cdtt_mindata.xls*, entries for Tsw 33 through Tsw 36). Dehydration of these small quantities is not expected to affect repository performance. Clays generally are of low abundance (CRWMS M&O 2000 [DIRS 138960], Section 6.3.3), and therefore are of little concern for dehydration reactions. Zeolites, principally clinoptilolite, are the minerals of greatest concern for dehydration reactions because they are widespread and abundant, especially below the planned repository. Volcanic glass is not a concern because it contains much less water compared to clinoptilolite and releases most of its water at much higher temperatures (Carey and Bish 1996 [DIRS 105200], p. 954; Vaniman et al. 1993 [DIRS 184332], p. 22,316, Table 3).

There is a prominent zone of zeolite-bearing tuffs in the lowermost Topopah Spring welded unit (tsw39) and in the underlying Calico Hills nonwelded unit (ch1, ch2, ch3, ch4, ch5, and ch6) (BSC 2004 [DIRS 169855], Section 5.2). The locations of these units below the planned repository are shown in Figure 6.1-2 of *Mountain-Scale Coupled Processes (TH/THC/THM) Models* (BSC 2005 [DIRS 174101]). Dehydration of zeolites below the repository would occur as zeolite water content decreases in response to any increase in temperature (Carey and Bish 1996 [DIRS 105200], p. 961). Such dehydration reactions could affect geohydrologic conditions in two ways: by release of water of hydration and by the resulting shrinkage of the zeolites. A mineralogic phase change from clinoptilolite, the most abundant zeolite, to analcime at temperatures above 85°C, could also occur, with greater shrinkage (Smyth and Caporuscio 1981 [DIRS 174060], pp. 11 and 12). Shrinkage could lead to formation of new rock fractures or expansion of existing fractures. Heating experiments (Bish 1984 [DIRS 104941], pp. 444, 449, and 451; 1990 [DIRS 183078], p. 773) suggest that long-term heating up to 100°C should not cause irreversible shrinkage of the clinoptilolite crystal lattice. However, the volumetric changes

in zeolitic rock due to dehydration and rehydration may not be fully reversible (Smyth and Caporuscio 1981 [DIRS 174060], pp. 25 and 26; Kranz et al. 1989 [DIRS 183167], p. 1,114).

Heating of the zeolitic tuffs below the repository could cause the zeolites to release water to the rock pores, especially if substantial rock dryout were to occur. Shrinkage of the zeolite crystal lattices due to heating and dehydration could change the rock porosity and permeability. Bulk shrinkage of the zeolitic tuff also could affect thermo-mechanical stresses in the zeolite-bearing tuffs and in the overlying repository host rock.

The amount of water held within zeolites in altered tuffs below the repository was estimated for a zeolitic tuff with bulk density of 1.57×10^3 kg/m^3 (DTN: GS960908312231.004 [DIRS 107065], Table S98219_002, Hydrologic Model Layer CHZ), mean porosity of 0.322, and 0.96 saturation (DTN: LB0207REVUZPRP.002 [DIRS 159672], file: *hydroprops_fin.xls*, worksheet: "summary," UZ model layer "ch[2-5]z"). One cubic meter of tuff contains 0.322 m^3 × 0.96 = 0.309 m^3 of pore water. If this tuff contains 60 wt % clinoptilolite with about 15 wt % intracrystalline water (Carey and Bish 1996 [DIRS 105200], p. 954), then the amount of water within the zeolite is about $1.57 \times 10^3 \times 0.60 \times 0.15 = 141$ kg or 0.141 m^3 of water per cubic meter of rock (assuming unit density of water). The water contained in zeolite is, thus, slightly less than one-half the amount of water in rock pores.

Dehydration of zeolitic tuff in response to predicted repository thermal-loading conditions has not been investigated, and the amount of zeolite dehydration as a function of temperature and pore-water saturation is not known. However, experimental data exist that allow bounds to be placed on the effects of dehydration. Experimental results suggest that loss of adsorbed zeolitic water increases in a linear manner with rising temperature up to the boiling point for clinoptilolite separates (Carey and Bish 1996 [DIRS 105200], Figure 10). Exploratory dehydration of saturated and unsaturated zeolitic tuffs with isothermal and step-wise heating was conducted without control or measurement of water-vapor pressure or initial water content (Smyth and Caporuscio 1981 [DIRS 174060], Appendices A and B). An approximate interpretation of the results is that rock weight loss upon heating reflects the progressive loss of a combination of rock-pore and zeolitic water. Pore water is more readily lost than zeolitic water. The composite rates of water loss from these two reservoirs show no large discontinuities with time for isothermal heating or with temperature for heating to 200°C (Smyth and Caporuscio [DIRS 174060], Figures A-1 and B-1). The zeolitic water behaves sufficiently like pore water that it would not need to be considered separately unless the rock were heated enough to cause a major decrease in pore-water saturation.

Results of the mountain-scale thermal-hydrologic model (BSC 2005 [DIRS 174101], Section 6.2.1.3, Figure 6.2-7c) indicate that matrix liquid saturation in zeolitic tuff at the base of the Topopah Spring welded unit (TSw) will remain between about 0.94 and 1.00 (full saturation) throughout the period of thermal perturbation. Peak temperatures at the base of TSw where the tuffs are zeolitized (northern part of Yucca Mountain) will remain below 75°C (BSC 2005 [DIRS 174101], Section 6.2.1.3, Figure 6.2-6c). The mountain-scale thermal-hydrologic model does not incorporate zeolite dehydration as a distinct process, but the potential effects are approximated by the incorporation of thermal and hydrologic property values (thermal conductivity, particle density, specific heat capacity, residual saturation) specific to zeolitic tuffs (BSC 2005 [DIRS 174101], Table 4.1-1; DTNs: LB0208UZDSCPMI.002 [DIRS 161243] and

LB0210THRMLPRP.001 [DIRS 160799]). Given that the matrix pores are near or at full saturation, and that pore water represents more than half the water in the tuff, the prediction of the mountain-scale thermal-hydrologic model still should be reasonably accurate. Zeolite dehydration is not expected to contribute significant additional water to the unsaturated-zone flow system.

Shrinkage of zeolitic tuffs from the combined effects of dehydration and heating has been investigated by laboratory experiments (Smyth and Caporuscio 1981 [DIRS 174060]; Kranz et al. 1989 [DIRS 183167]; and Bish et al. 2003 [DIRS 169638]). One study (Bish et al. 2003 [DIRS 169638]) provides shrinkage data for powdered clinoptilolite separates, and two studies (Smyth and Caporuscio 1981 [DIRS 174060], Appendices A and B; Kranz et al. 1989 [DIRS 183167]) provide data for intact zeolitic-tuff core. In all cases, the experimental conditions exceed the degree of dehydration or maximum temperatures predicted by the mountain-scale thermal-hydrologic model for zeolitic tuff below the repository. Therefore, tuff-shrinkage calculations based on the experimental results, presented below, place bounds on the effects of zeolite shrinkage if greater dehydration or higher temperatures than expected were to occur.

The powdered separate of a natural mixed-cation clinoptilolite from Yucca Mountain was equilibrated at 100% relative humidity and 23°C, then heated in the humid atmosphere (Bish et al. 2003 [DIRS 169638], p. 1,899). Volumetric shrinkage of the crystal lattice was measured in cubic angstroms ($Å^3$) at fifty-degree temperature increments, beginning at 50°C (Bish et al. 2003 [DIRS 169638], Figure 12, sample USW G-4 450.5). Approximate cumulative shrinkage values of $100(2{,}098Å^3 - 20{,}68Å^3)/2{,}098Å^3 = 1.43$ vol % at 50°C and $100(2{,}098Å^3 - 2{,}063Å^3)/2{,}098Å^3 = 1.67$ vol % at 100°C bound the zeolite crystal lattice shrinkage expected under conditions predicted by the mountain-scale thermal-hydrologic model.

The amount of rock shrinkage due to zeolite dehydration was estimated by considering the data from two experiments presented by Smyth and Caporuscio (1981 [DIRS 174060], Tables A-1 and B-1, sample YM-40), which record the volume and weight changes observed upon heating for two cylindrical rock samples from the zeolitized Calico Hills Formation. For the first experiment, the tuff was soaked in water at 91°C for 48 hours and then kept at approximately 95°C in a drying oven. The core was weighed and measured at the beginning of the experiment and periodically throughout the 32-hour dry-heating period. During the first hour of the heating period, the core expanded from its initial volume, possibly due to additional movement of water into the zeolite crystal lattice. Total volumetric shrinkage of the drying core, relative to the largest measured volume, amounted to $100(10.2814\ cm^3 - 10.1526\ cm^3)/10.2814\ cm^3 = 1.25$ vol %. However, the amount of water lost during the one-hour step between the highest measured volume (hour 1) and the next measurement (hour 2), relative to the total water lost during heating, was $100(19.7703\ g - 18.5134\ g)/(19.7703\ g - 17.9906\ g) = 70.6$ wt %. This step alone represents a greater drop in liquid saturation than that predicted by the mountain-scale thermal-hydrologic model (BSC 2005 [DIRS 174101], Section 6.2.1.3, Figure 6.2-7c). Therefore, the portion of core shrinkage associated with this step, $(10.2814\ cm^3 - 10.2028\ cm^3)/10.2814\ cm^3 = 0.76$ vol %, is a better bound on the amount of shrinkage that would occur under predicted repository conditions.

For the second experiment, air-dried zeolitic tuff was heated from 25°C to 500°C stepwise in increments of 75°C (first step) and 100°C (subsequent steps) (Smyth and Caporuscio 1981 [DIRS 174060], Table B-I, sample YM-40). The rock cylinder was initially equilibrated to room temperature and humidity, an indication that both the zeolites and the rock pores were under-saturated in water. This experiment thus under-represents the amount of water loss and shrinkage that could occur in nearly saturated zeolitic rocks below the repository. Therefore, the results of this experiment were not considered in evaluating the potential effects of zeolite dehydration.

In another experiment, a core of zeolitic tuff from the Calico Hills nonwelded unit was vacuum dehydrated and allowed to rehydrate at room temperature for 160 hours (Kranz et al. 1989 [DIRS 183167], p. 1,114). The cited reference does not provide data to calculate the volume change upon dehydration, but an approximate volume change during rehydration was estimated from the experimental procedure (Kranz et al. 1989 [DIRS 183167], p. 1,113) and Figure 2 of the cited paper (Kranz et al. 1989 [DIRS 183167]; note that Figures 1 and 2 are reversed with respect to their captions). Initial cylindrical core dimensions of 6.0 cm length and 2.54 cm diameter give a core volume of $\pi(2.54\ \text{cm}/2)^2 \times 6.0\ \text{cm} = 30.402\ \text{cm}^3$. From the final axial and radial expansive strains shown in Figure 2 of the cited paper, the calculated volume of the hydrated core would be $\pi[(2.54\ \text{cm}/2) + (2.54\ \text{cm}/2)(0.00196\ \text{cm})]^2 \times [6.0\ \text{cm} + (6.0\ \text{cm} \times 0.00226\ \text{cm})] = 30.591\ \text{cm}^3$. The volume increase upon hydration is $100(30.591\ \text{cm}^3 - 30.402\ \text{cm}^3)/(30.402\ \text{cm}^3) = 0.6$ vol %.

The 1.67 vol % shrinkage experienced by powdered clinoptilolite upon heating to 100°C under 100% relative humidity is a reasonable value for the maximum zeolite shrinkage that could occur under predicted repository heating conditions. However, the experimental data for cores of clinoptilolite-bearing tuff indicate that less shrinkage would occur in intact rock. The core shrinkage of 0.76 vol % upon heating is taken as a maximum value for rock shrinkage because it was observed under conditions of dehydration greater than predicted for the Calico Hills nonwelded unit. The core expansion of 0.6 vol % upon rehydration in another experiment is confirmatory and may be lower due to an irreversible component of shrinkage.

The potential effects of zeolite shrinkage on flow depend on how the shrinkage is accommodated by the zeolitic tuff. Physical changes in zeolitic tuff due to alternate wetting/drying cycles have been investigated for building stone (Colella et al. 2001 [DIRS 184454], p. 573, Figure 24). The weathering environment to which zeolitic building stone is subjected is much harsher than the expected conditions below the repository because the building blocks experience repeated wetting and drying that not only cause swelling and shrinkage but also result in salt deposition due to water evaporation. These processes lead to the possible formation of microcracks. A scanning-electron image of such a weathered zeolitic tuff shows microcracks with apertures of about one to two micrometers (Colella et al. 2001 [DIRS 184454], Figure 24). The microcracks formed largely along pre-existing intercrystalline pore spaces, without grain breakage.

Accommodation of zeolite shrinkage by aperture changes in scattered microcracks that largely correspond to preexisting porosity would be equivalent to a less than one percent change in matrix porosity. In the absence of strong preferred orientation of rock pores or microcracks, this process should not result in the formation of new throughgoing fractures. The apertures of preexisting fractures would be affected only by a subset of immediately adjacent microcracks. The overall effect of a less-than-one-percent change in matrix porosity is well within the range of

variability for matrix porosity in the affected units (DTN: LB0207REVUZPRP.002 [DIRS 159672], file: *hydroprops_fin.xls*, worksheet: "summary," UZ model layer "ch[2-5]z"). The permeability change associated with this small change in porosity also should be within the range of variability.

The potential effects of zeolite dehydration in rock below the repository on drift stability have not been explicitly investigated. However, this effect is implicitly addressed in excluded FEP 2.1.07.02.0A (Drift Collapse), which provides a summary of nonseismic processes affecting drift stability. *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 5.1.3) states an assumption that thermal expansion values used in the CHn1 and CHn2 (Calico Hills nonwelded unit) layers under the repository units (TSw2) are equal to those for the repository layers, which are densely welded and devitrified rather than nonwelded and zeolitic. The report states that temperature increase in the underlying layers is insignificant and thermally induced stresses are negligible. The cited discussion pertains to thermal expansion rather than contraction, but it verifies that other processes of volumetric change in the Calico Hills nonwelded unit are not part of the analysis.

As described above, the selected upper bounding value for volume reduction of initially saturated zeolitic tuff heated in air at 95°C was 0.76 vol % (Smyth and Caporuscio 1981 [DIRS 174060], Table A-1, sample YM-38). Actual rock shrinkage at Yucca Mountain should be less than that because predicted saturation will remain higher and temperatures will be lower than the experimental conditions. In addition, not all shrinkage will occur in a vertical direction, and this will reduce the potential effect on overlying rock. The combination of these factors should lead to insignificant or no subsidence of the rock containing the repository emplacement drifts.

Based on the previous discussion, omission of FEP 2.2.10.14.0A (Mineralogic Dehydration Reactions) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.11.01.0A

FEP NAME:

Gas Effects in the SZ

FEP DESCRIPTION:

Pressure variations due to gas generation may affect flow patterns and contaminant transport in the SZ. Degassing could affect flow and transport of gaseous contaminants. Potential gas sources include degradation of repository components and naturally occurring gases from clathrates, microbial degradation of organic material, or deep gases in general.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The justification for exclusion is developed with respect to the low consequence effects of naturally occurring gases.

There is no evidence of large-scale gas build-up in or flow through the saturated zone. Additionally, no significant volumes of oil or gas have been found in the Yucca Mountain vicinity, and there are no proven source rocks in the region (French 2000 [DIRS 107425], p. 5). While the geologic elements required for a petroleum system are present in the Yucca Mountain region, stratigraphic seals (important in a viable hydrocarbon producing region) are not well developed in the Yucca Mountain area, causing the hydrocarbon potential to be classified as low (French 2000 [DIRS 107425], p. 39).

The presence of clathrates and microbial degradation of organic components are two potential sources of gas that could affect flow and transport in the saturated zone. Clathrates, methane gas molecules bound in a cage-like structure made up of water molecules, form under high pressures and low temperatures. Clathrates are found in polar and deep oceanic regions (Kvenvolden 1998 [DIRS 166162], pp. 9 to 11) and are, therefore, not a potential hydrocarbon source in the Yucca Mountain vicinity.

Microbial degradation of organic components is not considered a potential gas source in the saturated zone. Analysis of groundwater samples taken from saturated zone wells near Yucca Mountain have found little to no organic carbon (DTN: GS010308312322.003 [DIRS 154734], Table S01053_003; DTN: GS011108312322.006 [DIRS 162911]). Organic carbon is a byproduct of microbial activity. Because there is little organic carbon found in saturated zone waters, there is little microbial activity and, thus, it is not expected that sufficient CO_2 could be produced to affect saturated zone flow and transport.

In the unexpected event that natural gas-generating processes occur in the sedimentary rocks below the tuffs, the influence on the flow and transport pathways would tend to be highly localized. Moreover, such influences are too small to make a significant impact on flow fields

and such perturbations are accounted for in the heterogeneity and parameter uncertainties in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Table 6-7[a]). Because gas-generating processes in the saturated zone do not have a significant effect on system parameters, there is negligible impact on radionuclide release to the accessible environment. In summary, the potential effects of naturally occurring gases in the geosphere can be excluded from the SZ flow and transport model on the basis of low consequence.

Degradation of repository components is a potential gas source for the saturated zone. Corrosion of EBS metal materials would mainly occur well beyond 10,000 years after repository closure and this would produce gas that might escape into the unsaturated zone. This process is considered by FEP 2.2.11.02.0A (Gas Effects in the UZ). However, gas pressurization in the unsaturated zone is not expected due to the presence of permeable fracture pathways that allow gas to flow away from its source and prevent formation of high-pressure gas pockets. Thus, if significant gas pressurization in the unsaturated zone due to the degradation of the waste is not expected, then it can be reasoned that such pressurization will also be unexpected in the saturated zone, where the water table is approximately 330 m below the repository sources of gas (DTN: SN0704T0510106.008 [DIRS 181283], file: *sz06_1302sur_10002.txt*; SNL 2007 [DIRS 179466]). In summary, degradation of repository components that would potentially produce gas will not affect flow and transport in the saturated zone.

Based on the previous discussion, omission of FEP 2.2.11.01.0A (Gas Effects in the SZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.11.02.0A

FEP NAME:

Gas Effects in the UZ

FEP DESCRIPTION:

Pressure variations due to gas generation may affect flow patterns and contaminant transport in the UZ or may intrude into the repository. Degassing could affect flow and transport of gaseous contaminants. Gases could also affect other contaminants if water flow is driven by large gas bubbles forming in the repository. Potential gas sources include degradation of repository components and naturally occurring gases from clathrates, microbial degradation of organic material, or deep gases in general.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

In the Yucca Mountain unsaturated zone, the build-up of any significant gas pressure is expected to be of low consequence. Permeable fracture pathways would allow gas to flow away from its source, preventing the formation of high pressure gas pockets that might alter flow and transport patterns (SNL 2007 [DIRS 184614], Section 6.4). In addition, gas-phase radionuclide transport is excluded on the basis of low consequence (see excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere)).

Studies have been performed to determine the potential impact of fracture sealing, caused by mineral precipitation during thermally induced processes, on pressure build-up and hydraulics. Thermal-hydrologic-chemical calculations that included gas transport and mineral precipitations during repository heating were performed, and results showed that potential sealing of fractures due to precipitation in the thermally perturbed repository environment would have a negligible effect on hydrogeologic response of the fractures (SNL 2007 [DIRS 177404], Section 8, Figure 8-1). The processes associated with this aspect of the FEP will not, therefore, significantly change radionuclide releases to the accessible environment and can be excluded on the basis of low consequence.

This FEP also addresses the possible effects of gas bubbles on the potential release of radionuclides from the repository to the accessible environment. Because the repository at Yucca Mountain is located within the unsaturated zone, gas bubbles would quickly be absorbed into the available gas phase surrounding the liquid. Therefore, bubbles could not drive substantial water flow. Thus, a bubble-release mechanism of radionuclides from the repository will be of low consequence relative to radionuclide transport to the accessible environment. This conclusion is valid regardless of the specific potential sources of gas generation (e.g., degradation of repository components over tens of thousands of years, or natural sources of gas). For more information on natural sources of gas, see excluded FEP 2.2.11.01.0A (Gas Effects in the SZ).

Based on the previous discussion, omission of FEP 2.2.11.02.0A (Gas Effects in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.11.03.0A

FEP NAME:

Gas Transport in Geosphere

FEP DESCRIPTION:

Gas released from the drifts and gas generated in the near-field rock will flow through fracture systems in the near-field rock and in the geosphere. Certain gaseous or volatile radionuclides may be able to migrate through the far-field faster than the groundwater advection rate.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Gas transport in the geosphere can occur either by gas-phase transport through unsaturated rock pores and fractures, or by aqueous-phase transport as dissolved gases in groundwater. Gases that are dissolved in groundwater would be transported by groundwater advection, with the rate of advection determining the rate of gas transport. Dissolved gas may exsolve from aqueous solution into the gaseous phase in unsaturated pores and fractures, and therefore become available for gas-phase migration to the accessible environment. This FEP is concerned with gas-phase transport through the geosphere, and its exclusion is based on the relatively low annual doses estimated for the gas-phase pathways compared to annual doses calculated for the aqueous-phase pathways.

The only radionuclides that would have a potential for gas transport are ^{14}C and ^{222}Rn. Although ^{129}I can exist in the gaseous phase, it is highly soluble, and therefore would be more likely to be dissolved in groundwater rather than exist as a gas. Other gas-phase isotopes have been eliminated in a screening analysis (DOE 2002 [DIRS 155970], Section I.3.3), primarily because they have short half-lives and are not decay products of long-lived isotopes. Note that for ^{14}C and ^{222}Rn, the process of inhalation is included in the biosphere model (SNL 2007 [DIRS 177399], Section 6.4.8).

Modeling of potential annual doses from gas-phase geosphere transport of ^{14}C shows that the individual maximum radiological dose is 1.8×10^{-10} mrem/yr, which corresponds to a maximum gas-phase release rate that occurs at 1,700 years following repository closure (DOE 2002 [DIRS 155970], Section I.7). This maximum annual dose from gas-phase ^{14}C releases may be compared with the maximum annual dose from aqueous releases of ^{14}C, which is calculated in TSPA to be approximately 10^{-3} mrem/yr for the early waste-package failure modeling case at 2,000 years following repository closure (SNL 2008 [DIRS 183478], Figure 8.2-6(a)). This comparison demonstrates that the predicted maximum annual dose of 1.8×10^{-10} mrem/yr for gas-phase geosphere transport of ^{14}C is insignificant relative to aqueous-phase transport.

In addition, about 2% of the ^{14}C in commercial SNF exists as a gas in the space between the fuel and the cladding (DOE 2002 [DIRS 155970], Section I.7). Even if the entire ^{14}C inventory were

released in the gas phase, the expected maximum annual dose from gas-phase geosphere transport of ^{14}C is only 9×10^{-9} mrem/yr ($50 \times 1.8 \times 10^{-10}$), which is still five orders of magnitude less than the peak annual dose from aqueous ^{14}C. Thus, the annual dose from the gas-phase release pathways is insignificant compared to the annual dose from the aqueous-phase pathways.

^{222}Rn is a decay product of the ^{238}U-decay series and would be generated for as long as any uranium remained in the repository. Based on gas flow studies, radon released from the repository in the gas phase is expected to radioactively decay before reaching the ground surface (DOE 2002 [DIRS 155970], Section I.7.3). Therefore, aqueous geosphere transport pathways will be the primary contributor to dose from ^{222}Rn, primarily through aqueous transport of uranium and generation of ^{222}Rn as a decay product in the accessible environment.

In summary, all radionuclides are transported in the aqueous phase between the repository and the accessible environment for all scenario classes except the eruptive modeling case of the igneous scenario class. The effects of gas-phase geosphere transport on radiological exposures and annual doses are insignificant relative to aqueous-phase geosphere transport.

Based on the previous discussion, omission of FEP 2.2.11.03.0A (Gas Transport in Geosphere) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.2.12.00.0A

FEP NAME:

Undetected Features in the UZ

FEP DESCRIPTION:

Undetected features in the UZ portion of the geosphere can affect long-term performance of the disposal system. Undetected but important features may be present, and may have significant impacts. These features include unknown active fracture zones, inhomogeneities, faults and features connecting different zones of rock, different geometries for fracture zones, and induced fractures due to the construction or presence of the repository.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Two kinds of undetected features in the unsaturated zone are of concern: (1) features which, on the basis of previous investigations, could be potentially present, and (2) features that are totally unexpected. Features that could potentially be present on the basis of previous investigations include buried Plio-Pleistocene basaltic intrusions. As discussed in excluded FEP 1.2.04.02.0A (Igneous Activity Changes Rock Properties), the effects of small intrusions, or more generally, any heterogeneous features approximating meter scale intrusions (or smaller), are expected to have a negligible effect on flow and transport behavior in the unsaturated zone. Also, induced fractures may occur near waste emplacement drifts due to the disturbance of the rock stress field caused by the presence of the drift openings. Induced fractures are not unexpected features, and are evaluated in underground testing and included in drift seepage modeling, as discussed in included FEP 2.2.01.01.0A (Mechanical Effects of Excavation and Construction in the Near-Field).

The scenario that a major, critical feature in the vicinity of Yucca Mountain, such as a large seismogenic fault zone, has been overlooked is not expected given the extensive site characterization conducted at Yucca Mountain (BSC 2004 [DIRS 169734], p. 1-1), and falls into the second category of "totally unexpected" undetected features. Furthermore, subsequent repository development will involve the excavation of more than 170 km of waste emplacement drifts (BSC 2007 [DIRS 179640], Table 10), providing detailed geological information for the entire repository area. Actual subsurface conditions from site characterization excavations will be confirmed by mapping of these emplacement drifts and mains (BSC 2004 [DIRS 172452], p. 3-10). Any previously undetected features will be reported and evaluated with respect to performance assessment results (BSC 2004 [DIRS 172452], p. 2-16 and Section 4.3).

Small undetected features are always possible because a direct inspection of the entire UZ model domain is not possible. However, the results of an analysis of smaller-scale heterogeneity indicates that unsaturated zone flow and transport are governed primarily by large-scale stratigraphy, structure, and associated hydrological properties rather than by smaller-scale

heterogeneity (SNL 2007 [DIRS 184614], Section 7.8.3.1; Zhou et al. 2003 [DIRS 162133], Section 6). Therefore, smaller-scale undetected features are expected to have a negligible effect on unsaturated zone flow and transport processes.

Undetected features above the repository are also not expected to have significant effects on water arrival at the repository. This is supported by the UZ flow model results, which show that existing major fault features carry only a small fraction of the flow (about 1%) within the repository footprint above the repository (SNL 2007 [DIRS 184614], Tables 6.6-1 and 6.6-2). Undetected features would not be expected to significantly alter the fraction of flow through features (detected and undetected) within the repository footprint.

The corresponding FEP for the saturated zone, FEP 2.2.12.00.0B (Undetected Features in the SZ), is included. The reasons that undetected features in the unsaturated zone are excluded while undetected features in the saturated zone are included reflect the differences in the domains and degree of site characterization for these two zones, as well as differences in the types of measurements available. The unsaturated zone model domain consists of an area of less than 60 square kilometers (SNL 2007 [DIRS 184614], Figure 6.1-1) and a depth of less than 1 kilometer (BSC 2004 [DIRS 169855], Figure C3-2) for a volume of less than 60 cubic kilometers. By comparison, the SZ site-scale flow modeling domain consists of an area in excess of 1,300 square kilometers (SNL 2007 [DIRS 177391], Figure 6-5) and is approximately 6 kilometers in depth (SNL 2007 [DIRS 177391], Table 6-4) for a volume of more than 7,800 cubic kilometers. Therefore, the SZ site-scale flow model domain is more than two orders of magnitude larger than the unsaturated zone model domain. Furthermore, a greater intensity of site characterization has been performed for the unsaturated zone modeling domain as compared with the saturated zone modeling domain (BSC 2004 [DIRS 169734], Figures 7-2 and 8-10). Given these differences in the domains and site characterization, major undetected features in the unsaturated zone model domain are not expected, whereas major undetected features could be present in the saturated zone modeling domain. However, the ability to conduct pump tests in the saturated zone allows for the identification of the effects of major features on saturated zone flow processes, even if the features themselves have not been detected. In this way, the effects on groundwater flow of undetected features in the volcanic units in the saturated zone, such as fracture zones and smaller faults, have been incorporated into the distribution for horizontal anisotropy in permeability in the SZ flow and transport abstraction model (SNL 2008 [DIRS 183750], Section 6.5.2.10). These differences have led to the exclusion of undetected features in the unsaturated zone and inclusion of undetected features in the saturated zone.

Based on the previous discussion, omission of FEP 2.2.12.00.0A (Undetected Features in the UZ) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319] on the basis of low consequence.

Undetected Features in the SZ

FEP DESCRIPTION:

Undetected features in the SZ portion of the geosphere can affect long-term performance of the disposal system. Undetected but important features may be present, and may have significant impacts. These features include unknown active fracture zones, inhomogeneities, faults and features connecting different zones of rock, and different geometries for fracture zones.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Potential impacts on groundwater flow from undetected features in the saturated zone, such as fracture zones, inhomogeneities, faults, gravel lenses, and channels in the alluvium, are incorporated in the SZ transport abstraction model and the SZ one-dimensional transport model through parameter distributions (SNL 2008 [DIRS 183750]), which ultimately propagate to TSPA through variation in radionuclide breakthrough curves. The generation of multiple flow and transport realizations, using stochastically sampled key parameters as input, significantly varies flow and transport pathways in the saturated zone (SNL 2008 [DIRS 183750]).

Modeling of natural processes is, in many instances, based on using scaled parameters. Scaled parameters are parameters that are based on empirical observations (i.e., not all processes or first order physics are explicitly understood or known). Hydraulic conductivity, permeability, and transmissivity are examples of scaled parameters. In matching hydraulic heads (a response to the system) with variable lumped parameters such as permeability, undetected features are implicitly incorporated into *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391], Section 6.6.1). The site-scale SZ transport model (SNL 2008 [DIRS 184806]) incorporates these effects by using the calibrated SZ site-scale flow model as its basis.

Groundwater specific discharge in the saturated zone may be enhanced due to the presence of undetected features. In the alluvium, features could be undetected gravel lenses and channels, and in the volcanic units these could be undetected faults and fractures or fracture clusters. Uncertainty in parameters related to these features are applied to the hydrogeologic units defined in the hydrogeologic framework model documented in *Hydrogeologic Framework Model for the Saturated Zone Site Scale Flow and Transport Model* (BSC 2005 [DIRS 174109]). Uncertainty in groundwater specific discharge in the saturated zone is based on data gathered from single- and multiwell hydrologic testing in the volcanic units near Yucca Mountain and field testing in the alluvium at the alluvial tracer complex. In the TSPA, the groundwater specific discharge multiplier parameter is a multiplication factor applied to all saturated zone permeability values and specified boundary fluxes (SNL 2008 [DIRS 183750], Section 6.5.2.1[a]) to effectively scale the simulated specific discharge and model the effects that undetected features may have on

groundwater specific discharge. Uncertainty in the flowing interval spacing parameter (BSC 2004 [DIRS 170014]) accounts for smaller-scale undetected features that transmit significant quantities of groundwater in the saturated zone. The assessment of horizontal anisotropy in permeability, as documented in *Saturated Zone In-Situ Testing* (SNL 2007 [DIRS 177394]), potentially includes the effects of preferentially oriented undetected features on groundwater flow in the saturated zone.

Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model (SNL 2007 [DIRS 174109]) documents the development of the 2006 hydrogeologic framework model (DTN: MO0610MWDHFM06.002 [DIRS 179352]). The HFM output is used in the site-scale saturated zone flow model. The TSPA disposition of included FEP 2.2.12.00.0B (Undetected Features in the SZ), is supported by *Hydrogeologic Framework Model for the Saturated Zone Site-Scale Flow and Transport Model* (SNL 2007 [DIRS 174109], Sections 6.4.3 and 8).

Key parameters that model undetected features (SNL 2008 [DIRS 183750]) are: (1) groundwater specific discharge, (2) porosity, (3) flowing interval spacing in the volcanics, (4) longitudinal dispersion, (5) horizontal anisotropy of permeability, (6) alluvial bulk density, and (7) sorption coefficients (K_d) for the nine classes of radionuclides modeled in both the alluvium and volcanic units (parameters are described in SNL 2008 [DIRS 183750], Sections 6.5.2.1[a], 6.5.2.3[a], and Tables 6-7[a] and 7-1[b]).

Additionally, in the SZ transport abstraction model (SNL 2008 [DIRS 183750], Section 6.5.2.2[a]), undetected features are accounted for through the probabilistic boundaries of the alluvium uncertainty zone. The western and northern boundaries of the alluvium uncertainty zone are defined with the sampled parameters. The above parameters that model undetected features are described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Sections 6.5.2.1[a], 6.5.2.2[a], 6.5.2.3[a], 6.5.2.4[a], 6.5.2.5, 6.5.2.7, 6.5.2.8, 6.5.2.10, respectively; also see Table 6-7[a]).

FEP: 2.2.14.09.0A

FEP NAME:

Far-Field Criticality

FEP DESCRIPTION:

Far-field criticality could occur if fissile material-bearing solution from the waste package is transported beyond the drift and the fissile material is precipitated into a critical configuration. Potential far-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3.b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the far-field location for those conditions that may lead to damage or failure of the waste package and allow water into the system, as idenitified in included FEPs 2.1.03.08.0A (Early Failure of Waste Packages) and 2.1.03.08.0B (Early Failure of Drip Shields). A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935]), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926]).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that would be less than 1 are not evaluated, but are conservatively set to 1.

Far-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the far-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in a favorable geometry. It then follows that the probability of far-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the far-field environment.

Because the quantity of material released by diffusion would be small due to the tortuousity of the path, advective flow of water is necessary for transporting fissile materials from the waste package to the near-field in any appreciable quantities to be considered for criticality (SNL 2007 [DIRS 181165], Section 6.2). An advective seepage flow path to a waste package for nominal repository conditions would occur due to misplacement of a drip shield leading to breaching of the waste package from localized corrosion. However, the probability of this type of event is very low (4.36×10^{-9} per drip shield; DTN: MO0705EARLYEND.000 [DIRS 180946], file: *Table 1.doc*, Table 1). Since this type of event occurs during the preclosure time period, it is independent of the postclosure time period. Using the total number of waste packages (11,162; MO0702PASTREAM.001 [DIRS 179925], file: *DTN-Inventory-Rev00.xls*, worksheet: "Unit Cell") as a conservative estimate for the number of drip shields (it is conservative because not all waste packages have sufficient quantities of fissile material to result in a criticality event) and multiplying by the probability of misplacing a drip shield results in an initiating event probability of 4.9×10^{-5}. This value is already below the regulatory screening criterion of 1 chance in 10,000 (10^{-4}) of occurrence within 10,000 years after disposal prior to consideration of probabilities (which would be less than 1.0) associated with the amount of degradation and accumulation into a favorable geometry for criticality that would only result in lowering the sequence probability.

As indicated in excluded FEP 2.1.14.12.0A (Far-Field Criticality Resulting from an Igneous Event) and excluded FEP 2.1.14.10.0A (Far-Field Criticality Resulting from a Seismic Event), the amount of fissile material accumulation in the far-field location is insufficient to pose a criticality concern. Note that the material degradation of the internals and subsequent accumulation in the far-field based on the seismic and igneous scenarios are bounding for nominal repository conditions because the seismic and igneous seepage fluxes are much higher. Therefore, under bounding seepage fluxes resulting from a sesimc or igneous initiating event, an insufficient amount of fissile material could accumulate in the far-field to pose a criticality concern, it can be concluded that under nominal reposity conditions, an insufficient amount of fissile material can accumulate in the far-field location to pose a criticality concern.

Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.2.14.10.0A

FEP NAME:

Far-Field Criticality Resulting from a Seismic Event

FEP DESCRIPTION:

Either during, or as a result of, a seismic disruptive event, far-field criticality could occur if fissile material-bearing solution from the waste package is transported beyond the drift and the fissile material is precipitated into a critical configuration. Potential far-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the far-field location for the seismic scenario, where far-field is defined as the region outside the drift. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935]), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926]).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that would be less than 1 are not evaluated, but are conservatively set to 1.

Far-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the near-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in a favorable geometry. It then follows that the probability of near-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the near-field environment.

If a waste package is breached, water and solutes might enter and leave the waste package by several mechanisms, including diffusion, condensation of vapor, and advection of liquid water. Leakage through a crack-damaged drip shield is an insignificant source for liquid water penetration through cracks in the underlying waste package especially when compared to the threshold flow rate (0.1 kg/yr) used in TSPA to define whether seepage occurs (excluded FEP 2.1.03.10.0 (Advection of Liquids and Solids through Cracks in the Waste Package)). Therefore, the predominant mechanism for water inflow and outflow through a breached waste package is through diffusive transport unless the drip shield has failed. *Geochemistry Model Validation Report: Material Degradation and Release Model* (SNL 2007 [DIRS 181165], Section 6.2) indicated that the quantity of material released by diffusion would be small due to the tortuosity of the path, and therefore the diffusion-only scenario is not considered a viable method for material transport. Thus, advective flow of water is necessary for transporting fissile materials from the waste package to the far-field in any appreciable quantities to be considered for criticality.

Vibratory ground motion (included FEP 1.2.03.02.0A (Seismic Ground Motion Damages EBS Components)), faulting (included FEP 1.2.02.03.0A (Fault Displacement Damages EBS Components)), seismic-induced drift collapse in the lithophysal units (included FEP 1.2.03.02.0C (Seismic-Induced Drift Collapse Damages EBS Components)), and seismic-induced rockfall (excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components)) are potential initiating events that are capable of creating advective flow paths into the waste package. Such failures may allow the influx of water (either advective or diffusive) into the waste package, which, in turn, has the potential to initiate processes leading to degradation and transport of the fissile material to the far-field location.

Note that excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) has been screened from performance assessment on the basis of low consequence, which is not directly applicable to criticality potential evaluations. FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components) indicates that seismic-induced damage to the waste package and its internals from rock block impacts in nonlithophysal units is screened out from the TSPA model on the basis of low probability. However, FEP 1.2.03.02.0B (Seismic-Induced

Rockfall Damages EBS Components) screens out tearing or rupture of the drip shield plates from large block impacts because of low consequence, which is not directly applicable to criticality potential evaluations. Drip shield failure could result in an advective flow path to the waste package OCB creating an environment for subsequent localized corrosion processes (FEP 2.1.03.03.0A (Localized Corrosion of Waste Packages)) that could breach the waste package OCB.

The probability of drip shield and waste package failure from a fault event varies with the magnitude of the earth quake but ranges from 1.2×10^{-4} to 4.3×10^{-4} for the TAD waste packages and from 3.0×10^{-5} to 6.9×10^{-4} for the codisposal waste packages (SNL 2008 [DIRS 173869], Table 6.4-7).

There are several hundred distinct types of DOE SNF and it is not practical to attempt to determine the impact of each individual type on repository performance. These fuels come from a wide range of reactor types, such as light- and heavy-water-moderated reactors, graphite-moderated reactors, and breeder reactors, with various cladding materials and enrichments, varying from depleted uranium to over 93% enriched ^{235}U. Many of these reactors, now decommissioned, had unique design features, such as core configuration, fuel element and assembly geometry, moderator and coolant materials, operational characteristics, and neutron spatial and spectral properties (DOE 2004 [DIRS 171271]).

Therefore, to facilitate DOE SNF waste form evaluations, the DOE SNF inventory was first reduced to 34 DOE SNF groups based on fuel matrix, cladding, cladding condition, and enrichment. These parameters are the fuel characteristics that were determined to have major impacts on the release of radionuclides from the DOE SNF and contributed to nuclear criticality scenarios (DOE 2000 [DIRS 118968], Section 5). Separate groups were further refined for the purposes of criticality, design basis events, and TSPA based on key parameters such as fuel matrix, cladding, and fuel condition, as well as fissile species and enrichment, and reactor and fuel design (DOE 2000 [DIRS 118968], Section 5.1). For criticality, nine DOE SNF criticality groups have been identified and are listed in *General Description of Database Information Version 5.0.1* (DOE 2007 [DIRS 182577], Table 6).

Within each of the nine DOE SNF criticality groups, a single fuel design was selected as being representative of the remaining fuel within each group. The term representative means that all fuels would perform similarly regarding chemical interactions within the waste package and basket, and that canister loading limits from the representative fuel (ranges of key parameters important to criticality such as linear fissile loading and total fissile mass) are established, which other fuels within the group can be shown to not exceed. Waste forms within a single criticality group that have configurations or key criticality parameters outside the range of applicability of the representative fuel will require supplemental analysis and/or additional reactivity control mechanisms.

Evaluations for naval fuel are conducted by the Naval Nuclear Propulsion Program. A miscellaneous waste form category which has a variety of fuel matrix properties originating from various postirradiation examinations and other testing are not included in the criticality evaluations for the fuel groups as they will need to be evaluated on a case-by-case basis. Thus,

the disposal criticality analysis methodology (YMP 2003 [DIRS 165505]) can be applied to nine DOE SNF representative fuel groups for criticality evaluations.

The minimum fissile mass necessary for criticality external to the waste packages is discussed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], Section 8.1.4[a]), where it was concluded that insufficient fissile material can collect over 10,000 years to achieve a critical mass for the seismic scenario. Note that the material degradation of the internals and subsequent accumulation in the near-field based on the seismic scenario are bounding for localized corrosion because the seismic seepage flux is based on the entire waste package footprint area collecting seeps whereas localized corrosion seeps would only be a fraction of the total area with a reduced seepage flux. In addition, these values are predicated on having an initiating event (i.e., seismic fault displacement rupturing the drip shield and waste package), which is an unlikely event (1.2×10^{-8} per year). The critical mass limits were evaluated for commercial SNF and DOE SNF waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]).

Model abstractions were performed for commercial SNF and three DOE SNF waste forms in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]) (i.e., N Reactor (DOE3), TMI (DOE9), and FFTF (DOE1)) (SNL 2008 [DIRS 173869], Table 4.1-2), which make up approximately 90% of the metric tons of heavy metal in the DOE SNF inventory expected to be stored in the repository. In addition to these waste forms making up ~90% of the inventory by mass, they were selected because they provide degradation and accumulation characteristics of uranium-metal (N Reactor), mixed-oxide (FFTF), and damaged uranium dioxide (TMI) waste forms which may be applicable to other representative DOE waste forms. Some of the other DOE SNF waste forms, such as Shippingport light-water breeder reactor (LWBR) (DOE5) and Ft. St. Vrain (DOE6) are not expected to be a concern for external criticality due to the corrosion resistance of the waste form (SNL 2007 [DIRS 181395], Section 6.9.3[a]).

Ft. St. Vrain fuels (DOE6) have an integral silicon carbide (SiC) protective layer that not only retains the fission products but also protects the uranium and thorium dicarbide (ThC_2) from oxidation and hydrolysis (DOE 2003 [DIRS 166027], p. 48). Comparative analysis has indicated that the Ft. St. Vrain fuel has the lowest degradation rate of all DOE SNF and should behave significantly better in terms of fissile material dissolution, transport, and accumulation. In some residual quantities (< 250 grams per block), ^{233}U bred into the ThC_2 fertile particles. A canister loaded with five Ft. St. Vrain blocks contains sufficient quantities of ^{233}U to have criticality potential in solution; however, a mechanism to separate the uranium from within the SiC-coated fertile particles, and then a mechanism to accumulate in a concentrated fissile mass in a favorable geometry, is not credible.

For Shippingport LWBR fuel (DOE5), a number of studies has indicated both air and water oxidation of uranium and thorium oxide fuel pellets [(Th, U)O_2] proceed more slowly than in pure uranium oxide (UO_2), and decreases with decreasing UO_2 content in the (Th, U)O_2 (DOE 2003 [DIRS 166027], p. 33). Tests have shown that the thorium oxide pellets in the Shippingport LWBR fuel have excellent corrosion resistance with an estimated solubility of

10^{-14} mol/L at 25°C and pH > 5 (DOE 2003 [DIRS 166027], p. 32). With the less-reactive degradation rate, a mechanism to separate the uranium, transporting, and accumulation into a favorable geometry is also not credible.

Table 2.2.14.10.0A-1 shows the ranges of minimum critical mass required to accumulate in the invert as well as the calculated accumulation or mass released from the waste package for the waste forms evaluated for external criticality. For each of the waste forms evaluated, the results indicate that an insufficient amount of fissile material accumulates to pose a criticality concern.

Table 2.2.14.10.0A-1. Summary of Seismic Scenario External Criticality Results

Scenario	Waste Package Type	Calculated Accumulation or Mass Released from Waste Package	Mass of Uranium or Plutonium (for FFTF) required to achieve critical limit of k_{eff} = 0.96		
		Uranium Mass, Unless Otherwise Noted (kg)	Fractured Tuff	Lithophysae Array	Large Lithophysae
Seismic	DOE3 (N Reactor)	Not calculated[a]	Infinite[b]	Not calculated[a]	Not calculated[a]
	DOE9 (TMI II Fuel)	Not calculated[a]	Infinite[b]	Not calculated[a]	Not calculated[a]
	Commercial SNF	90.3	Infinite[b]	Not calculated[a]	Not calculated[a]
	DOE1 (FFTF) (Plutonium Mass)	0	4.3	Not calculated[a]	Not calculated[a]

[a] "Not calculated" means that this scenario is bounded by the igneous scenario (FEP 2.2.14.12.0A) . In most cases, this means that if commercial SNF waste is very subcritical, then TMI and N Reactor waste had to be also.
[b] "Infinite" means that an infinite amount of fissile waste released in this model will not produce an arrangement that can reach the critical limit.

Source: SNL 2007 [DIRS 181395], Table 6.9-1[a].

DOE fuel groups in DOE2, DOE4, DOE7, and DOE8 representing UZrHx (TRIGA), high enriched uranium oxide (Shippingport PWR), aluminum-based (ATR), and U-Zr/U-Mo alloy (Fermi), respectively (SNL 2008 [DIRS 173869], Table 4.1-2), have not been analyzed in detail for external fissile mass transport and accumulation as the other waste forms have. However, considering the processes that must occur to allow advective seepage into a DOE SNF canister without substantial drainage to allow degradation of the internal components and waste form, along with the other conservative modeling parameters that have been used to create a process to facilitate fissile material transport to the external environment, and the bounding modeling parameters respective to maximizing criticality potential, these waste forms are not expected to result in an increase in the total probability of criticality in the far-field location.

Some of the conservative modeling parameters are provided as follows:

- The material degradation and release model (SNL 2007 [DIRS 181165]) uses constant corrosion rates for the SNF; however, laboratory experiments on the surface structure of commercial SNF during dissolution have shown that UO_2 dissolution is accompanied by the formation of a protective layer of secondary phases that retards further corrosion

(SNL 2007 [DIRS 181165], Section 6.6.2). Therefore, the release of uranium from the fuel would be slower and therefore less would be released.

- Experimental and field data indicate that actinides would be adsorbed on or incorporated into alteration products that form in the waste package (SNL 2007 [DIRS 181165], Section 6.6.3). This solid solution formation and adsorption would tend to lower actinide concentrations below those predicted by EQ6 and would delay release from the waste package.

- The material degradation and release model (SNL 2007 [DIRS 181165]) assumes the cladding and DOE SNF canister fail immediately, whereas the expected scenario would be that the failure would take place over many years. This would also delay the release of actinides.

- Many conservative modeling approximations are used to simplify the critical mass calculations presented in Table 2.2.14.10.0A-1. For the commercial SNF and low-enriched DOE fuels analyzed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]), the conservatisms are appropriate, because the results show that a criticality event is very unlikely. However, for the higher enriched DOE fuels, less conservative (increased detail) modeling parameters of the criticality potential are expected to generate similar conclusions.

Summary—The critical mass limits were evaluated for several waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]). Model abstractions were performed for commercial SNF and three DOE SNF waste forms and resulted in insufficient fissile material accumulation in the near-field location to pose a criticality concern. Therefore, based on these waste forms representing the majority (>95% of the total metric tons) of the waste for disposal in the mountain, and considering the conservative modeling parameters discussed above that would be further developed for other DOE representative fuel groups, in conjunction with the order of magnitude of the probability of a seismic faulting event causing waste package failure, the probability of far-field criticality is considered insignificant. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.2.14.11.0A

FEP NAME:

Far-Field Criticality Resulting from Rockfall

FEP DESCRIPTION:

Either during or as a result of a rockfall event, far-field criticality could occur if fissile material-bearing solution from the waste package is transported beyond the drift and the fissile material is precipitated into a critical configuration. Potential far-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the far-field location resulting from rockfall, where *far-field* is defined as the region outside the drift. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. All postclosure criticality FEP scenarios, internal and external, require the presence of water in liquid or vapor form to degrade the waste package internals and/or the waste form as intact configurations are designed to remain subcritical if fabricated and loaded according to design specifications as demonstrated in *CSNF Loading Curve Sensitivity Analysis* (SNL 2008 [DIRS 182788], Section 6.2.2), *DOE SNF Phase I and II Summary Report* (Radulescu et al. 2004 [DIRS 165482], Sections 10 and 11.4), *Intact and Degraded Mode Criticality Calculations for the Codisposal of TMI-2 Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 168935]), and *Intact and Degraded Mode Criticality Calculations for the Codisposal of ATR Spent Nuclear Fuel in a Waste Package* (BSC 2004 [DIRS 171926]).

For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that are less than 1 are not quantified, but rather are conservatively set to 1.

Far-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the far-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated. It then follows that the probability of far-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form
- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the far-field environment.

Excluded FEP 2.1.07.01.0A (Rockfall) indicates that rockfall related to nonseismic processes such as drift degradation induced by in situ gravitational and excavation-induced stresses as well as thermally induced stresses do not generate rock block sizes sufficient to tear or rupture the drip shield plates. Drip shield damage from rockfall induced by thermal loading is found to be minor since the block sizes for such rockfall are small with a mean mass of less than 0.2 MT (BSC 2004 [DIRS 166107], p. 6-102). In addition, drift degradation (i.e., considering thermal and time-dependent effects on drift collapse, but excluding seismic effects) results in only partial collapse of the emplacement drifts at 20,000 years (see excluded FEP 2.1.07.02.0A (Drift Collapse)). The conclusion for the nominal scenario is that negligible drift degradation will occur over the initial 10,000-year postclosure period (BSC 2004 [DIRS 166107], p. x).

A waste package must be breached in order to transport fissile material out. If a waste package is breached, water and solutes might enter and leave the waste package by several mechanisms, including diffusion, condensation of vapor, and advection of liquid water. Therefore, rockfall does not result in waste package outer barrier breaching. Without a waste package breach, there is no potential for external criticality.

Summary—Since the drip shield continues to function through rockfall events as described previously, the waste package will be protected from rockfall during the postclosure period, for as long as the drip shield remains intact, thereby precluding the introduction of water to the waste package, which is necessary to degrade the internals and transport material into the far-field location. The probability of the occurrence of configurations with criticality potential for the far-field location resulting from rockfall is insignificant since no damage to the waste package OCBs is expected from the nonseismically initiated rockfall events. Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability. This result is applicable for all waste forms and waste package variants.

FEP: 2.2.14.12.0A

FEP NAME:

Far-Field Criticality Resulting from an Igneous Event

FEP DESCRIPTION:

Either during or as a result of an igneous disruptive event, far-field criticality could occur if fissile material-bearing solution from the waste package is transported beyond the drift and the fissile material is precipitated into a critical configuration. Potential far-field critical configurations are defined in *Disposal Criticality Analysis Methodology Topical Report* (YMP 2003 [DIRS 165505], Figure 3.3b).

SCREENING DECISION:

Excluded – low probability

SCREENING JUSTIFICATION:

This FEP justification accounts for external criticality for the far-field location for the igneous scenario, where *far-field* is defined as the region outside the drift. A prerequisite for any of the spent fuel waste forms to have potential for criticality is the introduction of water in liquid or vapor form to the inside of the TAD or DOE SNF canister. For a criticality event to occur, the appropriate combination of materials (e.g., neutron moderators, neutron absorbers, fissile materials, or isotopes) and geometric configurations favorable to criticality must exist. Therefore, for a configuration to have potential for criticality, all of the following conditions must occur: (1) sufficient mechanical or corrosive damage to the waste package OCB to cause a breach, (2) presence of a moderator (i.e., water), (3) separation of fissionable material from the neutron absorber material or an absorber material selection error during the canister fabrication process, and (4) the accumulation (external) or presence of a critical mass of fissionable material in a critical geometric configuration. The probability of developing a configuration with criticality potential is insignificant unless all four conditions are realized, and then is only representative of a conservative estimate since the probability values associated with the many other events required to generate a critical configuration that would be less than 1 are not evaluated, but are conservatively set to 1.

Far-field criticality cannot occur unless the waste package and waste form are degraded. Water infiltration is required to degrade the waste package internals and waste form and transport them to the far-field location. Criticality cannot occur unless at least the minimum critical mass of a waste form can be accumulated in a favorable geometry. It then follows that the probability of far-field criticality must be less than the probability of water entering the waste package. This is because, in addition to the events evaluated to calculate the probability of water infiltrating a breached waste package, the probability of the following events or processes must also be considered for external criticality:

- Separation of the fissile materials from the degraded waste form

- Sufficient seepage water to transport fissile materials from the waste package
- Accumulating sufficient fissile material into a potentially critical configuration in the far-field environment.

Included FEP 1.2.04.03.0A (Igneous Intrusion into Repository) is an event where an igneous basaltic dike (magma-filled crack) intersects one or more repository drifts, followed by the intrusion of effusive (liquid) magma flow or pyroclastic flow (clots of melt in a stream of gas) into the drifts. The temperature of the waste package, the canister internals, and the SNF will heat up to near-magma temperatures in days to weeks (SNL 2007 [DIRS 177430], Figure 6-94) exceeding 700°C for one to nineteen months, depending on the temperature of the magma and the radioactive decay heat generated by the waste (SNL 2007 [DIRS 177430], Section 6.4.6). At these high waste package temperatures, the fuel and the materials surrounding the fuel (i.e., cladding and structural materials) may be affected. Iron-zirconium and nickel-zirconium liquid eutectics will form (starting at approximately 948°C (ASM International 1996 [DIRS 181641], iron-zirconium and nickel-zirconium phase diagrams)) but are not expected to provide any mechanisms causing appreciable removal of the neutron-absorber materials from their general locale in relation to the waste form since the eutectic is expected to contain both the absorber and waste form materials. In addition, thermal creep of the internal components resulting in internal slumping is also expected. In summary, it is expected that an igneous intrusion would sufficiently compromise the integrity of the waste packages, drip shields, and cladding in affected emplacement drifts to make them ineffective (i.e., a total loss of function in isolating waste packages and waste forms from seepage water when it returns after drifts have cooled).

The technical basis for inclusion of igneous intrusion into the repository in the TSPA is founded on the results of the Probabilistic Volcanic Hazard Analysis (PVHA) (CRWMS M&O 1996 [DIRS 100116]) described in *Characterize Framework for Igneous Activity at Yucca Mountain, Nevada* (BSC 2004 [DIRS 169989], Table 7-1), which indicates that the computed mean annual frequency of intersection of the repository footprint by a dike is 1.7×10^{-8}. The computed 5th and 95th percentiles of the uncertainty distribution for frequency of intersection are 7.4×10^{-10} and 5.5×10^{-8}, respectively.

Potential accumulation sites for fissile material beneath a degrading waste package in the far-field are within fractures of the host rock and within lithophysae distributed throughout the host rock. Lithophysae are hollow, bubble-like structures in the rock composed of concentric shells of finely crystalline alkali feldspar, quartz, and other materials. The primary mechanisms for accumulation are: (1) adsorption and (2) mixing of the actinide-laden source term with resident water, thus changing the chemistry sufficiently for fissile minerals to become insoluble and precipitate (SNL 2007 [DIRS 181395], Section 1).

In order for fissile material to accumulate in the far-field, the waste package effluent containing dissolved uranium and plutonium must flow through the invert without interaction with invert materials, enter the fractured tuff, and mix with water that was diverted around the drift that is now in these same fractures or lithophysae. After the effluent and "new" water mixes, uranium and plutonium may precipitate within the fractures and lithophysae.

For lithophysae to be available for accumulation of fissile material, the lithophysae must be connected to fractures that could transport the waste package effluent. In the event effluent reaches the lithophysa, it must mix with uncontaminated seepage water that flows into the lithophysa via another fracture. The mixing of the two solutions can result in a chemistry change which allows the fissile minerals to precipitate. More realistically, the waste package effluent would be adsorbed or precipitated in the invert and fractures before it ever reached the lithophysa. Many of the fractures observed in the repository are deflected around lithohysae (SNL 2007 [DIRS 181395], Section 6.4.8.4), and therefore the chances are low of two fractures intersecting a large lithophysa, each carrying different water solutions. In addition, *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.1.5) states that little water is expected to flow through lithophysal cavities, owing to the strong capillary barrier effect on seepage into cavities. Therefore, the accumulation in a large lithophysa is not expected. However, in order to determine the criticality potential of accumulation in a large lithophysa, the scenario was evaluated in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]).

There are several hundred distinct types of DOE SNF and it is not practical to attempt to determine the impact of each individual type on repository performance. These fuels come from a wide range of reactor types, such as light- and heavy-water-moderated reactors, graphite-moderated reactors, and breeder reactors, with various cladding materials and enrichments, varying from depleted uranium to over 93% enriched ^{235}U. Many of these reactors, now decommissioned, had unique design features, such as core configuration, fuel element and assembly geometry, moderator and coolant materials, operational characteristics, and neutron spatial and spectral properties (DOE 2004 [DIRS 171271]).

Therefore, to facilitate DOE SNF waste form evaluations, the DOE SNF inventory was first reduced to 34 DOE SNF groups based on fuel matrix, cladding, cladding condition, and enrichment. These parameters are the fuel characteristics that were determined to have major impacts on the release of radionuclides from the DOE SNF and contributed to nuclear criticality scenarios (DOE 2000 [DIRS 118968], Section 5). Separate groups were further refined for the purposes of criticality, design basis events, and TSPA based on key parameters such as fuel matrix, cladding, and fuel condition, as well as fissile species and enrichment, and reactor and fuel design. (DOE 2000 [DIRS 118968], Section 5.1). For criticality, nine DOE SNF criticality groups have been identified and are listed in *General Description of Database Information Version 5.0.1* (DOE 2007 [DIRS 182577], Table 6).

Within each of the nine DOE SNF criticality groups, a single fuel design was selected as being representative of the remaining fuel within each group. The term representative means that all fuels would perform similarly regarding chemical interactions within the waste package and basket, and that canister loading limits from the representative fuel (ranges of key parameters important to criticality such as linear fissile loading and total fissile mass) are established, which other fuels within the group can be shown to not exceed. Waste forms within a single criticality group that have configurations or key criticality parameters outside the range of applicability of the representative fuel will require supplemental analysis and/or additional reactivity control mechanisms.

Evaluations for naval fuel are conducted by the Naval Nuclear Propulsion Program. A miscellaneous waste form category which has a variety of fuel matrix properties originating from various postirradiation examinations and other testing is not included in the criticality evaluations for the fuel groups as they will need to be evaluated on a case-by-case basis. Thus, the disposal criticality analysis methodology (YMP 2003 [DIRS 165505]) can be applied to nine DOE SNF representative fuel groups for criticality evaluations.

The minimum fissile mass necessary for criticality external to the waste packages is discussed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], Section 8.1.4[a]), where it was concluded that insufficient fissile material can collect over 10,000 years to achieve a critical mass for the igneous scenario. In addition, these values are predicated on having an initiating event (i.e., igneous intrusive event causing drip shield and waste package failure), which is an unlikely event (1.7×10^{-8} per year). The critical mass limits were evaluated for commercial SNF and DOE SNF waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would most likely need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]).

Model abstractions were performed for commercial SNF and three DOE SNF waste forms in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395]) (i.e., N Reactor (DOE3), TMI (DOE9), and FFTF (DOE1)) (SNL 2008 [DIRS 173869], Section 4.1.15), which make up approximately 90% of the metric tons of heavy metal in the DOE SNF inventory expected to be stored in the repository. In addition to these waste forms making up ~90% of the inventory by mass, they were selected because they provide degradation and accumulation characteristics of uranium-metal (N Reactor), mixed-oxide (FFTF), and damaged uranium dioxide (TMI) waste forms which may be applicable to other representative DOE waste forms. Some of the other DOE SNF waste forms, such as Shippingport light-water breeder reactor (LWBR) (DOE5) and Ft. St. Vrain (DOE6) are not expected to be a concern for external criticality due to the corrosion resistance of the waste form (SNL 2007 [DIRS 181395], Section 6.9.3[a]).

Ft. St. Vrain fuels (DOE6) have an integral silicon carbide (SiC) protective layer that not only retains the fission products but also protects the uranium and thorium dicarbide (ThC_2) from oxidation and hydrolysis (DOE 2003 [DIRS 166027], p. 48). Comparative analysis has indicated that the Ft. St. Vrain fuel has the lowest degradation rate of all DOE SNF and should behave significantly better in terms of fissile material dissolution, transport, and accumulation. In some residual quantities (< 250 grams per block), ^{233}U bred into the ThC_2 fertile particles. A canister loaded with five Ft. St. Vrain blocks contains sufficient quantities of ^{233}U to have criticality potential in solution; however, a mechanism to separate the uranium from within the SiC-coated fertile particles, and then a mechanism to accumulate in a concentrated fissile mass in a favorable geometry is not credible.

For Shippingport LWBR fuel (DOE5), a number of studies has indicated that air and water oxidation of uranium and thorium oxide fuel pellets [$(Th, U)O_2$] proceeds more slowly than in pure uranium oxide (UO_2), and decreases with decreasing UO_2 content in the $(Th, U)O_2$ (DOE 2003 [DIRS 166027], p. 33). Tests have shown that the thorium oxide pellets in the Shippingport LWBR fuel have excellent corrosion resistance with an estimated solubility of

10^{-14} mol/L at 25°C and pH > 5 (DOE 2003 [DIRS 166027], p. 32). With the less-reactive degradation rate, a mechanism to separate the uranium, transporting, and accumulation into a favorable geometry is also not credible.

Table 2.2.14.12.0A-1 shows the ranges of minimum critical mass required to accumulate as well as the calculated accumulation or mass released from the waste package for the waste forms evaluated for external criticality. For each of the waste forms evaluated, the results indicate that an insufficient amount of fissile material accumulates to pose a criticality concern.

Table 2.2.14.12.0A-1. Summary of Igneous Scenario External Criticality Results

Scenario	Waste Package Type	Calculated Accumulation or Mass Released from Waste Package	Mass of Uranium or Plutonium (for FFTF) Required to Achieve Critical Limit of k_{eff} = 0.96		
		Uranium Mass, Unless Otherwise Noted (kg)	Fractured Tuff	Lithophysae Array	Large Lithophysa
Igneous	DOE3 (N Reactor)	0.109	Infinite[a]	Infinite	Infinite
	DOE9 (TMI II Fuel)	30.7	Infinite	Infinite	Infinite
	CSNF	74.8	Infinite	1,390	Infinite
	DOE1 (FFTF) (Plutonium Mass)	6.34×10^{-3}	4.3	4.0	2.2

[a] "Infinite" means that an infinite amount of fissile waste released in this model will not produce an arrangement that can reach the critical limit.

Source: SNL 2007 [DIRS 181395], Table 6.9-1[a].

DOE fuel groups in DOE2, DOE4, DOE7, and DOE8 representing UZrHx (TRIGA), high enriched uranium oxide (Shippingport PWR), aluminum-based (ATR), and U-Zr/U-Mo alloy (Fermi), respectively (SNL 2008 [DIRS 173869], Table 4.1-2), have not been analyzed in detail for external fissile mass transport and accumulation as the other waste forms have. However, considering the processes that must occur to allow advective seepage into a DOE SNF canister without substantial drainage to allow degradation of the internal components and waste form, along with the other conservative modeling parameters that have been used to create a process to facilitate fissile material transport to the external environment, and the bounding modeling parameters respective to maximizing criticality potential, these waste forms are not expected to result in an increase in the total probability of criticality in the far-field location.

Some of the conservative modeling parameters are provided as follows:

- The material degradation and release model (SNL 2007 [DIRS 181165]) uses constant corrosion rates for the SNF; however, laboratory experiments on the surface structure of commercial SNF during dissolution have shown that UO_2 dissolution is accompanied by the formation of a protective layer of secondary phases that retards further corrosion (SNL 2007 [DIRS 181165], Section 6.6.2). Therefore, the release of uranium from the fuel would be slower and therefore less would be released.

- Experimental and field data indicate that actinides would be adsorbed on or incorporated into alteration products that form in the waste package (SNL 2007 [DIRS 181165], Section 6.6.3). This solid solution formation and adsorption would tend to lower actinide concentrations below those predicted by EQ6 and would delay release from the waste package.

- Many conservative modeling approximations are used to simplify the critical mass calculations presented in Table 2.2.14.12.0A-1. For the commercial SNF and low-enriched DOE fuels analyzed in *Geochemistry Model Validation Report: External Accumulation Model* (SNL 2007 [DIRS 181395], the conservatisms are appropriate, because the results show that a criticality event is very unlikely However, for the higher enriched DOE fuels, less conservative modeling parameters of the criticality potential are expected to generate similar conclusions.

Summary—The critical mass limits were evaluated for several waste forms using bounding parameters with regards to optimizing reactivity potential, so the actual masses that would be necessary to achieve criticality would most likely need to be far greater than what was identified (SNL 2007 [DIRS 181395], Section 8.1.4[a]). Model abstractions were performed for commercial SNF and three DOE SNF waste forms and resulted in insufficient fissile material accumulation in the far-field location to pose a criticality concern. Therefore, based on the analyzed waste forms representing the majority (>95% of the total metric tons) of the waste for disposal in the mountain, and considering the conservative modeling parameters discussed above that would be further developed for other DOE representative fuel groups, in conjunction with the probablity of the igneous intrusive initiating event, the probability of near-field criticality is considered insignificant.

Accordingly, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability.

In addition, as documented in *Screening Analysis of Criticality Features, Events, and Processes for License Application* (SNL 2008 [DIRS 173869]), the probability of criticality for all locations is less than 1 chance in 10,000 of occurrence within 10,000 years after disposal. The results documented in this analysis are applicable for all waste forms and waste package variants.

FEP: 2.3.01.00.0A

FEP NAME:

Topography and Morphology

FEP DESCRIPTION:

This FEP is related to the topography and surface morphology of the disposal region. Topographical features include outcrops and hills, water-filled depressions, wetlands, recharge areas and discharge areas. Topography, precipitation, and surficial permeability distribution in the system will determine the flow boundary conditions (i.e., location and amount of recharge and discharge in the system).

SCREENING DECISION:

Included

TSPA DISPOSITION:

Topographical features (such as hillslopes, washes, and ridges), precipitation, and surficial permeability distribution are included in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.5.2[a] and Appendix B[a]), and are incorporated into the MASSIF model (DTN: SN0701T0502206.037 [DIRS 184289]), which is used to model infiltration. Precipitation and surficial permeability distributions are incorporated into the infiltration uncertainty analysis. Ranges of uncertain precipitation, permeability and many other parameters are sampled for simulations that comprise the uncertainty analysis (SNL 2008 [DIRS 182145], Sections 6.5.5 and 6.6[a], and Appendix I). Topography is captured in the MASSIF model (DTN: SN0701T0502206.037 [DIRS 184289]) using data from the Shuttle Radar Topography Mission. The Shuttle Radar Topography Mission dataset of the Yucca Mountain area has absolute errors of 12.6 m in geolocation (which is less than the 30 × 30 m grid cell size) and 7.0 m in height. "Sinks" in topography are filled to enable flow to downslope grid cells (SNL 2008 [DIRS 182145], Section B2.1[a]). This uncertainty in topography is small and not propagated through the TSPA calculations. Any increased localized net infiltration caused by topographical features will have an insignificant effect on seepage as a result of the damping and homogenizing of downward-moving percolation fluxes by the Paintbrush nonwelded hydrogeologic unit (SNL 2007 [DIRS 184614], Section 6.1.2).

The effects of surface construction and characterization activities at the ground surface on topography will be negligible because of the planned reclamation of the site ground surface. As stated in *Reclamation Implementation Plan* (YMP 2001 [DIRS 154386], Section 5.2.2.1), "Recontouring and erosion control practices include backfilling spoil material and grading disturbed sites, so that a stable land form is created that blends with the surrounding topography. Following site decommissioning, disturbed areas will be graded such that the natural drainage pattern (predisturbance drainage) is restored. The sites will be stabilized and recontoured to blend into the natural topography of the area." In addition, reclamation of lands disturbed by the repository is a design constraint listed in *Total System Performance Assessment Data Input*

Package for Requirements Analysis for Subsurface Facilities (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 09-04).

The impacts of topography and morphology on preferential flow/percolation in the unsaturated zone are incorporated into the TSPA through the unsaturated zone flow fields, which use the infiltration model results (DTNs: SN0609T0502206.024 [DIRS 179063], SN0609T0502206.028 [DIRS 178753], and SN0609T0502206.029 [DIRS 178862]) as upper boundary conditions (SNL 2007 [DIRS 184614], Section 6.5.7 and Appendix I). Topographical features from GFM2000 (BSC 2004 [DIRS 170029]) are captured in the unsaturated zone model grid developed in *Development of Numerical Grids for UZ Flow and Transport Modeling* (BSC 2004 [DIRS 169855]) and used in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.1.1). The incorporation of unsaturated zone flow fields into the TSPA is described in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.6).

FEP: 2.3.02.01.0A

FEP NAME:

Soil Type

FEP DESCRIPTION:

Soil type is determined by many different factors (e.g., formative process, geology, climate, vegetation, land use). The physical and chemical attributes of the surficial soils (such as organic matter content and pH) may influence the mobility of radionuclides.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Soil is a feature constituting part of the reference biosphere and is therefore included, consistent with the requirement that FEPs describing the reference biosphere be consistent with present knowledge of the conditions in the Yucca Mountain region (10 CFR 63.305(a) [DIRS 180319]). Soil is the biosphere medium containing the majority of the radionuclide inventory in the reference biosphere. Soil type is included in the biosphere model through the selection of the soil type-dependent values of model input parameters that may influence radionuclide transport to and from the surface soil. Specifically, the soil type is considered in the soil, plant, and ^{14}C submodels of the biosphere model. The characteristics of soils are based, in part, on the characteristics of soil types in northern Amargosa Valley (SNL 2007 [DIRS 179993]).

The biosphere model parameters relevant to soil type are surface soil (tillage) depth (BSC 2004 [DIRS 169673], Section 6.10), soil bulk density (SNL 2007 [DIRS 179993], Section 6.2), partition coefficients (SNL 2007 [DIRS 179993], Section 6.3), surface soil erosion rate (SNL 2007 [DIRS 179993], Section 6.4), enhancement factors for resuspension (SNL 2007 [DIRS 179993], Section 6.5), soil water content (SNL 2007 [DIRS 179993], Section 6.6), irrigation intensity (BSC 2004 [DIRS 169673], Section 6.6), and ^{14}C emission rate from soil (BSC 2004 [DIRS 169672], Section 6.7.1).

As described in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport), tephra redistribution may influence radionuclide transport to, and mobility in, soil at the RMEI location. Soil properties considered in the tephra redistribution model are ash density (SNL 2007 [DIRS 179347], Table 6.4-1) and effective diffusivity (SNL 2007 [DIRS 179347], Section 6.5.8).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario biosphere dose conversion factors (BDCFs), which are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses from the groundwater contamination are calculated as the product of radionuclide concentration in groundwater and the BDCFs. If a volcanic eruption occurs, this FEP is included through BDCFs for the volcanic ash

exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). In the event of a volcanic eruption, the annual doses are calculated as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standards (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards implicitly require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.02.02.0A

FEP NAME:

Radionuclide Accumulation in Soils

FEP DESCRIPTION:

Radionuclide accumulation in soils may occur as a result of upwelling of contaminated groundwater (leaching, evaporation at discharge location), deposition of contaminated water or particulates (irrigation water, runoff), and/or atmospheric deposition.

SCREENING DECISION:

Included

TSPA DISPOSITION:

This FEP focuses on radionuclide accumulation in soils as a result of irrigation with the contaminated water. The potential for radionuclide accumulation in soils as a result of upwelling of contaminated groundwater is discussed in detail in excluded FEP 2.2.08.11.0A (Groundwater Discharge to Surface within the Reference Biosphere). The impacts of air deposition on the accumulation of radionuclides in soil are discussed in included FEP 3.2.10.00.0A (Atmospheric Transport of Contaminants). Radionuclide accumulation in soils resulting from atmospheric deposition is also addressed in included FEP 1.2.04.07.0C (Ashfall) and in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport).

Radionuclide accumulation in soil as a result of long-term irrigation is an integral process in the modeling of biosphere transport of radionuclides. Radionuclide accumulation in soil is accounted for in the soil submodel of the biosphere model for the groundwater exposure scenario by assuming that radionuclides build up in the soil as a result of long-term irrigation (SNL 2007 [DIRS 177399], Section 6.4.1). The concentrations of radionuclides in the soil are calculated as a function of groundwater concentrations; the annual irrigation duration and irrigation rate for crops; and loss by radionuclide decay, leaching, and soil erosion (SNL 2007 [DIRS 177399], Section 6.4.1). This calculation is based on the conservation of the mass of radionuclides in the surface soil. Leaching is included in the soil submodel to account for the residence time of radionuclides in the surface soil and their removal to deeper soil. The leaching rate is a function of the amount of water that percolates below the surface soil (i.e., the overwatering rate that depends on the overall water balance in the surface soil and considers storage capacity of the soil, precipitation, and evapotranspiration), element-specific solid-liquid partition coefficients, and other soil properties (e.g., bulk density, soil porosity, and soil moisture content). In the present-day arid conditions at Yucca Mountain, leaching occurs primarily when irrigation water is added to flush accumulated salts from the surface soil to maintain plant productivity. In wetter climates, such as those predicted to occur in the future at Yucca Mountain, leaching will also occur when excess precipitation flows through the surface soil, primarily during winter. Other mechanisms of radionuclide loss from surface soil, such as runoff, are not directly included in the biosphere model. Soil erosion accounts for the loss of deposited radionuclides from irrigated lands by wind and water erosion. The rate of soil loss from erosion is dependent on soil

characteristics, land use, and stewardship. To incorporate these influences, the minimum soil erosion rate used in the biosphere model was selected based on the soil loss by erosion on noncultivated cropland in Nevada (SNL 2007 179993], Section 6.4).

Radionuclide accumulation in soils is incorporated into the performance assessment calculations through the following parameters: the annual average irrigation rate (BSC 2004 [DIRS 169673], Section 6.5; SNL 2007 [DIRS 177399], Section 6.4.1.1), overwatering rate (BSC 2004 [DIRS 169673], Section 6.9), surface soil depth (tillage depth) (BSC 2004 [DIRS 169673], Section 6.10), soil solid-liquid partition coefficient (SNL 2007 [DIRS 179993], Section 6.3), soil bulk density (SNL 2007 [DIRS 179993], Section 6.2), soil water content (SNL 2007 [DIRS 179993], Section 6.6), surface soil erosion rate (SNL 2007 [DIRS 179993], Section 6.4), irrigation duration (SNL 2007 [DIRS 179993], Section 6.7), and the thickness of the soil layer that can become resuspended (BSC 2004 [DIRS 169672], Section 6.8).

The degree of elemental solubility may have an effect on the rate of removal of radionuclides from soils by leaching, thereby affecting the magnitude and duration of radionuclide accumulation in soil. For the groundwater exposure scenario, where radionuclides are introduced into the biosphere from groundwater use, the solubility limits are not achieved for radionuclides introduced as solutes (i.e., the rate of radionuclide removal from soil by leaching is proportional to the radionuclide concentration in the soil) (SNL 2007 [DIRS 177399], Sections 6.4.1.1 to 6.4.1.3).

Those radionuclides that reach the biosphere irreversibly attached to colloidal particles will not take part in sorption exchange processes with soil and will, therefore, be transported through the soil system without any sorption build-up in soil. Because these radionuclides are not dissolved, they are not available for plant uptake (via soil to plant transfer). However, in the biosphere model, radionuclide transfer from the soil to crops via root uptake is proportional to the radionuclide concentration in the surface soil (SNL 2007 [DIRS 177399], Section 6.4.3.1) (i.e., all radionuclides (solutes and colloids) in groundwater are assumed to be dissolved and available for plant uptake). This is a conservative approach for cases where colloids are present, because the activity associated with colloids is made available for plant uptake.

For the volcanic ash exposure scenario, the mode of radionuclide release into the biosphere is a volcanic eruption through the repository with the resulting entrainment of contaminated waste in the tephra, followed by the atmospheric transport, deposition, and redistribution of radioactive contaminants to the location of the RMEI (SNL 2007 [DIRS 177399], Section 6.12.3). These transport processes, leading to radionuclide accumulation on the soil, are addressed in the atmospheric tephra dispersion and deposition model (SNL 2007 [DIRS 177431]) and in the tephra redistribution model (SNL 2007 [DIRS 179347]). The contaminated tephra transported from the drainage basin, as well as the primary deposit of contaminated tephra at the RMEI location, provide the initial conditions for the redistribution of contaminants in the soil column at the RMEI location. The tephra redistribution model considers the migration of contaminants in the soil as a diffusion process that includes suspension and redeposition of fine particles by infiltration and physical mixing of soil particles by freeze-thaw cycles and bioturbation. The processes of radionuclide accumulation in soil as a result of a volcanic eruption through the repository are addressed in included FEP 1.2.04.07.0A (Ashfall) and in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport).

Radionuclide accumulation in soils is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario biosphere dose conversion factors (BDCFs) that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). In the event of a volcanic eruption, the annual doses are calculated as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standards (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards implicitly require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.02.03.0A

FEP NAME:

Soil and Sediment Transport in the Biosphere

FEP DESCRIPTION:

Contaminated sediments can be transported to and through the biosphere by surface runoff and fluvial processes, and, to a lesser extent, by aeolian processes and bioturbation. Sediment transport and redistribution may cause concentration or dilution of radionuclides in the biosphere.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Soil and sediment transport are processes currently occurring in the Yucca Mountain region, and are included in the TSPA. This is consistent with the requirement that FEPs describing the reference biosphere be consistent with present knowledge of the conditions in the region surrounding the Yucca Mountain site (10 CFR 63.305(a) [DIRS180319]). This FEP is addressed in the soil and air submodels of the biosphere model (SNL 2007 [DIRS 177399], Table 6.7-1). The soil and sediment transport processes are also included in the tephra redistribution model (SNL 2007 [DIRS 179347]) through included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport).

Although the region around Yucca Mountain currently lacks permanent surface water bodies, sediment transport may occur by fluvial processes (e.g., during flash floods). The role of surface water in soil and sediment transport will increase if wetter climate conditions occur in the future. There are several environmental transport processes included in the biosphere model that result in soil and sediment transport. One of these processes is removal of radionuclides from the surface soil by erosion. Soil erosion in agricultural fields is incorporated into the soil submodel for the groundwater exposure scenario in calculation of the surface soil erosion removal rate constant (SNL 2007 [DIRS 177399], Section 6.4.1.4). Soil erosion includes soil loss and gain on farm fields (SNL 2007 [DIRS 179993], Section 6.4). The soil and sediment transport under the wetter climate would result in a greater rate of radionuclide removal from the surface soil than that for the present-day climate. This increased removal of contaminants from the reference biosphere was conservatively not accounted for in the biosphere model.

Bioturbation is the process of sediment or soil mixing by biological activity. However, in the case of a deep geologic repository, bioturbation cannot bring waste to the surface soil layer (see excluded FEP 2.3.09.01.0A (Animal Burrowing/Intrusion)). The process of bioturbation, although not explicitly included in the biosphere model, may contribute to radionuclide mixing in the soil, as modeled in the surface soil submodel of the biosphere model for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.1.1). Bioturbation may also play a

role in radionuclide diffusion in the soil, as represented in the tephra redistribution model (SNL 2007 [DIRS 179347]).

For a volcanic radionuclide release, the soil and sediment transport occurs after contaminated volcanic ash settles to the ground. The tephra redistribution model (SNL 2007 [DIRS 179347]) uses a spatially distributed analysis of hillslopes and channels in the Fortymile Wash drainage basin (upstream of the alluvial fan apex) to estimate the mass of contaminated tephra that is transported from the drainage basin to the alluvial fan by hillslope and fluvial processes. Materials on slopes greater than a specified critical angle and in active channels are mobilized, mixed, and diluted as they are transported toward the RMEI location during flood events. Sediment mixing in channels is estimated with a scour-dilution-mixing model that explicitly includes the vertical mixing of contaminants with uncontaminated channel sediments within the scour zone, and the model is applicable for both tributary and distributary channels like the Fortymile Wash system. The mixing depths in channels are defined by the depths to the tops of the carbonate and clay-rich soil horizons of reduced permeability compared to the active zones (i.e., the depths to the petrocalcic horizon). The contaminated tephra transported from the drainage basin and the primary deposit of contaminated tephra at the RMEI location provide the initial conditions for the redistribution of contaminants in the soil at the RMEI location. The model considers the migration of contaminants in the soil as a diffusion process that includes suspension and redeposition of fine particles by infiltration and physical mixing of soil particles by freeze-thaw cycles and bioturbation. The processes of soil and sediment transport as a result of tephra redistribution are addressed in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport).

Soil and sediment transport is accounted for in the biosphere soil and air submodels as represented by the following parameters: surface soil erosion rate (SNL 2007 [DIRS 179993], Section 6.4), soil bulk density (SNL 2007 [DIRS 179993], Section 6.2), dry deposition velocity (BSC 2004 [DIRS 169672], Section 6.2.2.1), enhancement factor (SNL 2007 [DIRS 179993], Section 6.5), tillage depth (BSC 2004 [DIRS 169673], Section 6.10), and mass loading decrease constant (BSC 2006 [DIRS 177101], Section 6.4). Distributions of the mass loading decrease constants were developed based, in part, on the influence of ash redistribution on changes in mass loading through time (BSC 2006 [DIRS 177101], Section 6.4).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.3.1). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated in TSPA as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standards (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards implicitly require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.04.01.0A

FEP NAME:

Surface Water Transport and Mixing

FEP DESCRIPTION:

Radionuclides released from an underground repository might enter the biosphere through discharge of deep groundwater into a lake or river. Transport and mixing within the surface water bodies affects the subsequent behavior and transport of radionuclides in the biosphere. Transport and mixing includes dilution, sedimentation, aeration, streamflow, and river meander.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The region around Yucca Mountain currently lacks permanent surface water bodies. Future climate forecasts, based on the analysis of paleoclimatic conditions in the Yucca Mountain region (BSC 2004 [DIRS 170002], Section 7.1), indicate that the climate will evolve to a cooler, wetter state over the next 10,000 years, as discussed in included FEP 1.3.01.00.0A (Climate Change). The role of surface water in radionuclide transport will increase if wetter climate conditions occur in the future. However, any surface water that may discharge under future climate states would occur south of the accessible environment (D'Agnese et 1999 [DIRS 120425], Figure 11).

The biosphere model for the groundwater exposure scenario can accomodate surface water transport and mixing because the model applies to the use of any contaminated water, regardless of its origin (surface water body or well), as long as the reference biosphere, water use practices, and the characteristics of the RMEI remain essentially unchanged. The biosphere dose conversion factors (BDCFs) calculated by the biosphere model for the groundwater exposure scenario are developed for unit radionuclide concentration in the water, and therefore the results of biosphere modeling are independent of the actual radionuclide concentration in the water and its origin. Therefore, this FEP is included in the conceptual biosphere model and is considered in the model analogous to included FEP 1.4.07.02.0A (Wells), in the soil, air, plant, animal, fish, ^{14}C, and ingestion submodels (SNL 2007 [DIRS 177399], Table 6.7-1).

The biosphere model conservatively assumes that only contaminated water is used in agriculture, animal husbandry, and for human consumption. This assumption bounds the possible effects of surface water transport and mixing (e.g., as a result of flooding) because such processes would reasonably result in dilution of radionuclide concentrations in the soil.

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model,

which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standards (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards implicitly require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.06.00.0A

FEP NAME:

Marine Features

FEP DESCRIPTION:

This FEP addresses marine and coastal features and processes. Processes include erosion, sedimentation, deposition, sea-level change, and storms.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Considering the location of Yucca Mountain relative to the continental boundaries of the United States (Stuckless and Levich 2007 [DIRS 181507], p. 10), the potential for impact of coastal or marine features and processes on the area around Yucca Mountain is considered to have negligible consequences.

Future climate forecasts based on the analysis of paleoclimatic conditions that have occurred in the Yucca Mountain region (BSC 2004 [DIRS 170002], Section 7.1) indicate that the climate will evolve to a cooler, wetter climate over the next 10,000 years. Monsoon and intermediate (glacial-transition) climate states are forecasted to last until 38,000 years after the present (Sharpe 2003 [DIRS 161591], Table 6-5). Although these climates are cooler and slightly wetter than the present-day interglacial climate, the changes are expected to have no effect on current coastlines relative to Yucca Mountain. Coastline evolution could also occur as a result of tectonic activity. However, the large scale tectonic events that would affect the physical properties of the Yucca Mountain region are not expected to occur, as discussed in exclude FEP 1.2.01.01.0A (Tectonic Activity – Large Scale).

Omission of FEP 2.3.06.00.0A (Marine Features) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.3.09.01.0A

FEP NAME:

Animal Burrowing/Intrusion

FEP DESCRIPTION:

Burrowing animals may intrude into the repository, promoting release and spread of contamination. Burrowing animals may also contact or ingest contaminated soil.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The overburden thickness from the emplacement area to the topographic surface at Yucca Mountain is at least 200 m (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-06). The depth of soil above the bedrock in the immediate vicinity of Yucca Mountain is shallow, with most soils having a median depth of 0.25 m (SNL 2008 [DIRS 182145], Figure 6.5.2.4-1[a] and Table 6.5.2.4-2[a]). A small fraction of soils are categorized as moderately deep and intermediate with median depths of about 12 and 2 m, respectively (SNL 2008 [DIRS 182145], Figure 6.5.2.4-1[a] and Table 6.5.2.4-2[a]). Because the soil depth is a small fraction of the overburden thickness, it is reasonable to conclude that the animal burrows would not extend to the repository level. The observed maximum depth of animal burrows in the arid Yucca Mountain environment is about 3 m for vertebrates (e.g., gophers, moles, ground squirrels, and lizards) and about 10 m for invertebrates (e.g., ants and termites) (Cochran et al. 2001 [DIRS 163189], Section 5.8). Therefore, although burrowing species are known to occur at Yucca Mountain (Cochran et al. 2001 [DIRS 163189], Appendix H; DOE 2002 [DIRS 155970], Section 3.1.5.1.2), it is very unlikely that wildlife will burrow to 200 m or more, and move radioactive waste to the ground surface where it could be subjected to transport by surficial geomorphic processes to the accessible environment.

In the location of the reference biosphere, if burrowing animals come in contact with contaminated soil they can cause bioturbation and thus contribute to the mixing of the contaminants in the soil. Bioturbation is included in the soil submodel of the biosphere model for the groundwater release, where it is assumed that the radionuclide concentration in the surface soil cannot be less than that for the uniformly mixed surface soil (SNL 2007 [DIRS 177399], Section 6.4.1.1). The effect of bioturbation is also included in the tephra redistribution model for igneous eruptive events (SNL 2007 [DIRS 179347]), where this process is considered to contribute to the migration of contaminants in the soil. Bioturbation as a transport process is addressed in included FEP 2.3.02.02.0A (Soil and Sediment Transport in the Biosphere).

If burrowing animals ingest soil, they could potentially enter the food chain of some other species at a higher trophic level. As these animals are primarily rodents (Cochran et al. 2001 [DIRS 163189], Appendix H; DOE 2002 [DIRS 155970], Section 3.1.5.1.2), it is not expected

that this food chain would include humans directly. Therefore, ingestion of contaminated soil by burrowing animals would have a negligible effect on the dose to the RMEI.

Although not specifically discussed in the FEP description, intrusion by bats is potentially relevant to Yucca Mountain because of its location above the water table. Backfill in the shafts and ramps that connect the waste disposal regions with the land surface (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-01) will prevent bat intrusion. Even if such intrusion occurs and bats become contaminated, effects on the dose to the RMEI would be negligible because of the distance from Yucca Mountain to the compliance location and because bats are not expected to significantly contribute to human exposure pathways, including the human food chain.

In summary, animal intrusion directly into the repository is not expected, and even if should it occur, for example, by burrowing animals or bats, the effect on the dose to the RMEI would be negligible. The effects of animal burrowing in contaminated soil at the compliance location would likewise have negligible impact the dose to the RMEI, beyond the indirect effect of soil bioturbation that is included in the biosphere model.

Because omission of FEP 2.3.09.01.0A (Animal Burrowing/Intrusion) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.3.11.01.0A

FEP NAME:

Precipitation

FEP DESCRIPTION:

Precipitation is an important control on the amount of infiltration, flow in the unsaturated zone, seepage into the repository, and groundwater recharge. It transports solutes with it as it flows downward through the subsurface or escapes as runoff. Precipitation influences agricultural practices of the receptor. The amount of precipitation depends on climate.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Precipitation is included in the model of the unsaturated zone above the repository, consistent with the requirements of proposed 10 CFR 63.114(a)(5) (70 FR 53313 [DIRS 178394]), and in the reference biosphere model, consistent with the requirements of 10 CFR 63.305 [DIRS 180319 and DIRS 178394]. Precipitation levels are currently low, ranging from 100 to 250 mm/yr (DOE 2002 [DIRS 155970], Section 3.1.2.2). Future climate forecasts (BSC 2004 [DIRS 170002]) indicate that the climate at Yucca Mountain is predicted to evolve to the cooler, wetter conditions of a glacial transition climate within the first 10,000 years after disposal, as discussed in included FEP 1.3.01.00.0A (Climate Change).

Precipitation affects net infiltration into the unsaturated zone. Water balance, climate, and snowpack are included in *Simulation of Net Infiltration for Present-Day and Potential Future Climate* (SNL 2008 [DIRS 182145], Section 6.4), and precipitation under present-day and potential future climate states is represented in that same report (SNL 2008 [DIRS 182145], Section 6.5.1). Long-term (1,000-year) daily precipitation data are stochastically generated using local site-specific data to generate the precipitation records for the present-day climate and using analogue site data to generate records for the future climate states. A total of 120 realizations of 1,000-year daily precipitation records are generated for three climate states (40 for present-day, 40 for monsoon, and 40 for glacial-transition climate states) (SNL 2008 [DIRS 182145], Section 6.5 and Appendix F[a]). Ten representative years are selected from each of these realizations resulting in 40 10-year precipitation records for each of the three climate states predicted to occur in the first 10,000 years postclosure for use in simulating infiltration using the MASSIF model (SNL 2008 [DIRS 182145], Section 6.4). Long duration, low intensity precipitation events are expected to result in net infiltration while short duration, high intensity precipitation events are expected to result in runoff of surface water. The effect of rainfall intensity on surface water runoff is included in *Simulation of Net Infiltration for Present-Day and Potential Future Climate* (SNL 2008 [DIRS 182145], Section 7.1.3[a]).

The net infiltration map outputs (DTNs: SN0609T0502206.028 [DIRS 178753], SN0609T0502206.024 [DIRS 179063], and SN0609T0502206.029 [DIRS 178862] for

present-day, monsoon, and glacial-transition climates, respectively) are used as a boundary condition for the UZ flow model (SNL 2007 [DIRS 184614], Sections 6.1.3 and 6.1.4). Flow fields developed for use in the TSPA (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) using the UZ flow model, therefore, include the effects of precipitation and changes of precipitation under future climate conditions, including the 10th, 30th, 50th, and 90th percentile maps of infiltration rates for present-day, monsoon, and glacial-transition climate states.

For the period beyond 10,000 years, within the period of geologic stability, the effects of precipitation are accounted for in the distribution of deep percolation rates at the repository horizon for the post-10,000-year period, specified in proposed 10 CFR 63.342(c)(2) (70 FR 53313 [DIRS 178394]). The proposed rule defines the deep percolation rates for that period as represented by a log-uniform probability distribution from 13 to 64 mm/yr. Unsaturated zone flow weighting factors were used to calibrate the UZ model using input from 12 infiltration maps representing the 10th, 30th, 50th, and 90th percentile infiltration scenarios for each of the present-day, monsoon, and glacial-transition climates. The weighting factors were calculated to be 0.62, 0.16, 0.16, and 0.06 for the 10th, 30th, 50th, and 90th percentile infiltration scenarios. The midpoints of these probability ranges for a cumulative probability distribution are at 0.31, 0.70, 0.86, and 0.97, respectively. These midpoints were applied to the log-uniform proposed percolation flux range of 13 to 64 mm/yr, resulting in targets of 21.29, 39.52, 51.05, and 61.03 mm/yr for the 10th, 30th, 50th, and 90th percentile infiltration scenarios, respectively. These midpoints were compared to the average infiltration calculated (over the repository footprint) for the 12 infiltration maps. Four maps were selected that most closely matched the midpoint values. The four infiltration maps that were selected and scaled are: the present-day 90th percentile, the glacial-transition 50th percentile, the glacial-transition 90th percentile, and the monsoon 90th percentile infiltration maps. These maps were scaled so that the average water flux rates through the repository footprint exactly matched the target values at the repository horizon. Once the infiltration boundary condition was determined, the methods used to generate the post-10,000-year flow fields were the same as those used to generate the pre-10,000-year flow fields (SNL 2007 [DIRS 184614], Section 6.1.4).

Although precipitation is not directly used as input to the mathematical biosphere model, it is used to derive the values of parameters, such as leaching rate and irrigation rates, which depend on the overall water balance (SNL 2007 [DIRS 177399], Table 6.2-1). Specifically, precipitation rate, along with irrigation rate and evapotranspiration rate, are used to calculate the overwatering rate (BSC 2004 [DIRS 169673], Section 6.9), a parameter that controls infiltration of water, and thus radionuclide transport, below the root zone. Distributions of parameters were developed based in part on variation and uncertainty in precipitation for the present-day and predicted future climate states (BSC 2004 [DIRS 169673], Sections 6.5 and 6.7 to 6.9).

Within the biosphere model, precipitation is addressed in the soil, plant, and ^{14}C submodels. The relevant parameters are annual average irrigation rate (BSC 2004 [DIRS 169673], Section 6.5), overwatering rate (BSC 2004 [DIRS 169673], Section 6.9), irrigation amount per application (BSC 2004 [DIRS 169673], Section 6.7), and daily irrigation rate (BSC 2004 [DIRS 169673], Section 6.8).

Precipitation is assumed to cause the transport of radioactive waste-contaminated tephra following a potential volcanic eruption through the repository. Precipitation is inherently included in the tephra redistribution model (DOE 2007 [DIRS 179347]), which uses a spatially distributed analysis of hillslopes and channels in the Fortymile Wash drainage basin to provide an estimate of the mass of contaminated tephra that is transported from the drainage basin to the alluvial fan by hillslope and fluvial processes.

The effects of precipitation in the reference biosphere are included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399]). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs.

The effects of precipitation in the reference biosphere are also included in the event of a volcanic eruption through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3) (because the mass loading levels and some agricultural parameters may depend on precipitation) and the radioactive waste concentration in the soil calculated by the tephra redistribution model (SNL 2007 [DIRS 179347]). The annual doses are calculated in the TSPA as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

In summary, precipitation is included in the TSPA model of the geosphere and biosphere transport for the performance assessments that demonstrate compliance with the individual protection standards in proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]). For the human intrusion event (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), only the post-10,000-year conditions are used, because the human intrusion event is not expected to occur before 10,000 years following disposal. For the performance assessment that demonstrates compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]), only those components of this FEP that address the geosphere transport are included.

FEP: 2.3.11.02.0A

FEP NAME:

Surface Runoff and Evapotranspiration

FEP DESCRIPTION:

Surface water runoff and evapotranspiration are components in the water balance, together with precipitation, infiltration, and change in soil water storage. Surface runoff produces erosion, and can feed washes, arroyos, and impoundments, where flooding may lead to increased recharge. Evapotranspiration removes water from soil and rock by evaporation and transpiration via plant root water uptake.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Evapotranspiration and surface runoff affect net infiltration, as discussed in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145], Section 6.4). The net infiltration map outputs (DTNs: SN0609T0502206.028 [DIRS 178753], SN0609T0502206.024 [DIRS 179063], and SN0609T0502206.029 [DIRS 178862]) are used as a boundary condition for the UZ flow model (SNL 2007 [DIRS 184614], Sections 6.1.3 and 6.1.4). Flow fields developed for use in the TSPA (DTNs: LB0612PDFEHMFF.001 [DIRS 179296], LB0701MOFEHMFF.001 [DIRS 179297], LB0701GTFEHMFF.001 [DIRS 179160], and LB0702PAFEM10K.002 [DIRS 179507]) using the UZ flow model, therefore, include the effects of runoff and evapotranspiration under present-day and future climate conditions. Four infiltration maps for each of the four climate states (present-day, monsoon, glacial transition, and post-10,000-year climate state) were used as boundary conditions for the calculation of the flow fields for TSPA. The four maps correspond to the 10th, 30th, 50th, and 90th percentiles of average annual net infiltration realizations for the present-day, monsoon, and glacial-transition climate states. For the post-10,000-year period, net infiltration maps representing present-day 90th percentile, glacial-transition 50th percentile, glacial-transition 90th percentile, and monsoon 90th percentile, respectively, are used to represent the four infiltration realizations.

FEP: 2.3.11.03.0A

FEP NAME:

Infiltration and Recharge

FEP DESCRIPTION:

Infiltration into the subsurface provides a boundary condition for groundwater flow in the unsaturated zone. The amount and location of the infiltration influences the amount of seepage entering the drifts; and the amount and location of recharge influences the height of the water table, the hydraulic gradient, and therefore specific discharge. Different sources of infiltration could change the composition of groundwater passing through the repository. Mixing of these waters with other groundwaters could result in mineral precipitation, dissolution, and altered chemical gradients in the subsurface.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Infiltration—The infiltration process is simulated by the net infiltration model MASSIF, described in *Simulation of Net Infiltration for Present-Day and Potential Future Climates* (SNL 2008 [DIRS 182145]). This model includes the effects of seasonal and climate variations, climate change, evapotranspiration, surface-water runoff, and site topography such as hill slopes and washes to simulate the spatial distribution of infiltration. The time dependence of infiltration results is linked to the timing of climate change, as discussed in included FEP 1.3.01.00.0A (Climate Change). The infiltration model output is in the form of infiltration maps that are used to propogate infiltration uncertainty through to the TSPA results.

The results of the infiltration model (infiltration maps) provide input to the unsaturated zone flow model, which simulates the spatial distribution of percolation fluxes within the unsaturated zone. Specifically, the UZ flow model uses the infiltration results as the top boundary condition for unsaturated zone flow calculations (SNL 2007 [DIRS 184614], Section 6.1.4). A total of 16 unsaturated zone flow fields are used in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478], Section 6.3.1.3). The flow conditions at the top boundary of the UZ flow model are provided from twelve net infiltration maps (four maps for the present-day, monsoon, and glacial-transition climate states that correspond to the 10th, 30th, 50th, and 90th percentile infiltration scenarios for each of these climate states) and four maps for the period from 10,000 years postclosure to the time of geologic stability. Unsaturated zone flow weighting factors were used to calibrate the probabilities of the infiltration boundary conditions in the UZ model using input from the present-day infiltration maps. The weighting factors were calculated to be 0.62, 0.16, 0.16, and 0.06 for the 10th, 30th, 50th, and 90th percentile infiltration scenarios, respectively. The midpoints of these probability ranges for a cumulative probability distribution are at 0.31, 0.70, 0.86, and 0.97, respectively (SNL 2007 [DIRS 184614], Section 6.1.4).

For the post-10,000-year period, proposed rule 10 CFR 63.342(c) (70 CFR 53313 [DIRS 178394]) defines the deep percolation rates for that period as based on a log-uniform probability distribution from 13 to 64 mm/yr. This distribution was divided into four intervals to develop four flow fields that most closely matched target rates based on the proposed rule. The midpoint of each interval was used to represent the average flux for the given flow field. The four midpoint values are 21.29, 39.52, 51.05, and 61.03 mm/yr (SNL 2007 [DIRS 184614], Table 6.1-3). Four corresponding net infiltration maps representing present-day 90th percentile, glacial-transition 50th percentile, glacial-transition 90th percentile, and monsoon 90th percentile, respectively, are used to represent these intervals. Net infiltration for these four cases was scaled so that the average water flux through the repository footprint matched the target values (interval midpoints) at the repository horizon. Once the infiltration boundary condition was determined, the method used to generate the post-10,000-year flow fields was the same as that used to generate the pre-10,000-year flow fields (SNL 2007 [DIRS 184614], Section 6.1.4).

Percolation fluxes are used to calculate seepage fluxes into the repository, condensation onto the drift walls, evolution of thermal-hydrologic and chemical conditions in the unsaturated zone and repository, and radionuclide transport from the repository to the saturated zone. These processes are all affected by changes in infiltration and are discussed in more detail in other FEPs (e.g., included FEP 1.3.01.00.0A (Climate Change)).

The effects of present-day water composition infiltrating from the ground surface are accounted for in the analysis of seepage-water chemistry by using the measured pore-water chemistry in the unsaturated zone (SNL 2007 [DIRS 177404], Table 6.2-1). However, pore-water chemistry varies by hydrologic unit (SNL 2007 [DIRS 177404], Figure 6.2-4). Variation in the composition of infiltrating water is dominated by rock–water interaction.

Recharge—Recharge to the saturated zone is important because it impacts transport time of radionuclides that could potentially escape from the repository. The hydrological effects of recharge are included in *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]). The recharge to the flow model was derived from three sources: *Death Valley Regional Ground-Water Flow System, Nevada and California - Hydrogeologic Framework and Transient Ground-Water Flow Model* (Belcher 2004 [DIRS 173179]), *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614]), and Fortymile Wash data (Savard 1998 [DIRS 102213]). Recharge from the UZ site-scale model (percolation flux) was taken as the flow through the base of that model, the domain of which includes approximately 40 km^2 (19.3 mi^2) that encompasses only the footprint of Yucca Mountain, a very small fraction of the saturated zone model domain. The technique for estimated recharge from all three sources is summarized here:

- The distributed vertical recharge, limited to the northernmost portion of the SZ site-scale flow model domain for areas not covered by the unsaturated zone model domain and forty-mile wash, was extracted from the 2004 SZ regional-scale flow model (DTN: MO0602SPAMODAR.000 [DIRS 177371]).

- The recharge through each node of the UZ flow model is extracted and the corresponding recharge to the saturated zone site-scale flow model node was calculated. This is necessary because the UZ flow model grid is finer than the saturated zone site-scale grid.

- Estimates of recharge from the infiltration of surface flows in Fortymile Wash are given by linear reaches (discrete segments) along the wash. Recharge estimates were interpolated to at least a 500-m (1,640-ft) -wide recharge zone for most of the wash and a broader area of tributary channels in the Amargosa Desert (BSC 2004 [DIRS 170015], Table 6-3, Figure 6-6).

Details as to how recharge to the saturated zone site-scale flow model is calculated are described in *Recharge and Lateral Groundwater Flow Boundary Conditions for the Saturated Zone Site-Scale Flow and Transport Model* (BSC 2004 [DIRS 170015], Sections 6.5 and 6.7).

The effects of present-day water composition entering the saturated zone from recharge are accounted for in the analysis of water chemistry described in Appendices A and B of *Saturated Zone Site-Scale Flow Model* (SNL 2007 [DIRS 177391]) and the site-scale saturated zone transport model (SNL 2008 [DIRS 184806]).

This FEP is included in the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319]. Groundwater protection requirements specified in 10 CFR 63.331 [DIRS 180319] are only applicable to the 10,000-year period after disposal. Therefore, the post-10,000-year climate is not included in the performance assessment conducted to evaluate compliance with the groundwater protection requirements.

FEP: 2.3.11.04.0A

FEP NAME:

Groundwater Discharge to Surface Outside the Reference Biosphere

FEP DESCRIPTION:

Radionuclides transported in groundwater as solutes or solid materials (colloids) from the far-field may discharge at specific "entry" points that are outside the reference biosphere. Natural surface discharge points, including those resulting from water table or capillary rise, may be surface water bodies (rivers, lakes), springs, wetlands, holding ponds, or unsaturated soils.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The reference biosphere is defined as the description of the environment inhabited by the RMEI (10 CFR 63.2 [DIRS 180319]). The postclosure individual protection standard is formulated in terms of annual dose limits to the RMEI (proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). Only those FEPs that affect the reference biosphere can affect the RMEI and, thereby, be included in the performance assessment. Therefore, groundwater discharge to the surface outside the reference biosphere is excluded by regulation.

FEP: 2.3.13.01.0A

FEP NAME:

Biosphere Characteristics

FEP DESCRIPTION:

The principal components, conditions, or characteristics of the biosphere system can influence radionuclide transport and affect the long-term performance of the disposal system. These include the characteristics of the reference biosphere such as climate, soils and microbes, flora and fauna, and their influences on human activities.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consideration of FEPs that describe the reference biosphere, and which are consistent with present knowledge of the conditions in the region surrounding Yucca Mountain, is required under 10 CFR 63.305(a) [DIRS 180319]. Biosphere characteristics based on cautious but reasonable assumptions consistent with present knowledge of potential changes in geology, hydrology, and climate are included in accordance with proposed 10 CFR 63.305(c) (70 FR 53313 [DIRS 178394]). Therefore, this FEP is included, consistent with the requirements of these regulatory sections.

Both the individual protection requirements (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the individual protection requirements for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) limit dose to the reasonably maximally exposed individual (RMEI). By definition, the RMEI lives in the reference biosphere (10 CFR 63.102(i) [DIRS 180319]). Therefore, biosphere characteristics are included in the performance assessments to demonstrate compliance with the individual protection and human intrusion requirements. In contrast, the groundwater protection standards do not limit the dose to the RMEI (10 CFR 63.331 [DIRS 180319]); therefore, this FEP is not included in the performance assessment to demonstrate compliance with the groundwater protection standard. The dose from drinking 2 liters of water per day from the representative volume is calculated by using a required daily consumption rate of water (10 CFR 63.331 [DIRS 180319]) without regard to the characteristics of the biosphere and the RMEI.

Biosphere characteristics encompass the principal components, conditions, and characteristics of the reference biosphere that influence contaminant transport from the point of release into the accessible environment to the receptor. This FEP includes the natural environment (e.g., climate, soils, flora, and fauna) and human activities, such as land and water use. The relationships among these components form the foundation of the biosphere model (SNL 2007 [DIRS 177399], Section 6.3.4). Some of these characteristics, particularly those relating to the soils, are also included in the tephra redistribution model (SNL 2007 [DIRS 179347]) (see included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport)).

Distributions of parameter values were developed based in part on variation and uncertainty in site-specific characteristics of the reference biosphere, such as temperature, wind speed, and evaporation rate (BSC 2004 [DIRS 169673], Sections 6.4 to 6.9; BSC 2005 [DIRS 172827], Section 6.3.4.2; BSC 2004 [DIRS 169672], Sections 6.2.2.1, 6.4.3, 6.5.2, and 6.7.2). This FEP is addressed in the soil, air, plant, animal, fish, inhalation, and ^{14}C submodels (SNL 2007 [DIRS 177399], Table 6.7-1) through many parameters, such as the annual average irrigation rate (BSC 2004 [DIRS 169673], Section 6.5), overwatering rate (BSC 2004 [DIRS 169673], Section 6.9), water evaporation rate (use rate) for evaporative coolers (BSC 2004 [DIRS 169672], Section 6.5.2), dry deposition velocity (BSC 2004 [DIRS 169672], Section 6.2.2.1), daily irrigation rate (BSC 2004 [DIRS 169673], Section 6.8), irrigation application (BSC 2004 [DIRS 169673], Section 6.7), irrigation intensity (BSC 2004 [DIRS 169673], Section 6.6), growing time (BSC 2004 [DIRS 169673], Section 6.4), water concentration modifying factor (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.5), annual average wind speed (BSC 2004 [DIRS 169672], Section 6.7.2), and evaporative cooler use factor (BSC 2005 [DIRS 172827], Section 6.3.4.2). Additional biosphere characteristics are covered by other included FEPs, such as FEP 1.3.01.00.0A (Climate Change), FEP 2.3.02.01.0A (Soil Type), and FEP 2.3.11.01.0A (Precipitation).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. Such an approach is possible because quantities calculated in the groundwater exposure scenario submodels of the biosphere model, including radionuclide concentrations in the environmental media and the annual dose from various exposure pathways, are proportional to the radionuclide concentration in the groundwater (SNL 2007 [DIRS 177399], Section 6.4.10.2). Thus, for this exposure scenario, the biosphere model contribution to the dose assessment (i.e., BDCFs) can be separated from the source (i.e., radionuclide concentration in the groundwater). The BDCF for a radionuclide is numerically equal to the dose for a unit activity concentration of the radionuclide in the water (SNL 2007 [DIRS 177399], Section 6.4.10.2).

In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses calculated in the event of a volcanic eruption depend primarily on radionuclide concentration in soil contaminated by radionuclides in volcanic tephra and the BDCFs. Because variation in radionuclide concentrations in the soil contaminated by deposited and redistributed volcanic tephra is not part of the biosphere model, BDCFs are calculated based on a unit radionuclide concentration in the soil (1 Bq/m^2 and 1 Bq/kg, depending on the exposure pathway) (SNL 2007 [DIRS 177399], Section 6.5). The TSPA model calculates radiation dose as a product of the time-dependent source terms, the source-independent BDCFs, and the mass loading time decay function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into

TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.13.02.0A

FEP NAME:

Radionuclide Alteration During Biosphere Transport

FEP DESCRIPTION:

Once in the biosphere, radionuclides may be transported and transferred through and between different compartments of the biosphere. Temporally and spatially dependent physical and chemical environments in the biosphere may lead to alteration of both the physical and chemical properties of the radionuclides as they move through or between the different compartments of the biosphere. These alterations could consequently control exposure to the human population.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The biosphere model is constructed around the radionuclide transfer interaction matrix (SNL 2007 [DIRS 177399], Sections 6.3.1.3 and 6.3.2.3, for the groundwater and volcanic ash exposure scenarios, respectively), which is constructed to identify the important processes leading to radionuclide transfer between biosphere components. Most of these transfer processes involve the change of physical and chemical forms of a radionuclide (alteration). Examples of processes involving the change of the physical form of radionuclides include the release of ^{14}C, initially present in groundwater, from the soil to the air as $^{14}CO_2$ (SNL 2007 [DIRS 177399], Section 6.4.6) and from the surface water (fish ponds) to the air (BSC 2004 [DIRS 169672], Section 6.4.4), the plant uptake of carbon dioxide from the air (SNL 2007 [DIRS 177399], Section 6.4.6.3), and release of gaseous species during operation of evaporative coolers (SNL 2007 [DIRS 177399], Section 6.4.2.2).

This FEP is also implicitly implemented through the use of element-specific partition coefficients (SNL 2007 [DIRS 179993], Section 6.3), radionuclide-specific and crop-type-specific soil-to-plant transfer factors (BSC 2004 [DIRS 169672], Section 6.2.1.2), correlation coefficients for the partition coefficients and transfer factors (BSC 2004 [DIRS 169672], Section 6.2.1.5), and radionuclide-specific and animal-product-specific transfer factors (BSC 2004 [DIRS 169672], Section 6.3.3) in the plant and animal submodels, respectively, as identified in *Biosphere Model Report* (SNL 2007 [DIRS 177399], Sections 6.4 and 6.5). In addition, this FEP is implemented in the following parameters: bioaccumulation factor for aquatic food (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.4), water concentration modification factor for fishpond water (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.5), fraction of radionuclides in evaporative cooler water transferred to air (BSC 2004 [DIRS 169672], Section 6.5.2), carbon emission rate constant for soil (BSC 2004 [DIRS 169672], Section 6.7.1), and fraction of air-derived and soil-derived carbon in plants (BSC 2004 [DIRS 169672], Section 6.7.3).

Radionuclide alteration during redistribution of volcanic tephra following a volcanic eruption (SNL 2007 [DIRS 179347]) is addressed in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. This FEP is also included in the TSPA volcanic eruption modeling case through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated in this TSPA modeling case as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the reasonably maximally exposed individual (RMEI) for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standards (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards implicitly require including the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because this standard does not require including the reference biosphere in the performance assessment calculations.

FEP: 2.3.13.03.0A

FEP NAME:

Effects of Repository Heat on the Biosphere

FEP DESCRIPTION:

Heat released from radioactive decay of the waste may increase the temperatures at the surface above the repository. This could result in local or extensive changes in the ecological characteristics.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

The only effect on repository performance of an increase in surface heating due repository thermal loading is a possible change of net infiltration due to changes in vegetation at the surface above the repository footprint. The following paragraphs show that this FEP can be excluded based on low consequence because the change in future net infiltration rates due to ecological changes from repository heating will be much smaller than the range of infiltration rates already included in TSPA.

The approach to predicting temperature changes near the surface is to determine the flux of repository-generated heat, multiply by depth, and divide by the thermal conductivity (Carslaw and Jaegar 1959 [DIRS 100968], Equation 2):

$$\Delta T = \frac{Q \Delta z}{AK} \qquad \text{(Eq. 2.3.13.03.0A-1)}$$

where Q/A is the heat flux (W/m^2), Δz is depth (m), and K is thermal conductivity of the near-surface (W/m-K). The heat flux is determined from a one-dimensional "SDT" submodel of the multiscale model (SNL 2008 [DIRS 184433], Section 6.2.15[a]), by examining the temperature difference across the top (rock) model layer (the tcw12 hydrostratigraphic unit). The STD submodel used in this calculation applied the thermal loading equivalent to the postclosure thermal reference case (SNL 2008 [DIRS 184433], Section 6.2.4). A maximum heat flux of 0.4 W/m^2 through this layer is calculated using the layer thickness (10.122 m) and its thermal conductivity (1.81 W/m-K) (Figure 2.3.13.03.0A-1). The greatest change in surface temperature will occur when the flux of heat upward to the surface is greatest, which is predicted to occur approximately 1,700 years after closure (Figure 2.3.13.03.0A-1; based on calculations reported in DTN: LL0702PA013MST.068 [DIRS 180553], files: /SDT/SDT55/*P3W-13-g_SDT55-03.ext* and /include_overall/*SDT-1Dds-06*, SDT submodel, output for node g3) corresponding to the monsoonal climate state (SNL 2008 [DIRS 183478], Section 6.3.1.2). Equation 2.3.13.03.0A-1 computes only the temperature change at the surface when a repository is present. The air temperature at the ground surface does not change greatly from ambient conditions due to

repository heating because the heat flux from the repository (0.4 W/m^2) is small compared to the average solar insolation at Yucca Mountain. For instance, in 2006, an annual averge solar flux at the meteorological monitoring station at Site 9 was 255 W/m^2 (DTN: MO0706METMND06.000 [DIRS 181887], parameter SOLAR_M in table for Site 9). Because the heat equation, which determines heat flow through rock or soil at the repository, is linear, temperature changes due to sources may be superimposed (added). As the surface temperature does not change much in response to the repository heat, the temperature change computed from Equation 2.3.13.03.0A-1 may be used to compute the temperature change due to the repository heat source at points below the surface.

Infiltration values averaged over the infiltration model domain for the monsoonal climate state range from 5 to as much as 80 mm/yr, a factor of 16 (DTN: SN0609T0502206.024 [DIRS 179063], file: *Monsoon_R1-R2_Parameter_Inputs.xls*). In field observations at Yucca Mountain during active transpiration periods, shrubs removed about 31% of the total precipitation that fell during the period studied (with a range of 12% to 54% at the seven study locations exhibiting a full range of plant species common to the region) (CRWMS M&O 1999 [DIRS 105031], Executive Summary). Total shrub cover at the sites ranged from about 8% to 16% (CRWMS M&O 1999 [DIRS 105031], Figure 9). An analysis of the percentage of shrub cover and of soil temperature at a depth of 45 cm suggests that for each 1°C increase in temperature, the shrub cover decreases by 1.2% and that of annual grasses increases by 5.5% (CRWMS M&O 1999 [DIRS 105031], Section 3.3). The grass species currently found at each of the study sites (*Bromus rubens*) increased coverage by 2.3% for every 1°C increase. This focus only on the effects of shrub loss due to increasing temperature, neglecting the increase in grass species, as a conservative approach for bounding the effect of repository heating.

Applying Equation 2.3.13.03.0A-1 with a shrub root depth range of 0.5 to 2 m (CRWMS M&O 1999 [DIRS 105031], p. 5), with K = 1.81 W/m-K, gives a temperature change in the range 0.11°C to 0.44°C. For a near-surface soil with K = 0.18 W/m-K (typical of unsaturated sand; averaging the three recent values from Table 5.5 of Jury et al. 1991 [DIRS 102010] and converting units), the predicted temperature change is in the range 1.1°C to 4.4°C. This result is a slight overestimate because the heat flux is calculated by fixing the surface temperature, and because convective and evaporative mechanisms of heat exchange (which tend to attenuate temperature increases at the surface) are not considered.

Applying the maximum temperature change of 4.4°C (computed at a depth of 2 m) and using the 1.2% per °C scrub cover loss relationship of *Final Report: Plant and Soil Related Processes Along a Natural Thermal Gradient at Yucca Mountain, Nevada* (CRWMS M&O 1999 [DIRS 105031], Section 3.3), the resulting percent cover of shrubs could decrease by a maximum of about 5.3% (i.e., 1.2% change per °C, multiplied by 4.4°C). Noting that transpiration by shrubs is only part of the total evapotranspiration that determines net infiltration, the reported values for percentage of shrub cover are used to further constrain the thermally driven changes in net infiltration as shown in Table 2.3.13.03.0A-1. Multiplying the reduction in shrub coverage by the fraction of total evapotranspiration attributed to shrubs (CRWMS M&O 1999 [DIRS 105031], Executive Summary and Figure 9) yields the reduction in evapotranspiration due to repository heating for sites corresponding to the lower, mean, and upper bounds of scrub cover (CRWMS (1999 [DIRS 105031], Executive Summary). The

maximum in Table 2.3.13.03.0A-1, 2.9%, is insignificant compared to the factor of 16 difference between the low and high monsoon infiltration rates used in TSPA.

The results in Table 2.3.13.03.0A-1 are conservative in that they do not account for the offsetting contribution to evapotranspiration from the increase in coverage by annual grasses (i.e., 2.3% increase in annual grasses for each 1°C). Additionally, any shifts in plant species are expected to be transient, and would potentially reverse as the repository cooled with time. Also, studies indicate that the resulting temperature changes will be within the adaptive range of some plant species now at Yucca Mountain (CRWMS M&O 1999 [DIRS 105031], Figure 8 and p. 41). For example, *Final Report: Plant and Soil Related Processes Along a Natural Thermal Gradient at Yucca Mountain, Nevada* (CRWMS M&O 1999 [DIRS 105031], Figure 8 and p. 20) notes that big sagebrush presently grows most abundantly at mid-elevation sites with moderate soil temperatures (+0.5 – 2°C at 45-cm depth compared to Yucca Mountain) and white bursage grows at lower elevation sites with (+2 – 3.5°C at 45-cm depth compared to Yucca Mountain). These shrubs may replace shrubs that die out due to increased temperature above the repository. Ground surface temperature increases may cause snow to melt more readily than predicted by the infiltration model. However, since sublimation represents such a a small fraction of the water budget during the glacial transition climate, such an effect would not significantly increase net infiltration (SNL 2008 [DIRS 182145], Table 6.5.7.4-3). Thus, expected increases in infiltration would be significantly less than stated above and insignificant compared to the uncertainty and variability in infiltration that are included in the TSPA model.

Based on the above discussion, exclusion of FEP 2.3.13.03.0A (Effects of Repository Heat on the Biosphere) will not result in a significant adverse change in the magnitude or time of radiological exposures to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 2.3.13.04.0A

FEP NAME:

Radionuclide Release Outside the Reference Biosphere

FEP DESCRIPTION:

Radionuclide releases outside the reference biosphere can occur. This could include areas surrounding distant springs and surface water bodies (such as at Ash Meadows), remote natural outfalls, discharge areas such as playas (e.g. Franklin Lake Playa), or forests, grasslands, or wetlands that occur in isolated areas in the region. This might also include withdrawal from wells in remote areas. Radionuclide accumulation could occur in these areas. Sediment transport and redistribution may cause concentration or dilution of radionuclides. Flora and fauna in these areas may be exposed and radionuclides be bioaccumulated and enter the food chain. Intermittent use of these areas by humans may also lead to exposure.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The reference biosphere is defined as the description of the environment inhabited by the RMEI (10 CFR 63.2 [DIRS 180319]). FEPs that describe the reference biosphere are those that affect the dose to the RMEI. The postclosure individual protection standards are formulated in terms of annual dose limits to the RMEI (proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). Only those FEPs that affect the reference biosphere can affect the RMEI and, thereby, be included in the performance assessment. Therefore, radionuclide release outside the reference biosphere is excluded by regulation.

FEP: 2.4.01.00.0A

FEP NAME:

Human Characteristics (Physiology, Metabolism)

FEP DESCRIPTION:

This FEP addresses human characteristics. These include physiology, metabolism, and variability among individual humans.

SCREENING DECISION:

Included

TSPA DISPOSITION:

A hypothetical human receptor, the RMEI, is used in the performance assessment calculations for both the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])). Characteristics of the RMEI are representative of the physiology and metabolic characteristics of adults, consistent with 10 CFR 63.312(e) [DIRS 180319], which specifies that the RMEI is an adult. As a result, consideration is limited to the physiology and metabolic characteristics of adults. Elements of human physiology and metabolism are inherent in the dose coefficients for radionuclide intakes used in the biosphere model (SNL 2007 [DIRS 177399], Sections 6.4.7.2, 6.4.8.5, 6.4.9.6, and 6.5.5.2) and in the breathing rates (BSC 2005 [DIRS 172827], Section 6.3.3), which are based on adult human physiologic and metabolic characteristics. These parameters are used, and thus this FEP is addressed, in the external exposure, inhalation, and ingestion submodels (SNL 2007 [DIRS 177399], Table 6.7-1) to calculate the values of BDCFs. This FEP is also considered in the discussion of the dependence of inhalation dose coefficients on particle sizes (BSC 2005 [DIRS 172827], Section 6.5.5). Variability among individual humans adds to the uncertainty in the values of parameters that depend on human characteristics, such as dose coefficients. Uncertainty in these parameters is discussed in *Biosphere Model Report* (SNL 2007 [DIRS 177399], Section 6.6.3).

The groundwater protection standards (10 CFR 63.331 [DIRS 180319]) do not use the concept of the RMEI, but require an estimation of the dose from ingesting 2 liters per day of contaminated water. Physiology and metabolism of the human receptor are considered in the biokinetic models that are used to develop dose coefficients for ingestion. These dose coefficients are used as inputs in calculation of the conversion factors used in the performance assessment for demonstration of compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3), and through the use of the conversion factors for demonstrating compliance with the

groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs or conversion factors. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessments to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])), the individual protection standards for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])), and with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]).

FEP: 2.4.04.01.0A

FEP NAME:

Human Lifestyle

FEP DESCRIPTION:

Human lifestyle, including everyday household activities and leisure activities, will influence the critical exposure pathways to humans.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Work and leisure activities included in the TSPA are representative of the current residents of Amargosa Valley. This is consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the lifestyle of the RMEI must be based on the people who reside in Amargosa Valley. Human lifestyle information is used to select values for exposure parameters, which, in addition to food and water consumption rates (included FEP 3.3.04.01.0A (Ingestion)), include the amount of time spent indoors and outdoors for work and recreation. The current lifestyle also includes certain uses of wild and natural resources (e.g., hunting and consumption of game products) (see included FEP 2.4.08.00.0A (Wild and Natural Land and Water Use)), but it is not intended to represent the hunter/gatherer lifestyle. This FEP is considered in the air, external exposure, inhalation, and ingestion submodels of the biosphere model (SNL 2007 [DIRS 177399], Table 6.7-1).

Distributions of the parameters related to human lifestyle are based, in part, on variation and uncertainty in the lifestyles and characteristics of people living in Amargosa Valley (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3; BSC 2005 [DIRS 172827], Sections 6.3 and 6.4). Influence of human lifestyle on external exposure is considered in the biosphere models for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Equation 6.4.7-1) and for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Equation 6.5.5-1). Influence of human lifestyle on inhalation pathway is also considered in both models (SNL 2007 [DIRS 177399], Equations 6.4.8-2 to 6.4.8-7 for the groundwater exposure scenario; SNL 2007 [DIRS 177399], Equations 6.5.6-2 and 6.5.6-3 for the volcanic ash exposure scenario). Similarly, influences on the ingestion pathway are considered in both models (SNL 2007 [DIRS 177399], Equations 6.4.9-2 to 6.4.9-6 for the groundwater exposure scenario; SNL 2007 [DIRS 177399], Equations 6.5.7-2 to 6.5.7-4 for the volcanic ash exposure scenario). The following parameters address this FEP: mass loading for receptor environments (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3), population proportion (BSC 2005 [DIRS 172827], Section 6.3.1), and exposure time (BSC 2005 [DIRS 172827], Section 6.3.2). The consumption rates of locally produced food are addressed in included FEP 3.3.04.01.0A (Ingestion).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes

involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in the soil contaminated by radionuclides in volcanic tephra and the BDCF components. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI in the performance assessment calculations.

FEP: 2.4.07.00.0A

FEP NAME:

Dwellings

FEP DESCRIPTION:

This FEP addresses human dwellings, and the ways in which dwellings might affect human exposures. Exposure pathways might be influenced by building materials and location.

SCREENING DECISION:

Included

TSPA DISPOSITION:

The choice of dwellings is one of the attributes of a lifestyle (see included FEP 2.4.04.01.0A (Human Lifestyle)). Characteristics of dwellings that are included in the TSPA are representative of the residences of Amargosa Valley, consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the lifestyle of the RMEI must be based on the people who reside in the Town of Amargosa Valley. The location of dwellings that are included in the TSPA model is consistent with the location of the RMEI, above the highest concentration of radionuclides in the groundwater plume of contamination (10 CFR 63.312(a) [DIRS 180319]).

This FEP is incorporated into the biosphere model through consideration of the characteristics of the dwellings in Amargosa Valley and their effects on the inhalation and external exposure pathways. Data from *The 1997 "Biosphere" Food Consumption Survey Summary Findings and Technical Documentation* (DOE 1997 [DIRS 100332], Table 2.4.2) indicate that the predominant housing type is manufactured housing and that most residences have evaporative coolers. This information was used in selecting values for several pertinent parameters such as ventilation rate, evaporative cooler use factor, and evaporative cooler water evaporation rate. This FEP is addressed in the air, inhalation, and external exposure submodels by including characteristics of the dwellings in Amargosa Valley and their effects on the inhalation and external exposure pathways (SNL 2007 [DIRS 177399], Tables 6.2-1 and 6.7-1).

The parameter distributions used in the biosphere model are based, in part, on uncertainty and variation in the characteristics of types of dwellings in Amargosa Valley (BSC 2005 [DIRS 172827], Sections 6.3.4.1, 6.3.4.2, and 6.6; BSC 2004 [DIRS 169672], Sections 6.5.2 and 6.6.2). Specifically, this FEP is addressed through the following parameters: evaporative cooler water evaporation rate (BSC 2004 [DIRS 169672], Section 6.5.2), evaporative cooler air flow rate (BSC 2004 [DIRS 169672], Section 6.5.2), interior wall height (BSC 2004 [DIRS 169672], Sections 6.5.2 and 6.6.2), house ventilation rate (BSC 2004 [DIRS 169672], Section 6.6.2), correlation coefficient for airflow and water use in evaporative coolers (BSC 2004 [DIRS 169672], Section 6.5.2), building shielding factor (shielding provided by building materials) (BSC 2005 [DIRS 172827], Section 6.6), fraction of houses with evaporative coolers (BSC 2005 [DIRS 172827], Section 6.3.4.1), and evaporative cooler use factor (BSC 2005 [DIRS 172827], Section 6.3.4.2).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenarios (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides, volcanic tephra, and the BDCF components. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI in the performance assessment calculations.

FEP: 2.4.08.00.0A

FEP NAME:

Wild and Natural Land and Water Use

FEP DESCRIPTION:

Human uses of wild and natural lands (forests, bush, coastlines) and water (lakes, rivers, oceans) may affect the long-term performance of the repository. Wild and natural land use will be primarily controlled by natural factors (topography, climate, etc.).

SCREENING DECISION:

Included

TSPA DISPOSITION:

The lifestyle and behavior of the current residents of Amargosa Valley implicitly include certain uses of wild and natural lands and water. Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, future uses of wild and natural lands and water are assumed to be the same as the current uses.

This FEP is incorporated in the biosphere model by combining the consumption of game with the consumption rate for all meats, and by considering the time the RMEI spends in the outdoor environment (SNL 2007 [DIRS 177399], Sections 6.4.4 and 6.4.7). This FEP is addressed in the air, external exposure, inhalation, and ingestion submodels of the biosphere model. The parameters that address this FEP are mass loading for receptor environments (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3), exposure time (BSC 2005 [DIRS 172827], Section 6.3.2), and annual consumption rate of locally produced animal products (BSC 2005 [DIRS 172827], Sections 6.4 and 6.4.2). Parameter distributions were developed and based in part on uncertainty and variation in the use of wild and natural lands, and the rate of consumption of wild game by the receptor (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3; BSC 2005 [DIRS 172827], Sections 6.3.2 and 6.4.2).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399],

Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI in the performance assessment calculations.

FEP: 2.4.09.01.0A

FEP NAME:

Implementation of New Agricultural Practices or Land Use

FEP DESCRIPTION:

Agricultural land use depends on many interrelated factors including climate, geology, topography, human lifestyle, and economics. Land use may include practices such as traditional crop farming, greenhouses, and hydroponics. Agricultural practices have the potential for radionuclide transfer through the food chain and may influence alternate pathways. Changes in current agricultural practices could change the significance of various exposure pathways.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

10 CFR 63.305(b) [DIRS 180319] specifically states, "DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology. In all analyses done to demonstrate compliance with this part, the DOE must assume that all of those factors remain constant as they are at the time of submission of the license application." 10 CFR 63.312(b) [DIRS 180319] also states that the RMEI "has a diet and living style representative of the people who now reside in the Town of Amargosa Valley, Nevada." Therefore, speculation concerning changes in current agricultural practices or land use is excluded by regulation.

10 CFR 63. 2007. Energy: Disposal of High-Level Radioactive Wastes in a Geologic Repository at Yucca Mountain, Nevada. [DIRS 180319]	10 CFR 63.305(b)	DOE should not project changes in society, the biosphere (other than climate), human biology, or increases or decreases in human knowledge or technology

FEP: 2.4.09.01.0B

FEP NAME:

Agricultural Land Use and Irrigation

FEP DESCRIPTION:

Agricultural areas exist near Yucca Mountain, particularly in the direction of groundwater flow. Current practices include irrigation, plowing, fertilization, crop storage, and soil modification and amendment. Existing practices may play a significant role in determining exposure pathways and dose.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Agricultural land use and irrigation form part of the lifestyle and behavior of the current residents of Amargosa Valley (BSC 2004 [DIRS 169673], Appendix A). In accordance with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, future agricultural practices are assumed to be consistent with the current practices.

This FEP is considered in the soil, air, plant, animal, ^{14}C, fish, external exposure, and inhalation submodels of the biosphere model (SNL 2007 [DIRS 177399], Table 6.7-1). Agricultural land use and irrigation are represented in the model through the fraction of overhead irrigation (BSC 2004 [DIRS 169673], Section 6.3), exposure times for conducting outdoor and indoor activities (BSC 2005 [DIRS 172827], Section 6.3.2), annual average irrigation rate (BSC 2004 [DIRS 169673], Section 6.5; SNL 2007 [DIRS 177399], Section 6.4.1.1), overwatering rate (BSC 2004 [DIRS 169673], Section 6.9), mass loading for receptor environments (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3), mass loading for crops (BSC 2006 [DIRS 177101], Sections 6.2.5 and 6.3.5), crop growing time (BSC 2004 [DIRS 169673], Section 6.4), tillage depth (BSC 2004 [DIRS 169673], Section 6.10), irrigation intensity (BSC 2004 [DIRS 169673], Section 6.6), irrigation amount per application (BSC 2004 [DIRS 169673], Section 6.7), daily irrigation rate (BSC 2004 [DIRS 169673], Section 6.8), animal consumption rate of water (BSC 2004 [DIRS 169672], Section 6.3.2), surface area of irrigated land (SNL 2007 [DIRS 177399], Section 6.4.6.2), water concentration modifying factor (BSC 2004 [DIRS 169672], Section 6.4.3), and duration of irrigation (SNL 2007 [DIRS 179993], Section 6.7).

Irrigation rates are developed based, in part, on variation and uncertainty in cultivated land and water use practices in Amargosa Valley (BSC 2004 [DIRS 169673], Sections 6.3 to 6.9; BSC 2004 [DIRS 169672], Section 6.7.2). Agricultural use of water, the rates and durations, is included in the soil (SNL 2007 [DIRS 177399], Section 6.4.1), plant (SNL 2007 [DIRS 177399],

Section 6.4.3), animal (SNL 2007 [DIRS 177399], Section 6.4.4), fish (SNL 2007 [DIRS 177399], Section 6.4.5), and ^{14}C (SNL 2007 [DIRS 177399], Section 6.4.7) submodels of the groundwater scenario. Irrigation of agricultural land with contaminated water may give rise to the leaching of radionuclides from the soil, the transport of radionuclides by deep percolation to the water table, and the recapture of the radionuclides by the water supply well. However, this process has been excluded, as discussed in FEP 1.4.07.03.0A (Recycling of Accumulated Radionuclides from Soil to Groundwater).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3) (see included FEP 2.3.02.01.0A (Soil Type) for a more detailed description of the volcanic BDCF components).

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI and the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI or the reference biosphere in the performance assessment calculations.

FEP: 2.4.09.02.0A

FEP NAME:

Animal Farms and Fisheries

FEP DESCRIPTION:

Domestic livestock or fish could become contaminated through the intake of contaminated feed, water, or soil. Such contamination could then enter the food chain.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Animal farms and fisheries form part of the lifestyle and behavior of the current residents of Amargosa Valley. Socioeconomic and dietary survey data (DOE 1997 [DIRS 100332], Section 2.3) indicate that residents raise and consume locally produced domestic livestock and fish. Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, future use of animal farms and fisheries is assumed to be the same as the current use.

This FEP is addressed in the animal and fish submodels of the biosphere model (SNL 2007 [DIRS 177399], Table 6.7-1) and is represented in the model by animal consumption rates of locally produced feed, contaminated water, and contaminated soil (BSC 2004 [DIRS 169672], Section 6.3.2), and water concentration modifying factor (BSC 2004 [DIRS 169672], Section 6.4.3). Relevant parameters are developed based in part on variation and uncertainty in animal and fish farming practices in Amargosa Valley (BSC 2004 [DIRS 169672], Sections 6.3.2, 6.4.3, and 6.4.5).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). (For the volcanic ash scenario, a fish consumption pathway is not included because of its insignificant contribution to the BDCFs, and thus fisheries are not considered.) The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI and the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI or the reference biosphere in the performance assessment calculations.

FEP: 2.4.10.00.0A

FEP NAME:

Urban and Industrial Land and Water Use

FEP DESCRIPTION:

Urban and industrial uses of land and water (industry, urban development, earthworks, energy production, etc.) may affect the long-term performance of the repository. Urban and industrial land use will be controlled by both natural factors (topography, climate, etc.) and human factors (economics, population density, etc.).

SCREENING DECISION:

Included

TSPA DISPOSITION:

The lifestyle and behavior of the current residents of Amargosa Valley implicitly include certain uses of urban and industrial land and water. Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, future uses of urban and industrial land and water are assumed to be the same as the current uses.

This FEP is addressed in the model by considering land and water use practices in residential and industrial settings in Amargosa Valley (BSC 2006 [DIRS 177101], Sections 6.2 and 6.3; BSC 2005 [DIRS 172827], Section 6.3.2; BSC 2004 [DIRS 169672], Section 6.5). The use of contaminated water in residential and urban environments is included in the soil submodel (SNL 2007 [DIRS 177399], Section 6.4.1) and air submodel (SNL 2007 [DIRS 177399], Section 6.4.2) of the groundwater exposure scenario. The biosphere model also implicitly includes urban industrial land and water use through the proportion of time that the RMEI spends away from the agricultural environment. Parameters that address urban and industrial land and water use are annual average irrigation rate (BSC 2004 [DIRS 169673], Section 6.5), mass loading for the receptor environments (BSC 2006 [DIRS 177101], Sections 6.2.1 to 6.2.4 and 6.3.1 to 6.3.4), evaporative cooler water evaporation rate (BSC 2004 [DIRS 169672], Section 6.5.2), and exposure time (BSC 2005 [DIRS 172827], Section 6.3.2).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the

TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI and the reference biosphere in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI or the reference biosphere in the performance assessment calculations.

FEP: 3.1.01.01.0A

FEP NAME:

Radioactive Decay and Ingrowth

FEP DESCRIPTION:

Radioactivity is the spontaneous disintegration of an unstable atomic nucleus that results in the emission of subatomic particles. Radioactive species (isotopes) of a given element are known as radionuclides. Radioactive decay of the fuel in the repository changes the radionuclide content in the fuel with time and generates heat. Radionuclide quantities in the system at any time are the result of the radioactive decay and the ingrowth of decay products as a consequence of that decay. Over a 10,000-year performance period, these processes will produce decay products that need to be considered in order to adequately evaluate the release and transport of radionuclides to the accessible environment.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Radionuclides originating in the waste form will decay at rates set by their half-lives. For TSPA, the subset of radionuclides that are potentially important dose contributors is identified (SNL 2007 [DIRS 177424], Table 7-1). Radioactive decay and ingrowth are modeled for these radionuclides in (1) the waste package and emplacement drift, (2) the unsaturated zone, (3) the saturated zone, and (4) the accessible environment or biosphere. The inclusion of radioactive decay and ingrowth in the TSPA is discussed as follows:

(1) *Waste Package and Emplacement Drift*: As discussed in included FEP 2.1.01.01.0A (Waste Inventory), initial average waste package inventories of each of the important radionuclides, together with the associated uncertainties in these inventories (SNL 2007 [DIRS 180472], Sections 6.4, 6.6, and 7.1[a]) are provided as input to the TSPA Model. The GoldSim contaminant transport module (GoldSim Technology Group 2007 [DIRS 183214]) in the TSPA model calculates and updates the radionuclide inventories in the waste packages and emplacement drift modeling cells at subsequent times to account for radioactive decay and ingrowth of decay products.

(2) *Unsaturated Zone*: In TSPA calculations, radioactive decay and ingrowth in the unsaturated zone are simulated through the use of the FEHM code (FEHM V. 2.24-01 [DIRS 179419], STN: 10086-2.24-01-00), which uses an effective integration algorithm described in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Section 6.4.4). This algorithm can handle multiple species decay and ingrowth processes. Radionuclide half-lives and decay products considered in the UZ transport abstraction model are documented in *Particle Tracking Model and Abstraction of Transport Processes* (SNL 2008 [DIRS 184748], Table 6-25 in AD01).

In the TSPA calculations for the human intrusion scenario, unsaturated zone transport, including radioactive decay and ingrowth, is modeled using the functions of the GoldSim radionuclide transport module. Specifically, radionuclide transport through the human intrusion borehole is modeled with a GoldSim pipe pathway (SNL 2008 [DIRS 183478], Section 6.7.3.2), which includes the decay and ingrowth calculations.

The output of the UZ radionuclide transport model is a boundary condition for the SZ radionuclide transport model, which accounts for decay and ingrowth during radionuclide transport as described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.3).

(3) *Saturated Zone*: Radionuclide transport in the saturated zone for the TSPA is simulated using two models, the SZ flow and transport abstraction model and the SZ one-dimensional transport model. The SZ flow and transport abstraction model is based on multiple realizations of radionuclide transport with the three-dimensional site-scale SZ transport model. The resulting radionuclide breakthrough curves are coupled to the TSPA model using the convolution integral method. The SZ one-dimensional transport model is implemented directly in the TSPA model and consists of streamtubes extracted from the three-dimensional site-scale SZ transport model. Both abstraction models are described in *Saturated Zone Flow and Transport Model Abstraction* (SNL 2008 [DIRS 183750], Section 6.3).

Radioactive decay during transport in the saturated zone is included in the TSPA. The convolution integral method, as implemented in the SZ flow and transport abstraction model, is not able to calculate radioactive ingrowth. Consequently, ingrowth is accounted for in two different ways in the TSPA saturated zone models. First, the radionuclide mass entering the saturated zone at the water table is adjusted to account for the potential ingrowth of some radioactive decay products, resulting in a "boosting" of the initial inventory of some radioactive decay products (SNL 2008 [DIRS 183750], Section 6.3.1[a]). This approach is a conservative simplification that overestimates the mass of these radioactive decay products being transported in the saturated zone. Second, a separate set of saturated zone transport calculations are performed to account for the decay and ingrowth for the four main radionuclide decay series chains. Within the TSPA, these calculations are performed using the SZ one-dimensional transport model (SNL 2008 [DIRS 183750], Sections 6.3.2 and 6.5.1.2[b]). The SZ one-dimensional transport model is used to calculate only the release of some decay products resulting from ingrowth in the saturated zone from the four decay series chains. These two ways of accounting for ingrowth in the saturated zone transport simulations differ from the approach used in the unsaturated zone transport simulations because of the differing numerical methods used.

(4) *Biosphere*: The biosphere model was constructed to estimate the dose from the primary long-lived radionuclides considered important for the TSPA (SNL 2007 [DIRS 177399], Section 6.1.3), and it includes consideration of the short-lived decay products of these radionuclides (SNL 2007 [DIRS 177399], Section 6.3.5). Radionuclide decay and ingrowth are included in the soil (SNL 2007 [DIRS 177399], Sections 6.4.1.1 and 6.4.1.2), external exposure (SNL 2007 [DIRS 177399],

Section 6.4.7), inhalation (SNL 2007 [DIRS 177399], Section 6.4.8), and ingestion (SNL 2007 [DIRS 177399], Section 6.4.9) submodels of the groundwater exposure scenario. They are also included in the external exposure (SNL 2007 [DIRS 177399], Section 6.5.5), inhalation (SNL 2007 [DIRS 177399], Section 6.5.6), and ingestion (SNL 2007 [DIRS 177399], Section 6.5.7) submodels of the volcanic ash exposure scenario for the biosphere model.

This FEP is included in the calculation of radionuclide buildup in the soil for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Sections 6.4.1.1 and 6.4.1.2) and in the calculation of effective dose coefficients for external exposure, inhalation, and ingestion (SNL 2007 [DIRS 177399], Sections 6.4.7.2, 6.4.8.5, 6.4.9.6, and 6.5.5.2). These coefficients include dose contributions from short-lived decay products of the primary radionuclides. The contribution from long-lived and short-lived decay products of primary radionuclides is also considered in the calculations of the organ and the whole body conversion factors for evaluating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1). This is done through the use of effective dose coefficients for ingestion.

This FEP is dispositioned in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). Radioactive decay and ingrowth is also included in the TSPA through the use of the conversion factors for evaluating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1).

This FEP is also included in the TSPA volcanic eruption modeling case through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.1.3), as described in included FEP 3.3.04.02.0A (Inhalation). Annual doses are calculated in the TSPA as the product of radionuclide concentrations in the soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function (SNL 2007 [DIRS 177399], Section 6.12.3). Radionuclide concentrations in the soil are adjusted for radionuclide decay and ingrowth using elements of the GoldSim radionuclide transport module. Decay and ingrowth factors for each radionuclide are calculated through time, and the radionuclide concentrations are adjusted by multiplying the calculated concentrations by the decay and ingrowth factors. These adjusted concentrations are used to determine dose.

FEP: 3.2.07.01.0A

FEP NAME:

Isotopic Dilution

FEP DESCRIPTION:

Mixing or dilution of the radioactive species from the waste with species of the same element from other sources (i.e., stable and/or naturally occurring isotopes of the same element) could lead to a reduction of the radiological consequences.

SCREENING DECISION:

Excluded – low consequence

SCREENING JUSTIFICATION:

Mixing of radionuclide isotopes from the repository waste with naturally occurring stable isotopes of the same element in groundwater would occur for some radionuclides (e.g., ^{129}I mixing with stable ^{127}I; ^{36}Cl mixing with stable ^{35}Cl and ^{37}Cl; and ^{90}Sr mixing with stable ^{84}Sr, ^{86}Sr, ^{87}Sr, and ^{88}Sr). Chemical and physical processes that result in competition among radioactive and stable isotopes may limit the uptake or retention of some radionuclides in the biosphere and the RMEI, leading to an isotopic dilution effect. The magnitude of the effect of isotopic dilution depends on the relative amounts of the radioactive and corresponding stable isotopes of the same element, as well as the competitive effects on uptake and retention for that element.

The effects of isotopic dilution from sources of stable isotopes specific to the natural system at Yucca Mountain are excluded from the TSPA model on the basis of low consequence. In general, for radionuclides that are rare in the natural environment, such as isotopes of technetium, plutonium, and americium, isotopic dilution of radionuclides of repository origin by natural sources would not occur, and, therefore it is appropriate to exclude possible effects of dilution for such radionuclides. Transport models used in the TSPA take into account the presence of multiple radioactive isotopes originating from the waste form (e.g., uranium, plutonium, americium, thorium, and other elements occur as multiple radionuclides) and account for possible competition affects by allocating individual isotopes of each element according to their relative abundance in the inventory (SNL 2008 [DIRS 183478], Section 6.3.7.5.3). Effects of mixing and competition among anthropogenic radionuclides, as opposed to dilution with naturally occurring isotopes, are therefore accounted for in the performance assessment.

For those radionuclides with common stable isotopes present in the environment, the potential effect of isotopic dilution was also not explicitly modeled, but has been taken into account through the regulatory specification of the stylized RMEI and the approach to calculating dose. Consistent with regulatory requirements (proposed 10 CFR 63.2 (70 FR 53313 [DIRS 178394])) and Federal Guidance Report 13 (EPA 2002 [DIRS 175544]), dose coefficients used in the biosphere model (SNL 2007 [DIRS 177399], Section 6.4.9.6) were developed using the International Commission on Radiological Protection metabolic and dosimetric models that

include, where appropriate, the stable element intake representative of a diet of a reference person (e.g., ICRP 1989 [DIRS 183654], Sections 2 and 7). The actual dietary intake of stable elements may be different than that for the reference diet, which could result in a different isotopic dilution, and thus, different metabolism of a radioactive isotope of an element. Because the locally produced food is a small fraction of the average diet for the Amargosa Valley population, site-specific conditions are not expected to strongly affect the intake of stable isotopes by an average person. Therefore, it is not appropriate to introduce a site-specific correction to the RMEI's dietary intake of stable isotopes.

Based on the previous discussion, omission of FEP 3.2.07.01.0A (Isotopic Dilution) will not result in a significant adverse change in the magnitude or timing of either radiological exposure to the RMEI or radionuclide releases to the accessible environment. Therefore, this FEP is excluded from the performance assessments conducted to demonstrate compliance with proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low consequence.

FEP: 3.2.10.00.0A

FEP NAME:

Atmospheric Transport of Contaminants

FEP DESCRIPTION:

Atmospheric transport includes radiotoxic and chemotoxic species in the air as gas, vapor, particulates, or aerosol. Transport processes include wind, plowing and irrigation, degassing, saltation, and precipitation.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Atmospheric transport of radionuclides is included in the biosphere model through the effects of resuspension of contaminated soil, gaseous emission of radionuclides from soil to air followed by atmospheric dispersion, deposition of airborne particulate matter, as well as generation of atmospheric aerosols (evaporative cooler), and gases (radon and $^{14}CO_2$). The biosphere model does not include processes related to long-range atmospheric transport and dispersion of airborne radionuclides because these have been excluded, as discussed in FEP 2.2.11.03.0A (Gas Transport in Geosphere). The biosphere model, however, does include the removal of radionuclides from the surface soil by erosion, which may involve atmospheric transport of contaminants. Soil erosion in agricultural fields is incorporated into the soil submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.1.4) in calculation of the surface soil removal constant (SNL 2007 [DIRS 177399], Section 6.4.1.4). Soil erosion includes soil loss and gain on farm fields (SNL 2007 [DIRS 179993], Section 6.4). For a volcanic eruption, the processes of long-range atmospheric transport are addressed in the atmospheric dispersion and tephra deposition model (SNL 2007 [DIRS 177431]) and in included FEP 1.2.04.07.0A (Ashfall). Aeolian transport following a volcanic eruption is addressed in the tephra redistribution model (SNL 2007 [DIRS 179347]) and in included FEP 1.2.04.07.0C (Ash Redistribution via Soil and Sediment Transport). These processes are not included in the biosphere model because they occur outside the reference biosphere.

Radiotoxic and chemotoxic species are outside the scope of performance assessment because the performance standards for the repository do not concern radiological or chemical toxicity (see excluded FEPs 3.3.06.00.0A (Radiological Toxicity and Effects) and 3.3.07.00.0A (Non-Radiological Toxicity and Effects)).

The process of atmospheric transport is included in the biosphere air submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.2), the air submodel for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.5.2), and the ^{14}C special submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.6). The associated parameters include mass loading for crops (BSC 2006 [DIRS 177101], Sections 6.2.5 and 6.3.5), mass loading for the receptor environments

(BSC 2006 [DIRS 177101], Sections 6.2 and 6.3), soil bulk density (SNL 2007 [DIRS 179993], Section 6.2), tillage depth (BSC 2004 [DIRS 169673], Section 6.10), resuspension enhancement factor (SNL 2007 [DIRS 179993], Section 6.5), fraction of radionuclides in evaporative cooler water transferred to air (BSC 2004 [DIRS 169672], Section 6.5.2), water evaporation rate for evaporative coolers (BSC 2004 [DIRS 169672], Section 6.5.2), evaporative cooler air flow rate (BSC 2004 [DIRS 169672], Section 6.5.2), radon release factor (BSC 2004 [DIRS 169672], Section 6.6.1), interior wall height (BSC 2004 [DIRS 169672], Sections 6.5.2 and 6.6.2), house ventilation rate (BSC 2004 [DIRS 169672], Section 6.6.2), fraction of ^{222}Rn from soil entering the house (BSC 2004 [DIRS 169672], Section 6.6.2), ratio of ^{222}Rn concentration in air to flux density from soil (BSC 2004 [DIRS 169672], Section 6.6.1), ^{14}C emission rate for soil (BSC 2004 [DIRS 169672], Section 6.7.1), surface area of irrigated land (SNL 2007 [DIRS 177399], Section 6.4.6.2), annual average wind speed (BSC 2004 [DIRS 169672], Section 6.7.2), ^{14}C mixing height (BSC 2004 [DIRS 169672], Section 6.7.2), concentration of stable carbon in air (BSC 2004 [DIRS 169672], Section 6.7.3), and correlation coefficient for airflow and water use in evaporative coolers (BSC 2004 [DIRS 169672], Section 6.5.2).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only groundwater pathways must be included.

FEP: 3.3.01.00.0A

FEP NAME:

Contaminated Drinking Water, Foodstuffs and Drugs

FEP DESCRIPTION:

This FEP addresses human diet and fluid intake. Consumption of food, water, soil, drugs, etc., will affect human exposure to radionuclides. Other influences include filtration of water, dilution of diet with uncontaminated food, and food preparation techniques.

SCREENING DECISION:

Included

TSPA DISPOSITION:

A hypothetical human receptor, the RMEI, is used in the performance assessment calculations for both the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the individual protection standard for human intrusion (proposed 10 CFR 63.321 321 (70 FR 53313 [DIRS 178394])). The diet and lifestyle of the RMEI are representative of the diet and lifestyle of the current residents of Amargosa Valley, consistent with 10 CFR 63.312(b) [DIRS 180319]. Dietary survey data (DOE 1997 [DIRS 100332], Section 2.3) indicate that residents consume locally grown foods and groundwater. The consumption of contaminated locally grown crops, animal products, fish, as well as water and soil, is addressed in the ingestion submodel of the biosphere model through the consumption rates of these media (BSC 2005 [DIRS 172827], Sections 6.4.2 and 6.4.3). Consumption rates used in the model only concern locally produced crops and animal products and are based on the survey of the Amargosa Valley population. Therefore, dilution of diet with uncontaminated food is not considered. The biosphere model conservatively also does not consider radioactivity loss due to filtration of water or food preparation. There is no evidence of the production of drugs in Amargosa Valley using local materials.

The ingestion submodel includes the intake of food, water, and soil for the groundwater scenario (SNL 2007 [DIRS 177399]), Section 6.4.9) and for the volcanic ash scenario (SNL 2007 [DIRS 177399]), Section 6.5.7). This FEP also considers the calculation of radionuclide concentrations in foodstuffs (SNL 2007 [DIRS 177399]), Sections 6.4.3 to 6.4.6, 6.5.3, and 6.5.4). The parameters related to consumption of contaminated drinking water and foodstuffs include consumption rates of well water and locally produced food (BSC 2005 [DIRS 172827], Section 6.4) and inadvertent soil ingestion rate (BSC 2005 [DIRS 172827], Section 6.4.3). Only the portion of this FEP that relates to ingestion in contaminated groundwater is considered in the calculations of conversion factors for demonstrating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3).

The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. The contaminated water aspect of this FEP is also included in the TSPA through the use of the conversion factors for demonstrating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1). In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require the use of the concept of the RMEI in the performance assessment calculations. Only the portion of this FEP that relates to ingestion in contaminated groundwater is included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the use of the concept of the RMEI in the performance assessment calculations.

FEP: 3.3.02.01.0A

FEP NAME:

Plant Uptake

FEP DESCRIPTION:

Uptake and accumulation of contaminants by plants could affect potential exposure pathways. Plant uptake from contaminated soils and irrigation water is possible. Particulate deposition onto plant surfaces is also possible. These plants may be used as feed for livestock and/or consumed directly by humans.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, plant uptake is included in the TSPA model. A dietary survey (DOE 1997 [DIRS 100332], Section 2.3) indicates that Amargosa Valley residents consume locally grown crops from home gardens irrigated with water obtained from a local ground source. The human ingestion pathway represented by this consumption includes plant uptake of radionuclides, deposition of radionuclides on plant surfaces, and subsequent transfer to humans via ingestion. For all radionuclides, two plant uptake routes are included in the biosphere model: root uptake and direct deposition on crops due to the interception of irrigation water and resuspended soil particles. For ^{14}C, an additional uptake mechanism is considered because plants can acquire from the air gaseous $^{14}CO_2$, which is used in photosynthesis. Crops considered in the model include leafy vegetables, other vegetables, fruit, grain, and animal feed (SNL 2007 [DIRS 177399], Sections 6.3.1.6 and 6.3.2.6). The process of plant uptake of radionuclides (also referred to as radionuclide accumulation, bioconcentration, or biomagnification) is included in the plant submodel for the groundwater (SNL 2007 [DIRS 177399], Section 6.4.3) and volcanic ash exposure scenarios (SNL 2007 [DIRS 177399], Section 6.5.3), and in the ^{14}C special submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.6).

There are a number of model parameters related to plant uptake associated with these submodels, including soil-to-plant transfer factor (BSC 2004 [DIRS 169672], Sections 6.2.1.2 through 6.2.1.5), dry-to-wet ratio (BSC 2004 [DIRS 169673], Section 6.2), fraction of overhead irrigation (BSC 2004 [DIRS 169673], Section 6.3), translocation factor (BSC 2004 [DIRS 169672], Section 6.2.2.2), weathering rate constant (BSC 2004 [DIRS 169672], Section 6.2.2.3), crop growing time (BSC 2004 [DIRS 169673], Section 6.4), crop wet yield (BSC 2004 [DIRS 169673], Section 6.11), daily irrigation rate (BSC 2004 [DIRS 169673], Section 6.8), crop dry biomass (BSC 2004 [DIRS 169673], Section 6.1), irrigation amount per application (BSC 2004 [DIRS 169673], Section 6.7), irrigation intensity (BSC 2004 [DIRS 169673],

Section 6.6), dry deposition velocity (BSC 2004 [DIRS 169672], Section 6.2.2.1), soil bulk density (SNL 2007 [DIRS 179993], Section 6.2), tillage depth (BSC 2004 [DIRS 169673], Section 6.10), fraction of air-derived carbon in plants (BSC 2004 [DIRS 169672], Section 6.7.3), fraction of soil-derived carbon in plants (BSC 2004 [DIRS 169672], Section 6.7.3), fraction of stable carbon in crops (BSC 2004 [DIRS 169672], Section 6.7.3), fraction of stable carbon in soil (BSC 2004 [DIRS 169672], Section 6.7.3), concentration of stable carbon in air (BSC 2004 [DIRS 169672], Section 6.7.3), and correlation coefficient for transfer factors and partition coefficients (BSC 2004 [DIRS 169672], Section 6.2.1.5).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathways must be included.

FEP: 3.3.02.02.0A

FEP NAME:

Animal Uptake

FEP DESCRIPTION:

Livestock may accumulate radionuclides as a result of ingestion (water, feed and soil/sediment) and inhalation (aerosols and particulates). Depending on the livestock, they may be used for human consumption directly, or their produce (milk, eggs, etc.) may be consumed.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, animal uptake is included in the TSPA model. A dietary survey (DOE 1997 [DIRS 100332], Section 2.3) indicates that Amargosa Valley residents consume locally produced animal products. The human ingestion pathway represented by this consumption includes radionuclide accumulation in animals and their products, and subsequent transfer to humans via ingestion. Three mechanisms of animal uptake are included in the model: consumption of contaminated water, feed, and soil. Radionuclide concentrations are calculated using equilibrium transfer factors, which relate daily animal intake of an element to the concentration of that element in animal tissue or product. Animal products include meat, milk, poultry, and eggs (SNL 2007 [DIRS 177399], Sections 6.3.1.6 and 6.3.2.6). This FEP is addressed in the animal and ^{14}C submodels of the biosphere model (SNL 2007 [DIRS 177399], Table 6.7-1).

For the groundwater exposure scenario, the animal uptake submodel includes ingestion of contaminated water, animal feed, and soil to assess the resulting radionuclide concentrations in animal products (SNL 2007 [DIRS 177399], Section 6.4.4). For the volcanic ash exposure scenario, the groundwater contains no radionuclides, so ingestion of contaminated water by animals is not included (SNL 2007 [DIRS 177399], Section 6.5.4). Animal uptake is also included in the ^{14}C special submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.6.4). The contribution of inhaled contaminated soil to the activity concentration in an animal product was evaluated and found to be small in comparison to the contributions from the ingestion pathways (SNL 2007 [DIRS 177399], Section 7.4.5). As a result, this subpathway was not further considered. Dermal exposure of animals to contaminated soil and dust with possible uptake of radionuclides through the skin is relatively insignificant and was not included because it would be small relative to the daily soil ingestion by animals, which for cows is, on average, 0.7 kg/day or more (SNL 2007 [DIRS 177399], Table 6.6-3).

The following input parameters support modeling of animal uptake: animal transfer coefficients (BSC 2004 [DIRS 169672], Section 6.3.3), animal consumption rate of feed, water, and soil (BSC 2004 [DIRS 169672], Section 6.3.2), fraction of stable carbon in animal products (BSC 2004 [DIRS 169672], Section 6.7.4), fraction of air-derived carbon in plants (BSC 2004 [DIRS 169672], Section 6.7.3), fraction of soil-derived carbon in plants (BSC 2004 [DIRS 169672], Section 6.7.3), and concentration of stable carbon in farm animal water (BSC 2004 [DIRS 169672], Section 6.7.4).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathways must be included.

FEP: 3.3.02.03.0A

FEP NAME:

Fish Uptake

FEP DESCRIPTION:

Uptake and bioaccumulation of contaminants in aquatic organisms could affect potential exposure pathways.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, and with 10 CFR 63.305(a) [DIRS 180319], which requires that the reference biosphere be consistent with present knowledge of the conditions in the region, fish uptake is included in the TSPA model. Uptake of radionuclides by aquatic organisms is a process that is expected to occur during commercial fish farming. A dietary survey (DOE 1997 [DIRS 100332], Section 2.3) indicated that Amargosa Valley residents consumed locally grown fish; therefore, the accumulation of radionuclides in aquatic organisms is included.

This FEP applies to the uptake of radionuclides by fish due to the use of contaminated groundwater in fish farming. The fish uptake FEP is addressed in the fish submodel, which includes the bioaccumulation of radionuclides in fish (SNL 2007 [DIRS 177399], Section 6.4.5). The transfer process, as represented by the bioaccumulation factor, is based on equilibria between radionuclide concentrations in the water, the aquatic environment, and concentrations in the edible part of fish (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.4). Because the fish are fed uncontaminated, commercially produced feed (Roe 2002 [DIRS 160674], p. 2), bioaccumulation factors provide an upper bound of activity concentration in the fish. The parameters involved in modeling of this process include the bioaccumulation factor (BSC 2004 [DIRS 169672], Section 6.4.3) and fishpond water concentration-modifying factor (BSC 2004 [DIRS 169672], Sections 6.4.3 and 6.4.4).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. The ingestion of contaminated fish is not included in the volcanic ash exposure scenario because of its negligible dose contribution (SNL 2007 [DIRS 177399], Appendix E).

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to

the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathways must be included.

FEP: 3.3.03.01.0A

FEP NAME:

Contaminated Non-Food Products and Exposure

FEP DESCRIPTION:

Contaminants may be concentrated in various products: clothing (e.g., hides, leather, linen, wool); furniture (e.g., wood, metal); building materials (e.g., stone, clay for bricks, wood, dung); fuel (e.g., peat), tobacco, pets.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Various products, such as leather, wool, wood, or clay for bricks, could be produced locally using contaminated water and thus become contaminated. Contamination of non-food products could result in external exposure because such products are usually not ingested intentionally. Inadvertent soil ingestion is addressed in included FEP 3.3.04.01.0A (Ingestion).

Exposure to non-food products is not explicitly included in the biosphere model; rather, it is bounded by external exposure to contaminated soil. In general, exposure to contaminated non-food products would be lower than exposure to contaminated soil, which is the medium that contains the majority of the radionuclide inventory in the biosphere. Furthermore, exposure to contaminated soil occurrs at all times while the RMEI is indoors and outdoors in the contaminated area. Parameters that address this FEP are the same as those for included FEP 3.3.04.03.0A (External Exposure).

Other possible pathways resulting from exposure to contaminated non-food products include the use of locally grown tobacco products. However, the socioeconomic surveys conducted in Amargosa Valley (CRWMS M&O 1997 [DIRS 101090], Section 3.4; YMP 1999 [DIRS 158212], Section 3.4) and other biosphere studies (Horak and Carns 1997 [DIRS 124149]) did not provide evidence of this crop in Amargosa Valley. Therefore, inhalation exposure from smoking tobacco is not included in the model.

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399],

Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only groundwater pathways must be included.

FEP: 3.3.04.01.0A

FEP NAME:

Ingestion

FEP DESCRIPTION:

Ingestion is human exposure to repository-derived radionuclides through eating contaminated foodstuffs or drinking contaminated water.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Consistent with 10 CFR 63.312(b) [DIRS 180319], which states that the RMEI has a diet and lifestyle representative of the current residents of Amargosa Valley, ingestion is included in the TSPA model. Dietary survey data collected in the Yucca Mountain area (DOE 1997 [DIRS 100332], Section 2.3) indicate that consumption of groundwater and locally grown produce, livestock, and fish does occur in Amargosa Valley. This FEP is addressed through the ingestion rates of locally produced food and groundwater in the ingestion submodel (SNL 2007 [DIRS 177399], Table 6.7-1). For the groundwater exposure scenario, the ingestion exposure pathways include consumption of water from a groundwater well; consumption of locally produced plant foodstuffs, animal products, and fish; as well as inadvertent soil ingestion (SNL 2007 [DIRS 177399], Section 6.3.1.6). For the volcanic ash scenario, only the ingestion of locally produced plant foodstuffs, animal products, and inadvertent soil ingestion are considered (SNL 2007 [DIRS 177399], Section 6.3.2.6).

Within the mathematical representation of the ingestion submodel for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.9), the annual water consumption rate is defined at 2 liters per day, as specified in 10 CFR 63.312(d) [DIRS 180319]. Exposure to contaminated plant foodstuffs is addressed through annual consumption rates of each of four locally grown crop food types (leafy vegetables, other vegetables, fruits, and grains) (BSC 2005 [DIRS 172827], Section 6.4.2) and their associated radionuclide-specific activity concentration (SNL 2007 [DIRS 177399], Section 6.4.3). Selection of crop types used in the biosphere model is addressed by *Biosphere Model Report* (SNL 2007 [DIRS 177399], Section 6.4.3). Similarly, exposure to contaminated animal products is the product of the consumption rates of each of four types of locally produced animal products (meat, milk, poultry, and eggs) (BSC 2005 [DIRS 172827], Section 6.4.2) and their associated radionuclide-specific activity concentration (SNL 2007 [DIRS 177399], Section 6.4.4). Selection of animal product types used in the biosphere model is discussed in *Biosphere Model Report* (SNL 2007 [DIRS 177399], Section 6.4.4). Ingestion of fish is addressed within this submodel as the annual consumption rate of locally produced fish (BSC 2005 [DIRS 172827], Section 6.4.2) times the radionuclide-specific activity concentration in fish (SNL 2007 [DIRS 177399], Section 6.4.5). The inadvertent intake of soil, contaminated as a result of long-term irrigation of crops, is addressed in this submodel as the product of the mass activity concentration of each of the

primary radionuclides in soil (SNL 2007 [DIRS 177399], Section 6.4.1) times the annual consumption rate of soil (BSC 2005 [DIRS 172827], Section 6.4.3). Related parameters also include dose coefficients for ingestion of radionuclides (SNL 2007 [DIRS 177399], Section 6.4.9.6). Deliberate soil ingestion is not included (BSC 2005 [DIRS 172827], Section 6.4.3).

The mathematical representation of the ingestion submodel for the volcanic ash exposure scenario is similar to that for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.5.7). The consumption of contaminated water, and crop and animal products, contaminated as a result of irrigation, are not considered because the groundwater is assumed to be uncontaminated for this exposure scenario.

Only the portion of this FEP that relates to ingestion of contaminated groundwater is considered in the calculations of conversion factors for calculating beta-photon dose from drinking 2 L per day of water taken from the representative volume, which are used for evaluating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3) and through the use of the conversion factors for evaluating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways, including ingestion (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is also included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards require the consideration of the groundwater ingestion pathway.

FEP: 3.3.04.02.0A

FEP NAME:

Inhalation

FEP DESCRIPTION:

Inhalation pathways for repository-derived radionuclides should be considered. Two possible pathways are: inhalation of gases and vapors emanating directly from the ground after transport through the far-field; and inhalation of suspended, contaminated particulate matter (e.g., decay products of radon, dust, smoke, pollen, and soil particles).

SCREENING DECISION:

Included

TSPA DISPOSITION:

Inhalation of gases, vapors, and suspended particulate matter are processes by which the RMEI may be exposed to radionuclides in the reference biosphere. This FEP is addressed in the biosphere inhalation submodels for the groundwater (SNL 2007 [DIRS 177399], Section 6.4.8) and the volcanic ash (SNL 2007 [DIRS 177399], Section 6.5.6) exposure scenarios. The inhalation submodel for the groundwater exposure scenario includes inhalation of contaminated resuspended particles, aerosols from evaporative coolers, ^{14}C, and radon decay products (SNL 2007 [DIRS 177399], Section 6.4.8). For the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.5.6), inhalation of ^{14}C is not included because ^{14}C is not a primary radionuclide for this scenario. In addition, inhalation of atmospheric aerosols produced by evaporative coolers is not considered in the volcanic ash exposure scenario because the groundwater is assumed to be uncontaminated (SNL 2007 [DIRS 177399], Section 6.3.2). Transport of gases and vapors emanating directly from the ground after transport through the far-field and their radiological impact is evaluated in excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere).

Within the mathematical representations of this FEP, human lifestyles, behavior, and physiology are accounted for through the use of the following parameters: environment-specific breathing rates (BSC 2005 [DIRS 172827], Section 6.3.3), fraction of houses with evaporative coolers (BSC 2005 [DIRS 172827], Section 6.3.4.1), evaporative cooler use factor (BSC 2005 [DIRS 172827], Section 6.3.4.2), population proportions (BSC 2005 [DIRS 172827], Section 6.3.1), and environment- and population group-specific exposure times (BSC 2005 [DIRS 172827], Section 6.3.2). The exposure source terms for the submodels are quantified, as applicable, by the following parameters: activity concentration in air for radionuclides attached to resuspended particles (SNL 2007 [DIRS 177399], Sections 6.4.2.1 and 6.5.2.1), activity concentration in air for radionuclides resulting from the use of an evaporative cooler (SNL 2007 [DIRS 177399], Section 6.4.2.2), activity concentration of ^{14}C in air (SNL 2007 [DIRS 177399], Section 6.4.6.2), and activity concentration of ^{222}Rn in air (SNL 2007 [DIRS 177399], Sections 6.4.2.3 and 6.5.2.2). The other parameters of the inhalation submodel include dose coefficient for inhalation of radon decay products (BSC 2005 [DIRS 172827], Section 6.5.4),

dose coefficients for inhalation of other radionuclides (SNL 2007 [DIRS 177399], Section 6.4.8.5), mass loading time function for the receptor environments (BSC 2006 [DIRS 177101], Section 6.4), equilibrium factor for ^{222}Rn decay products (BSC 2004 [DIRS 169672], Section 6.6.3), and critical thickness of soil for resuspension (BSC 2004 [DIRS 169672], Section 6.8).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways (SNL 2007 [DIRS 177399], Section 6.12.3). The first component accounts for exposure to sources external to the body, ingestion, and inhalation of radon decay products. The second and third BDCF components (the short-term and long-term inhalation components) account for inhaling airborne particulates. The short-term inhalation component is numerically equal to the incremental increase in inhalation exposure during the first year following a volcanic eruption. This term is used together with the time function to calculate short-term increase in inhalation exposure relative to the conditions existing before and long after an eruption. With time, particulate concentration in air returns to the preeruption level. These conditions are described by the long-term inhalation component, which represents inhalation of resuspended particulates under nominal conditions (i.e., when the mass loading is not elevated as the result of volcanic eruption) (SNL 2007 [DIRS 177399], Section 6.12.3).

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathways must be included.

FEP: 3.3.04.03.0A

FEP NAME:

External Exposure

FEP DESCRIPTION:

External exposure is human exposure to repository-derived radionuclides by contact, use, or exposure to contaminated materials.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Amargosa Valley residents include people with lifestyles that bring them into contact with environmental media that may potentially become contaminated. Depending upon lifestyle, the RMEI may become externally exposed to radionuclides through the use of, contact with, or exposure to contaminated materials.

The biosphere model includes exposure to contaminated soil. Indoor exposures are mitigated by building materials providing shielding from contaminated soil. The model does not include other external exposure pathways (e.g., by air submersion, water immersion, and dermal absorption). Comparisons of the potential dose from air or water submersion pathways with that from exposure to contaminated soils indicate that the dose from air or water submersion is inconsequential (SNL 2007 [DIRS 177399], Section 7.4.8). Because the skin is generally an effective barrier against absorption of radionuclides, dermal absorption is also a very minor exposure pathway for the radionuclides included in the TSPA model (SNL 2007 177399], Section 7.3.7).

This FEP is addressed in the external exposure submodels for the groundwater (SNL 2007 [DIRS 177399], Section 6.4.7) and the volcanic ash (SNL 2007 [DIRS 177399], Section 6.5.5) exposure scenarios. For the groundwater exposure scenario, soil is considered contaminated to an infinite depth in order to account for the emissions from radionuclides that have been leached from the surface soil but still contribute to the external radiation field (SNL 2007 [DIRS 177399], Section 6.4.7.1). For the volcanic ash exposure scenario, it is assumed that all of the radioactivity deposited on the soil surface can be treated as the surface contamination regardless of the thickness of the contaminated layer (SNL 2007 [DIRS 177399], Section 6.5.5.1). Within the mathematical representation of this FEP (SNL 2007 [DIRS 177399], Sections 6.4.7 and 6.5.5), parameters such as building shielding factor (BSC 2005 [DIRS 172827], Section 6.6), exposure time (BSC 2005 [DIRS 172827], Section 6.3.2), and population proportion (BSC 2005 [DIRS 172827], Section 6.3.1) are used to account for receptor behavior and lifestyle. The exposure–dose relationship is represented through the dose coefficients for exposure to soil contaminated to an infinite depth and exposure to a contaminated ground surface (SNL 2007 [DIRS 177399], Sections 6.4.7.2 and 6.5.5.2).

Another parameter supporting this FEP is tillage depth (BSC 2004 [DIRS 169673], Section 6.10).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.1.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. The present-day climate BDCFs are used for the assessment of doses to the RMEI for the entire period of the geologic stability (SNL 2007 [DIRS 177399], Section 6.11.3). In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenarios (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decrease function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways, including external exposure (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because both these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is not included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]) because these standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathways must be included.

FEP: 3.3.05.01.0A

FEP NAME:

Radiation Doses

FEP DESCRIPTION:

The radiation dose is calculated from exposure rates (external, inhalation, and ingestion) and dose coefficients. The latter are based upon radiation type, human metabolism, metabolism of the element of concern in the human body, and duration of exposure.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Regulations 10 CFR 63.113(b) and (d) [DIRS 180319] establish postclosure performance objectives for the repository in terms of limits on radiological exposure to the RMEI. The limits specified in proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) are expressed as an annual dose to the RMEI. In addition, 10 CFR 63.113(c) [DIRS 180319] establishes postclosure performance objectives for the repository in terms of limits on radionuclides in the representative volume of groundwater. The limits are specified in 10 CFR 63.331 [DIRS 180319] and include a limit on dose from ingesting 2 L/day of water from the representative volume. The dietary and lifestyle characteristics of the RMEI are representative of the current residents of Amargosa Valley, consistent with 10 CFR 63.312(b) [DIRS 180319]; the metabolic and physiological characteristics of the RMEI are those of an adult, consistent with 10 CFR 63.312(e) [DIRS 180319].

Within the biosphere model, the external exposure, ingestion, and inhalation submodels address this FEP (SNL 2007 [DIRS 177399], Table 6.7-1). The exposure rates depend on radionuclide concentrations in environmental media and on the dietary and lifestyle characteristics of the receptor. The doses arising from these exposures depend on radiation type, physiology, metabolism, and the biometrics of the receptor. In the model, the annual radiation dose from each of the primary radionuclides is the sum of the annual effective dose from the external exposure to each radionuclide and the annual committed effective dose from the ingestion and inhalation of each radionuclide (SNL 2007 [DIRS 177399], Section 6.4.10 for the groundwater exposure scenario, and Section 6.5.8 for the volcanic ash exposure scenario). For the annual dose from the ingestion or inhalation of each of the radionuclides of interest, the dose is the product of the individual radionuclide annual activity intakes into the body times the appropriate radionuclide-specific effective dose coefficient (SNL 2007 [DIRS 177399], Sections 6.4.8, 6.4.9, 6.5.6, and 6.5.7; BSC 2005 [DIRS 172827], Section 6.5.4). Effective dose coefficients for inhalation and ingestion are calculated using the appropriate dose coefficients and radionuclide branching fractions to account for the contribution from the short-lived decay products (SNL 2007 [DIRS 177399], Sections 6.4.8.5 and 6.4.9.6). External exposure is calculated using the radionuclide concentration in contaminated soil, various times of exposure to the contaminated soil, and radionuclide-specific effective dose coefficients (SNL 2007

[DIRS 177399], Sections 6.4.7 and 6.5.5). Effective dose coefficients for external exposure are also calculated using the appropriate dose coefficients and radionuclide branching fractions to account for the contribution from the short-lived decay products (SNL 2007 [DIRS 177399], Sections 6.4.7.2 and 6.5.5.2). This FEP is also considered in the calculations of conversion factors for evaluating compliance with the groundwater protection standards (SNL 2007 [DIRS 177399], Section 6.15.1).

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs and through the use of the conversion factors for groundwater protection standards (SNL 2007 [DIRS 177399], Sections 6.1.3 and 6.15.1). For the TSPA scenario classes involving groundwater as a source of radionuclides, annual doses are calculated as the product of radionuclide concentration in groundwater and BDCFs generated in the biosphere model (or conversion factors for the groundwater protection requirements calculation). Such an approach is possible because quantities calculated in the submodels of the biosphere model for the groundwater exposure scenario, including radionuclide concentrations in the environmental media and the annual dose from various exposure pathways, are proportional to the radionuclide concentration in the groundwater (SNL 2007 [DIRS 177399], Section 6.4.10.2). Thus, for this exposure scenario, the biosphere model contribution to the dose assessment (i.e., BDCFs) can be separated from the source (i.e., radionuclide concentration in the groundwater). The BDCF for a radionuclide is numerically equal to the dose for a unit activity concentration of the radionuclide in the water (SNL 2007 [DIRS 177399], Section 6.4.10.2).

In the event of a volcanic eruption, this FEP is included in the TSPA through BDCFs for the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.12.3). Because variation in radionuclide concentrations in deposited and redistributed volcanic tephra is not part of the biosphere model, BDCFs are calculated based on a unit radionuclide concentration in the soil (1 Bq/m^2 and 1 Bq/kg, depending on the exposure pathway) (SNL 2007 [DIRS 177399], Section 6.5). The TSPA model calculates annual radiation dose as a product of the time-dependent source terms, the source-independent BDCFs, and the mass loading time decay function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model. The first component accounts for exposure to sources external to the body, ingestion, and inhalation of radon decay products. The second and third BDCF components (the short-term and long-term inhalation components) account for inhaling airborne particulates. The short-term inhalation component is numerically equal to the incremental increase in inhalation exposure during the first year following a volcanic eruption. This term is used together with the time function to calculate short-term increase in inhalation exposure relative to the conditions existing before and long after an eruption. With time, particulate concentration in air returns to the preeruption level. These conditions are described by the long-term inhalation component, which represents inhalation of resuspended particulates under nominal conditions (i.e., when the mass loading is not elevated as the result of volcanic eruption) (SNL 2007 [DIRS 177399], Section 6.12.3).

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

FEP: 3.3.06.00.0A

FEP NAME:

Radiological Toxicity and Effects

FEP DESCRIPTION:

This FEP addresses the estimation of human health effects resulting from radiation doses.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) address the protection of individuals from future radionuclide releases by placing limits on the annual dose from radiation that may be received by the RMEI. The RMEI, per 10 CFR 63.312(e) [DIRS 180319], is an adult with metabolic and physiological characteristics consistent with present knowledge of adults. The dose limits reflect the risk to the health and safety of the public, using the RMEI as a conservative surrogate for the public. The groundwater protection standards in 10 CFR 63.331 [DIRS 180319] are based on radionuclide concentrations in groundwater and on a radiation dose from drinking water.

No performance standards for possible radiological toxicity effects of radiation on human health have been imposed by the NRC. The regulations require calculation of radiation doses and radionuclide concentrations in the groundwater. They do not require estimating radiological health effects resulting from exposure to radiation. Therefore, this FEP is excluded on the basis of inconsistency with the regulations in proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and 10 CFR 63.331 [DIRS 180319].

FEP: 3.3.06.01.0A

FEP NAME:

Repository Excavation

FEP DESCRIPTION:

Excavation of the repository and/or its contents may result in the production of tailings, which may subsequently release toxic contaminants.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

The handling of excavation spoils during construction of the repository is a preclosure operational concern, whereas the TSPA focus for FEP inclusion and exclusion is on postclosure assessment. Therefore, the effects of excavation spoils associated with the construction of the repository are excluded from the TSPA based on regulation. Future mining of the repository for its waste content constitutes human intrusion, and postclosure excavation of repository contents would constitute deliberate human intrusion. These activities are discussed in excluded FEPs 1.4.02.01.0A (Deliberate Human Intrusion) and 1.4.05.00.0A (Mining and Other Underground Activities (Human Intrusion)), both of which are excluded by regulation.

The NRC states that a performance assessment is to demonstrate compliance with postclosure performance objectives (10 CFR 63.102(j) [DIRS 180319]). The creation and handling of excavation spoils is part of preclosure operations; the surface facilities will be removed and the surface restored prior to repository closure (SNL 2007 [DIRS 179466], Table 4-3, Parameter Number 09-04). Also, the NRC indicates that the postclosure performance objectives are to be based on protecting the RMEI against radiation exposures and releases of radioactive material to the accessible environment (proposed 10 CFR 63.311 and 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319]). The regulation does not specify chemical toxicity as a postclosure performance criterion, nor does it require the estimation of health effects resulting from non-radiological toxicity. This is consistent with exclusion of FEP 3.3.07.00.0A (Non-Radiological Toxicity and Effects). In conclusion, the effects of repository excavation are excluded from the TSPA based on regulation.

FEP: 3.3.06.02.0A

FEP NAME:

Sensitization to Radiation

FEP DESCRIPTION:

Human and other organisms may become sensitized to radiation exposure so that its effects are more severe.

SCREENING DECISION:

Excluded – by regulation

SCREENING JUSTIFICATION:

Proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]) address protection of individuals from future radionuclide releases by placing limits on the annual dose from radiation that may be received by the RMEI. The RMEI, per 10 CFR 63.312(e) [DIRS 180319], is an adult with metabolic and physiological characteristics consistent with present knowledge of adults. The dose limits reflect the risk to the health and safety of the public, using the RMEI as a conservative surrogate for the public. The groundwater protection standards in 10 CFR 63.331 [DIRS 180319] are based on radionuclide concentrations in groundwater and on a radiation dose from drinking water.

No performance standards for possible effects of sensitization to radiation on human health and on other organisms have been imposed by the NRC. The regulations require calculation of radiation doses and radionuclide concentrations in the groundwater. They do not require estimating radiological health or other effects, such as the sensitization to radiation, resulting from radiation exposure. Therefore this FEP is excluded on the basis of inconsistency with the regulations in proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and 10 CFR 63.331 [DIRS 180319].

FEP: 3.3.08.00.0A

FEP NAME:

Radon and Radon Decay Product Exposure

FEP DESCRIPTION:

This FEP addresses human exposure to radon and radon decay products. ^{226}Ra occurs in nuclear fuel waste and it gives rise to ^{222}Rn gas, the radioactive decay products of which can result in radiation doses to humans upon inhalation.

SCREENING DECISION:

Included

TSPA DISPOSITION:

Radon (^{222}Rn) is a decay product of one of the primary radionuclides considered in the TSPA (SNL 2007 [DIRS 177399], Table 6.3-7). Human exposure to radon and radon decay products occurs through inhalation.

Exposure to radon (^{222}Rn) and radon decay products is included in the air and inhalation submodels of the groundwater (SNL 2007 [DIRS 177399], Sections 6.4.2.3 and 6.4.8.4) and volcanic ash (SNL 2007 [DIRS 177399], Sections 6.5.2.2 and 6.5.6.2) exposure scenarios. Concentrations of radon and radon decay products are calculated in the air submodels for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.2.3) and volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.5.2.2). The consequences of inhalation of radon and the decay products are included in the inhalation submodels for the groundwater exposure scenario (SNL 2007 [DIRS 177399], Section 6.4.8.4) and the volcanic ash exposure scenario (SNL 2007 [DIRS 177399], Section 6.5.6.2). The parameters supporting this FEP include radon release factor (BSC 2004 [DIRS 169672], Section 6.6.1), interior wall height (BSC 2004 [DIRS 169672], Sections 6.5.2 and 6.6.2), house ventilation rate (BSC 2004 [DIRS 169672], Section 6.6.2), fraction of ^{222}Rn from soil entering the house (BSC 2004 [DIRS 169672], Section 6.6.2), ratio of ^{222}Rn concentration in air to flux density from soil (BSC 2004 [DIRS 169672], Section 6.6.1), equilibrium factor for ^{222}Rn decay products (BSC 2004 [DIRS 169672], Section 6.6.3), fraction of radionuclide transfer from water to air for evaporative coolers (BSC 2004 [DIRS 169672], Section 6.5.2), and dose coefficient for inhalation of radon decay products (BSC 2005 [DIRS 172827], Section 6.5.4). As discussed in excluded FEP 2.2.11.03.0A (Gas Transport in Geosphere), exposure to ^{222}Rn that migrates directly from the repository to the land surface in the gas phase is negligible and is not included in the pathways evaluated in the biosphere model.

This FEP is included in the biosphere component of the TSPA model through the use of groundwater exposure scenario BDCFs that are direct inputs to the TSPA for the scenario classes involving radionuclide release to the groundwater (SNL 2007 [DIRS 177399], Section 6.11.3). The annual doses are calculated as the product of radionuclide concentration in groundwater and the BDCFs. In the event of a volcanic eruption, this FEP is included in the TSPA through

BDCFs for the volcanic ash exposure scenarios (SNL 2007 [DIRS 177399], Section 6.12.3). The annual doses are calculated as the product of radionuclide concentration in soil contaminated by radionuclides in volcanic tephra, the BDCF components, and the mass loading time decay function. For the volcanic ash exposure scenario, three BDCF components are provided to the TSPA model that account for various RMEI exposure pathways, including inhalation of radon and its decay products (SNL 2007 [DIRS 177399], Section 6.12.3). See included FEP 3.3.04.02.0A (Inhalation) for a more detailed description of the volcanic BDCF components.

The BDCFs for all biosphere model realizations are provided as inputs to the TSPA model, which randomly samples these inputs to propagate uncertainty from the biosphere model into TSPA dose calculations. The present-day climate BDCFs are used for the assessment of doses to the RMEI for 10,000 years following disposal, as well as after 10,000 years, but within the period of the geologic stability (SNL 2007 [DIRS 177399], Sections 6.11.3 and 6.12.3).

This FEP is included for the performance assessment to demonstrate compliance with the individual protection standard (proposed 10 CFR 63.311 (70 FR 53313 [DIRS 178394])) and the performance assessment to demonstrate compliance with the individual protection standard for human intrusion (proposed 10 CFR 63.321 (70 FR 53313 [DIRS 178394])) because these standards require consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations. This FEP is also included for the performance assessment to demonstrate compliance with the groundwater protection standards (10 CFR 63.331 [DIRS 180319]). These standards do not require the consideration of all potential pathways of radionuclide transport and exposure in the performance assessment calculations; rather, only the groundwater ingestion pathway must be included. Radon decay products contribute to the beta-photon dose for that pathway.

7. CONCLUSIONS

This analysis report documents the screening decisions for the current Yucca Mountain disposal system FEPs, along with their technical bases. The results of these FEP screening analyses, documented in Section 6.2, are summarized in Table 7-1. The included FEPs become part of the total system performance assessment described in *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]).

The technical product output from these screening analyses is contained in the electronic database *FY 2007 LA FEP List and Screening* (DTN: MO0706SPAFEPLA.001). This database is useful to catalog and display the screening decisions and detailed FEP information. It is acknowledged that the FEP justification and implementation text provided in Section 6.2 may differ from that contained within the output DTN, but only at an editorial level.

Other technical product output from this report includes:

- DTN: SN0705WFLOWSCC.001—Output from Appendix C containing seepage flux analyses for flow through cracks (support exclusion justification for FEPs 2.1.03.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package) and 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield)).

- DTN: MO0707NONLITHO.000—Output from Appendix E calculations demonstrating low consequence from seismic-induced rock block impacts in the nonlithophysal units (support exclusion justification for FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components)).

- DTN: SN0712CEMENTEQ.001—Output from Appendix J used to corroborate and thereby qualify a direct input source of data.

Section 7.1 presents a discussion of the applicable NUREG-1804 (NRC 2003 [DIRS 163274]) acceptance criteria, which were identified in Section 4.2, and how these criteria are met.

1.2.10.02.0A	Hydrologic Response to Igneous Activity	Excluded
1.3.01.00.0A	Climate Change	Included
1.3.04.00.0A	Periglacial Effects	Excluded
1.3.05.00.0A	Glacial and Ice Sheet Effect	Excluded

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
1.3.07.01.0A	Water Table Decline	Excluded
1.3.07.02.0A	Water Table Rise Affects SZ	Included
1.3.07.02.0B	Water Table Rise Affects UZ	Included
1.4.01.00.0A	Human Influences on Climate	Excluded
1.4.01.01.0A	Climate Modification Increases Recharge	Included
1.4.01.02.0A	Greenhouse Gas Effects	Excluded
1.4.01.03.0A	Acid Rain	Excluded
1.4.01.04.0A	Ozone Layer Failure	Excluded
1.4.02.01.0A	Deliberate Human Intrusion	Excluded
1.4.02.02.0A	Inadvertent Human Intrusion	Included
1.4.02.03.0A	Igneous Event Precedes Human Intrusion	Excluded
1.4.02.04.0A	Seismic Event Precedes Human Intrusion	Excluded
1.4.03.00.0A	Unintrusive Site Investigation	Excluded
1.4.04.00.0A	Drilling Activities (Human Intrusion)	Included
1.4.04.01.0A	Effects of Drilling Intrusion	Included
1.4.05.00.0A	Mining and Other Underground Activities (Human Intrusion)	Excluded
1.4.06.01.0A	Altered Soil Or Surface Water Chemistry	Excluded
1.4.07.01.0A	Water Management Activities	Included
1.4.07.02.0A	Wells	Included
1.4.07.03.0A	Recycling of Accumulated Radionuclides from Soils to Groundwater	Excluded
1.4.08.00.0A	Social and Institutional Developments	Excluded
1.4.09.00.0A	Technological Developments	Excluded
1.4.11.00.0A	Explosions and Crashes (Human Activities)	Excluded
1.5.01.01.0A	Meteorite Impact	Excluded
1.5.01.02.0A	Extraterrestrial Events	Excluded
1.5.02.00.0A	Species Evolution	Excluded
1.5.03.01.0A	Changes in the Earth's Magnetic Field	Excluded
1.5.03.02.0A	Earth Tides	Excluded
2.1.01.01.0A	Waste Inventory	Included
2.1.01.02.0A	Interactions Between Co-Located Waste	Excluded
2.1.01.02.0B	Interactions Between Co-Disposed Waste	Included
2.1.01.03.0A	Heterogeneity of Waste Inventory	Included
2.1.01.04.0A	Repository-Scale Spatial Heterogeneity of Emplaced Waste	Included
2.1.02.01.0A	DSNF Degradation (Alteration, Dissolution, and Radionuclide Release)	Included
2.1.02.02.0A	CSNF Degradation (Alteration, Dissolution, and Radionuclide Release)	Included
2.1.02.03.0A	HLW Glass Degradation (Alteration, Dissolution, and Radionuclide Release)	Included
2.1.02.04.0A	Alpha Recoil Enhances Dissolution	Excluded
2.1.02.05.0A	HLW Glass Cracking	Included
2.1.02.06.0A	HLW Glass Recrystallization	Excluded
2.1.02.07.0A	Radionuclide Release from Gap and Grain Boundaries	Included
2.1.02.08.0A	Pyrophoricity from DSNF	Excluded
2.1.02.09.0A	Chemical Effects of Void Space in Waste Package	Included

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.1.02.10.0A	Organic/Cellulosic Materials in Waste	Excluded
2.1.02.11.0A	Degradation of Cladding from Waterlogged Rods	Excluded
2.1.02.12.0A	Degradation of Cladding Prior to Disposal	Included
2.1.02.13.0A	General Corrosion of Cladding	Excluded
2.1.02.14.0A	Microbially Influenced Corrosion (MIC) of Cladding	Excluded
2.1.02.15.0A	Localized (Radiolysis Enhanced) Corrosion of Cladding	Excluded
2.1.02.16.0A	Localized (Pitting) Corrosion of Cladding	Excluded
2.1.02.17.0A	Localized (Crevice) Corrosion of Cladding	Excluded
2.1.02.18.0A	Enhanced Corrosion of Cladding from Dissolved Silica	Excluded
2.1.02.19.0A	Creep Rupture of Cladding	Excluded
2.1.02.20.0A	Internal Pressurization of Cladding	Excluded
2.1.02.21.0A	Stress Corrosion Cracking (SCC) of Cladding	Excluded
2.1.02.22.0A	Hydride Cracking of Cladding	Excluded
2.1.02.23.0A	Cladding Unzipping	Included
2.1.02.24.0A	Mechanical Impact on Cladding	Excluded
2.1.02.25.0A	DSNF Cladding	Excluded
2.1.02.25.0B	Naval SNF Cladding	Included
2.1.02.26.0A	Diffusion-Controlled Cavity Growth in Cladding	Excluded
2.1.02.27.0A	Localized (Fluoride Enhanced) Corrosion of Cladding	Excluded
2.1.02.28.0A	Grouping of DSNF Waste Types Into Categories	Included
2.1.02.29.0A	Flammable Gas Generation from DSNF	Excluded
2.1.03.01.0A	General Corrosion of Waste Packages	Included
2.1.03.01.0B	General Corrosion of Drip Shields	Included
2.1.03.02.0A	Stress Corrosion Cracking (SCC) of Waste Packages	Included
2.1.03.02.0B	Stress Corrosion Cracking (SCC) of Drip Shields	Excluded
2.1.03.03.0A	Localized Corrosion of Waste Packages	Included
2.1.03.03.0B	Localized Corrosion of Drip Shields	Excluded
2.1.03.04.0A	Hydride Cracking of Waste Packages	Excluded
2.1.03.04.0B	Hydride Cracking of Drip Shields	Excluded
2.1.03.05.0A	Microbially Influenced Corrosion (MIC) of Waste Packages	Included
2.1.03.05.0B	Microbially Influenced Corrosion (MIC) of Drip Shields	Excluded
2.1.03.06.0A	Internal Corrosion of Waste Packages Prior to Breach	Excluded
2.1.03.07.0A	Mechanical Impact on Waste Package	Excluded
2.1.03.07.0B	Mechanical Impact on Drip Shield	Excluded
2.1.03.08.0A	Early Failure of Waste Packages	Included
2.1.03.08.0B	Early Failure of Drip Shields	Included
2.1.03.09.0A	Copper Corrosion in EBS	Excluded
2.1.03.10.0A	Advection of Liquids and Solids Through Cracks in the Waste Package	Excluded
2.1.03.10.0B	Advection of Liquids and Solids Through Cracks in the Drip Shield	Excluded
2.1.03.11.0A	Physical Form of Waste Package and Drip Shield	Included
2.1.04.01.0A	Flow in the Backfill	Excluded
2.1.04.02.0A	Chemical Properties and Evolution of Backfill	Excluded
2.1.04.03.0A	Erosion or Dissolution of Backfill	Excluded

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.1.04.04.0A	Thermal-Mechanical Effects of Backfill	Excluded
2.1.04.05.0A	Thermal-Mechanical Properties and Evolution of Backfill	Excluded
2.1.04.09.0A	Radionuclide Transport in Backfill	Excluded
2.1.05.01.0A	Flow Through Seals (Access Ramps and Ventilation Shafts)	Excluded
2.1.05.02.0A	Radionuclide Transport Through Seals	Excluded
2.1.05.03.0A	Degradation of Seals	Excluded
2.1.06.01.0A	Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS	Excluded
2.1.06.02.0A	Mechanical Effects of Rock Reinforcement Materials in EBS	Excluded
2.1.06.04.0A	Flow Through Rock Reinforcement Materials in EBS	Excluded
2.1.06.05.0A	Mechanical Degradation of Emplacement Pallet	Excluded
2.1.06.05.0B	Mechanical Degradation of Invert	Excluded
2.1.06.05.0C	Chemical Degradation of Emplacement Pallet	Included
2.1.06.05.0D	Chemical Degradation of Invert	Excluded
2.1.06.06.0A	Effects of Drip Shield on Flow	Included
2.1.06.06.0B	Oxygen Embrittlement of Drip Shields	Excluded
2.1.06.07.0A	Chemical Effects at EBS Component Interfaces	Excluded
2.1.06.07.0B	Mechanical Effects at EBS Component Interfaces	Excluded
2.1.07.01.0A	Rockfall	Excluded
2.1.07.02.0A	Drift Collapse	Excluded
2.1.07.04.0A	Hydrostatic Pressure on Waste Package	Excluded
2.1.07.04.0B	Hydrostatic Pressure on Drip Shield	Excluded
2.1.07.05.0A	Creep of Metallic Materials in the Waste Package	Excluded
2.1.07.05.0B	Creep of Metallic Materials in the Drip Shield	Excluded
2.1.07.06.0A	Floor Buckling	Excluded
2.1.08.01.0A	Water Influx at the Repository	Included
2.1.08.01.0B	Effects of Rapid Influx into the Repository	Excluded
2.1.08.02.0A	Enhanced Influx at the Repository	Included
2.1.08.03.0A	Repository Dry-Out Due to Waste Heat	Included
2.1.08.04.0A	Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps)	Included
2.1.08.04.0B	Condensation Forms at Repository Edges (Repository-Scale Cold Traps)	Included
2.1.08.05.0A	Flow Through Invert	Included
2.1.08.06.0A	Capillary Effects (Wicking) in EBS	Included
2.1.08.07.0A	Unsaturated Flow in the EBS	Included
2.1.08.09.0A	Saturated Flow in the EBS	Excluded
2.1.08.11.0A	Repository Resaturation Due to Waste Cooling	Included
2.1.08.12.0A	Induced Hydrologic Changes in Invert	Excluded
2.1.08.14.0A	Condensation on Underside of Drip Shield	Excluded
2.1.08.15.0A	Consolidation of EBS Components	Excluded
2.1.09.01.0A	Chemical Characteristics of Water in Drifts	Included
2.1.09.01.0B	Chemical Characteristics of Water in Waste Package	Included
2.1.09.02.0A	Chemical Interaction With Corrosion Products	Included

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.1.09.03.0A	Volume Increase of Corrosion Products Impacts Cladding	Excluded
2.1.09.03.0B	Volume Increase of Corrosion Products Impacts Waste Package	Excluded
2.1.09.03.0C	Volume Increase of Corrosion Products Impacts Other EBS Components	Excluded
2.1.09.04.0A	Radionuclide Solubility, Solubility Limits, and Speciation in the Waste Form and EBS	Included
2.1.09.05.0A	Sorption of Dissolved Radionuclides in EBS	Included
2.1.09.06.0A	Reduction-Oxidation Potential in Waste Package	Included
2.1.09.06.0B	Reduction-Oxidation Potential in Drifts	Included
2.1.09.07.0A	Reaction Kinetics in Waste Package	Included
2.1.09.07.0B	Reaction Kinetics in Drifts	Included
2.1.09.08.0A	Diffusion of Dissolved Radionuclides in EBS	Included
2.1.09.08.0B	Advection of Dissolved Radionuclides in EBS	Included
2.1.09.09.0A	Electrochemical Effects in EBS	Excluded
2.1.09.10.0A	Secondary Phase Effects on Dissolved Radionuclide Concentrations	Excluded
2.1.09.11.0A	Chemical Effects of Waste-Rock Contact	Excluded
2.1.09.12.0A	Rind (Chemically Altered Zone) Forms in the Near-Field	Excluded
2.1.09.13.0A	Complexation in EBS	Excluded
2.1.09.15.0A	Formation of True (Intrinsic) Colloids in EBS	Excluded
2.1.09.16.0A	Formation of Pseudo-Colloids (Natural) in EBS	Included
2.1.09.17.0A	Formation of Pseudo-Colloids (Corrosion Product) in EBS	Included
2.1.09.18.0A	Formation of Microbial Colloids in EBS	Excluded
2.1.09.19.0A	Sorption of Colloids in EBS	Excluded
2.1.09.19.0B	Advection of Colloids in EBS	Included
2.1.09.20.0A	Filtration of Colloids in EBS	Excluded
2.1.09.21.0A	Transport of Particles Larger Than Colloids in EBS	Excluded
2.1.09.21.0B	Transport of Particles Larger Than Colloids in the SZ	Excluded
2.1.09.21.0C	Transport of Particles Larger Than Colloids in the UZ	Excluded
2.1.09.22.0A	Sorption of Colloids at Air-Water Interface	Excluded
2.1.09.23.0A	Stability of Colloids in EBS	Included
2.1.09.24.0A	Diffusion of Colloids in EBS	Included
2.1.09.25.0A	Formation of Colloids (Waste-Form) By Co-Precipitation in EBS	Included
2.1.09.26.0A	Gravitational Settling of Colloids in EBS	Excluded
2.1.09.27.0A	Coupled Effects on Radionuclide Transport in EBS	Excluded
2.1.09.28.0A	Localized Corrosion on Waste Package Outer Surface Due to Deliquescence	Excluded
2.1.09.28.0B	Localized Corrosion on Drip Shield Surfaces Due to Deliquescence	Excluded
2.1.10.01.0A	Microbial Activity in EBS	Excluded
2.1.11.01.0A	Heat Generation in EBS	Included
2.1.11.02.0A	Non-Uniform Heat Distribution in EBS	Included
2.1.11.03.0A	Exothermic Reactions in the EBS	Excluded
2.1.11.05.0A	Thermal Expansion/Stress of in-Package EBS Components	Excluded
2.1.11.06.0A	Thermal Sensitization of Waste Packages	Excluded

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.1.11.06.0B	Thermal Sensitization of Drip Shields	Excluded
2.1.11.07.0A	Thermal Expansion/Stress of in-Drift EBS Components	Excluded
2.1.11.08.0A	Thermal Effects on Chemistry and Microbial Activity in the EBS	Included
2.1.11.09.0A	Thermal Effects on Flow in the EBS	Included
2.1.11.09.0B	Thermally-Driven Flow (Convection) in Waste Packages	Excluded
2.1.11.09.0C	Thermally Driven Flow (Convection) in Drifts	Included
2.1.11.10.0A	Thermal Effects on Transport in EBS	Excluded
2.1.12.01.0A	Gas Generation (Repository Pressurization)	Excluded
2.1.12.02.0A	Gas Generation (He) from Waste Form Decay	Excluded
2.1.12.03.0A	Gas Generation (H_2) from Waste Package Corrosion	Excluded
2.1.12.04.0A	Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation	Excluded
2.1.12.06.0A	Gas Transport in EBS	Excluded
2.1.12.07.0A	Effects of Radioactive Gases in EBS	Excluded
2.1.12.08.0A	Gas Explosions in EBS	Excluded
2.1.13.01.0A	Radiolysis	Excluded
2.1.13.02.0A	Radiation Damage in EBS	Excluded
2.1.13.03.0A	Radiological Mutation of Microbes	Excluded
2.1.14.15.0A	In-Package Criticality (Intact Configuration)	Excluded
2.1.14.16.0A	In-Package Criticality (Degraded Configurations)	Excluded
2.1.14.17.0A	Near-Field Criticality	Excluded
2.1.14.18.0A	In-Package Criticality Resulting from a Seismic Event (Intact Configuration)	Excluded
2.1.14.19.0A	In-Package Criticality Resulting from a Seismic Event (Degraded Configurations)	Excluded
2.1.14.20.0A	Near-Field Criticality Resulting from a Seismic Event	Excluded
2.1.14.21.0A	In-Package Criticality Resulting from Rockfall (Intact Configuration)	Excluded
2.1.14.22.0A	In-Package Criticality Resulting from Rockfall (Degraded Configurations)	Excluded
2.1.14.23.0A	Near-Field Criticality Resulting from Rockfall	Excluded
2.1.14.24.0A	In-Package Criticality Resulting from an Igneous Event (Intact Configuration)	Excluded
2.1.14.25.0A	In-Package Criticality Resulting from an Igneous Event (Degraded Configurations)	Excluded
2.1.14.26.0A	Near-Field Criticality Resulting from an Igneous Event	Excluded
2.2.01.01.0A	Mechanical Effects of Excavation and Construction in the Near-Field	Included
2.2.01.01.0B	Chemical Effects of Excavation and Construction in the Near-Field	Excluded
2.2.01.02.0A	Thermally-Induced Stress Changes in the Near-Field	Excluded
2.2.01.02.0B	Chemical Changes in the Near-Field from Backfill	Excluded
2.2.01.03.0A	Changes In Fluid Saturations in the Excavation Disturbed Zone	Excluded
2.2.01.04.0A	Radionuclide Solubility in the Excavation Disturbed Zone	Excluded
2.2.01.05.0A	Radionuclide Transport in the Excavation Disturbed Zone	Excluded
2.2.03.01.0A	Stratigraphy	Included
2.2.03.02.0A	Rock Properties of Host Rock and Other Units	Included
2.2.06.01.0A	Seismic Activity Changes Porosity and Permeability of Rock	Excluded

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.2.06.02.0A	Seismic Activity Changes Porosity and Permeability of Faults	Excluded
2.2.06.02.0B	Seismic Activity Changes Porosity and Permeability of Fractures	Excluded
2.2.06.03.0A	Seismic Activity Alters Perched Water Zones	Excluded
2.2.06.04.0A	Effects of Subsidence	Excluded
2.2.06.05.0A	Salt Creep	Excluded
2.2.07.01.0A	Locally Saturated Flow at Bedrock/Alluvium Contact	Excluded
2.2.07.02.0A	Unsaturated Groundwater Flow in the Geosphere	Included
2.2.07.03.0A	Capillary Rise in the UZ	Included
2.2.07.04.0A	Focusing of Unsaturated Flow (Fingers, Weeps)	Included
2.2.07.05.0A	Flow in the UZ from Episodic Infiltration	Excluded
2.2.07.06.0A	Episodic Or Pulse Release from Repository	Excluded
2.2.07.06.0B	Long-Term Release of Radionuclides from The Repository	Included
2.2.07.07.0A	Perched Water Develops	Included
2.2.07.08.0A	Fracture Flow in the UZ	Included
2.2.07.09.0A	Matrix Imbibition in the UZ	Included
2.2.07.10.0A	Condensation Zone Forms Around Drifts	Included
2.2.07.11.0A	Resaturation of Geosphere Dry-Out Zone	Included
2.2.07.12.0A	Saturated Groundwater Flow in the Geosphere	Included
2.2.07.13.0A	Water-Conducting Features in the SZ	Included
2.2.07.14.0A	Chemically-Induced Density Effects on Groundwater Flow	Excluded
2.2.07.15.0A	Advection and Dispersion in the SZ	Included
2.2.07.15.0B	Advection and Dispersion in the UZ	Included
2.2.07.16.0A	Dilution of Radionuclides in Groundwater	Included
2.2.07.17.0A	Diffusion in the SZ	Included
2.2.07.18.0A	Film Flow into the Repository	Included
2.2.07.19.0A	Lateral Flow from Solitario Canyon Fault Enters Drifts	Included
2.2.07.20.0A	Flow Diversion Around Repository Drifts	Included
2.2.07.21.0A	Drift Shadow Forms Below Repository	Excluded
2.2.08.01.0A	Chemical Characteristics of Groundwater in the SZ	Included
2.2.08.01.0B	Chemical Characteristics of Groundwater in the UZ	Included
2.2.08.03.0A	Geochemical Interactions and Evolution in the SZ	Excluded
2.2.08.03.0B	Geochemical Interactions and Evolution in the UZ	Excluded
2.2.08.04.0A	Re-Dissolution of Precipitates Directs More Corrosive Fluids to Waste Packages	Excluded
2.2.08.05.0A	Diffusion in the UZ	Excluded
2.2.08.06.0A	Complexation in the SZ	Included
2.2.08.06.0B	Complexation in the UZ	Included
2.2.08.07.0A	Radionuclide Solubility Limits in the SZ	Excluded
2.2.08.07.0B	Radionuclide Solubility Limits in the UZ	Excluded
2.2.08.07.0C	Radionuclide Solubility Limits in the Biosphere	Excluded
2.2.08.08.0A	Matrix Diffusion in the SZ	Included
2.2.08.08.0B	Matrix Diffusion in the UZ	Included
2.2.08.09.0A	Sorption in the SZ	Included

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.2.08.09.0B	Sorption in the UZ	Included
2.2.08.10.0A	Colloidal Transport in the SZ	Included
2.2.08.10.0B	Colloidal Transport in the UZ	Included
2.2.08.11.0A	Groundwater Discharge to Surface Within The Reference Biosphere	Excluded
2.2.08.12.0A	Chemistry of Water Flowing into the Drift	Included
2.2.08.12.0B	Chemistry of Water Flowing into the Waste Package	Included
2.2.09.01.0A	Microbial Activity in the SZ	Excluded
2.2.09.01.0B	Microbial Activity in the UZ	Excluded
2.2.10.01.0A	Repository-Induced Thermal Effects on Flow in the UZ	Excluded
2.2.10.02.0A	Thermal Convection Cell Develops in SZ	Excluded
2.2.10.03.0A	Natural Geothermal Effects on Flow in the SZ	Included
2.2.10.03.0B	Natural Geothermal Effects on Flow in the UZ	Included
2.2.10.04.0A	Thermo-Mechanical Stresses Alter Characteristics of Fractures Near Repository	Excluded
2.2.10.04.0B	Thermo-Mechanical Stresses Alter Characteristics of Faults Near Repository	Excluded
2.2.10.05.0A	Thermo-Mechanical Stresses Alter Characteristics of Rocks Above and Below The Repository	Excluded
2.2.10.06.0A	Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)	Excluded
2.2.10.07.0A	Thermo-Chemical Alteration of the Calico Hills Unit	Excluded
2.2.10.08.0A	Thermo-Chemical Alteration in the SZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution)	Excluded
2.2.10.09.0A	Thermo-Chemical Alteration of the Topopah Spring Basal Vitrophyre	Excluded
2.2.10.10.0A	Two-Phase Buoyant Flow/Heat Pipes	Included
2.2.10.11.0A	Natural Air Flow in the UZ	Excluded
2.2.10.12.0A	Geosphere Dry-Out Due to Waste Heat	Included
2.2.10.13.0A	Repository-Induced Thermal Effects on Flow in the SZ	Excluded
2.2.10.14.0A	Mineralogic Dehydration Reactions	Excluded
2.2.11.01.0A	Gas Effects in the SZ	Excluded
2.2.11.02.0A	Gas Effects in the UZ	Excluded
2.2.11.03.0A	Gas Transport in Geosphere	Excluded
2.2.12.00.0A	Undetected Features in the UZ	Excluded
2.2.12.00.0B	Undetected Features in the SZ	Included
2.2.14.09.0A	Far-Field Criticality	Excluded
2.2.14.10.0A	Far-Field Criticality Resulting from a Seismic Event	Excluded
2.2.14.11.0A	Far-Field Criticality Resulting from Rockfall	Excluded
2.2.14.12.0A	Far-Field Criticality Resulting from an Igneous Event	Excluded
2.3.01.00.0A	Topography and Morphology	Included
2.3.02.01.0A	Soil Type	Included
2.3.02.02.0A	Radionuclide Accumulation in Soils	Included
2.3.02.03.0A	Soil and Sediment Transport in the Biosphere	Included
2.3.04.01.0A	Surface Water Transport and Mixing	Included
2.3.06.00.0A	Marine Features	Excluded

Table 7-1. Yucca Mountain Project Features, Events, and Processes List and Screening Decisions Listed by FEP Number (Continued)

FEP Number	FEP Name	Screening Decision
2.3.09.01.0A	Animal Burrowing/Intrusion	Excluded
2.3.11.01.0A	Precipitation	Included
2.3.11.02.0A	Surface Runoff and Evapotranspiration	Included
2.3.11.03.0A	Infiltration and Recharge	Included
2.3.11.04.0A	Groundwater Discharge to Surface Outside The Reference Biosphere	Excluded
2.3.13.01.0A	Biosphere Characteristics	Included
2.3.13.02.0A	Radionuclide Alteration During Biosphere Transport	Included
2.3.13.03.0A	Effects of Repository Heat on The Biosphere	Excluded
2.3.13.04.0A	Radionuclide Release Outside The Reference Biosphere	Excluded
2.4.01.00.0A	Human Characteristics (Physiology, Metabolism)	Included
2.4.04.01.0A	Human Lifestyle	Included
2.4.07.00.0A	Dwellings	Included
2.4.08.00.0A	Wild and Natural Land and Water Use	Included
2.4.09.01.0A	Implementation of New Agricultural Practices Or Land Use	Excluded
2.4.09.01.0B	Agricultural Land Use and Irrigation	Included
2.4.09.02.0A	Animal Farms and Fisheries	Included
2.4.10.00.0A	Urban and Industrial Land and Water Use	Included
3.1.01.01.0A	Radioactive Decay and Ingrowth	Included
3.2.07.01.0A	Isotopic Dilution	Excluded
3.2.10.00.0A	Atmospheric Transport of Contaminants	Included
3.3.01.00.0A	Contaminated Drinking Water, Foodstuffs and Drugs	Included
3.3.02.01.0A	Plant Uptake	Included
3.3.02.02.0A	Animal Uptake	Included
3.3.02.03.0A	Fish Uptake	Included
3.3.03.01.0A	Contaminated Non-Food Products and Exposure	Included
3.3.04.01.0A	Ingestion	Included
3.3.04.02.0A	Inhalation	Included
3.3.04.03.0A	External Exposure	Included
3.3.05.01.0A	Radiation Doses	Included
3.3.06.00.0A	Radiological Toxicity and Effects	Excluded
3.3.06.01.0A	Repository Excavation	Excluded
3.3.06.02.0A	Sensitization to Radiation	Excluded
3.3.07.00.0A	Non-Radiological Toxicity and Effects	Excluded
3.3.08.00.0A	Radon and Radon Decay Product Exposure	Included

Output DTN: MO0706SPAFEPLA.001.

7.1 RELEVANT ACCEPTANCE CRITERIA

The following acceptance criterion from NUREG-1804 (NRC 2003 [DIRS 163274], Section 2.2.1.2.1.3), identified previously in Section 4.2, is addressed in this report:

NUREG-1804 Section 2.2.1.2.1.3, Acceptance Criterion 2: Screening of the List of Features, Events, and Processes Is Appropriate.

1. The U.S. Department of Energy has identified all features, events, and processes related to either the geologic setting or to the degradation, deterioration, or alteration of engineered barriers (including those processes that would affect the performance of natural barriers) that have been excluded;

2. The U.S. Department of Energy has provided justification for those features, events, and processes that have been excluded. An acceptable justification for excluding features, events, and processes is that either the feature, event, and process is specifically excluded by regulation; probability of the feature, event, and process (generally an event) falls below the regulatory criterion; or omission of the feature, event, and process does not significantly change the magnitude and time of the resulting radiological exposures to the reasonably maximally exposed individual, or radionuclide releases to the accessible environment; and

3. The U.S. Department of Energy has provided an adequate technical basis for each feature, event, and process, excluded from the performance assessment, to support the conclusion that either the feature, event, or process is specifically excluded by regulation; the probability of the feature, event, and process falls below the regulatory criterion; or omission of the feature, event, and process does not significantly change the magnitude and time of the resulting radiological exposures to the reasonably maximally exposed individual, or radionuclide releases to the accessible environment.

How Addressed

1. Complete identification of the excluded FEPs.

2. As described in Section 6.1, each FEP was evaluated against regulatory-based screening criteria and documented in Section 6.2 with a screening decision, screening justification (for excluded FEPs), or TSPA disposition (for included FEPs). A FEP that satisfied any one of the exclusion screening criteria (low probability, low consequence, or by regulation) was excluded from the TSPA model. A FEP that did not satisfy any of the exclusion screening criteria was included in the TSPA model. These screening decisions are summarized in Table 7-1.

3. The documentation in Section 6.2 provides the appropriate justification and technical basis of exclusion, or a TSPA model implementation description of inclusion, for each FEP. The screening decisions and technical bases consider site-specific information, design, and regulations.

163558 LA0303HV831352.002. Colloid Retardation Factors for the Saturated Zone Fractured Volcanics. Submittal date: 03/31/2003.

163422 LA0305RR831222.001. Chlorine-36 and Cl in Salts Leached from Rock Samples for the Chlorine-36 Validation Study. Submittal date: 05/22/2003.

164090 LA0307RR831222.002. Chloride, Bromide, Sulfate, and Chlorine-36 Analyses of Salts Leached from ESF 36Cl Validation Drillcore Samples in FY99. Submittal date: 07/09/2003.

167015 LA0311AM831341.001. Correlation Matrix for Sampling of Sorption Coefficient Probability Distributions. Submittal date: 11/06/2003.

166924 LA0311BR831229.001. UZ Transport Abstraction Model, Transfer Function Calculation Files. Submittal date: 11/17/2003.

170621 LA0407AM831341.002. Batch Sorption Coefficient Data for Cesium on Yucca Mountain Tuffs in Representative Water Compositions. Submittal date: 07/12/2004.

170626 LA0407AM831341.003. Batch Sorption Coefficient Data for Strontium on Yucca Mountain Tuffs in Representative Water Compositions. Submittal date: 07/12/2004.

170806 LA0407BR831371.001. UZ Transport Abstraction Model, Transport Parameters and Base Case Simulation Results. Submittal date: 07/13/2004.

179987 LA0612DK831811.001. Magma and Eruption Properties for Potential Volcano at Yucca Mountain. Submittal date: 03/23/2007.

180497 LA0701PANS02BR.003. UZ Transport Parameters. Submittal date: 04/23/2007.

184763 LA0702AM150304.001. Probability Distribution Functions and Correlations for Sampling of Sorption Coefficient Probability Distributions of Radionuclides in the SZ at the YM. Submittal date: 01/17/2008.

180322 LA0702PANS02BR.001. Repository and Water Table Bins. Submittal date: 04/16/2007.

113495 LA9908JC831321.001. Mineralogic Model "MM3.0" Version 3.0. Submittal date: 08/16/1999.

146447 LA9912SL831151.001. Fracture Mineralogy of Drill Core ESF-HD-TEMP-2. Submittal date: 01/04/2000.

146449 LA9912SL831151.002. Percent Coverage by Fracture-Coating Minerals in Core ESF-HD-TEMP-2. Submittal date: 01/05/2000.

161277 LB0101DSTTHCR1.002. Attachment II - Mineral Initial Volume Fractions for TPTPLL THC Model for AMR N0120/U0110 REV01, "Drift-Scale Coupled Processes (Drift-Scale Test and THC Seepage) Models." Submittal date: 01/26/2001.

159525 LB0205REVUZPRP.001. Fracture Properties for UZ Model Layers Developed from Field Data. Submittal date: 05/14/2002.

159526 LB0207REVUZPRP.001. Revised UZ Fault Zone Fracture Properties. Submittal date: 07/03/2002.

159672 LB0207REVUZPRP.002. Matrix Properties for UZ Model Layers Developed from Field and Laboratory Data. Submittal date: 07/15/2002.

161243 LB0208UZDSCPMI.002. Drift-Scale Calibrated Property Sets: Mean Infiltration Data Summary. Submittal date: 08/26/2002.

160799 LB0210THRMLPRP.001. Thermal Properties of UZ Model Layers: Data Summary. Submittal date: 10/25/2002.

163689 LB0301DSCPTHSM.002. Drift-Scale Coupled Process Model for Thermohydrologic Seepage: Data Summary. Submittal date: 01/29/2003.

162354 LB03023DKMGRID.001. UZ 3-D Site Scale Model Grids. Submittal date: 02/26/2003.

164744 LB0302DSCPTHCS.001. Drift-Scale Coupled Processes (THC Seepage) Model: Simulations. Submittal date: 02/11/2003.

161976 LB0302DSCPTHCS.002. Drift-Scale Coupled Processes (THC Seepage) Model: Data Summary. Submittal date: 02/11/2003.

165992 LB0304RDTRNSNS.001. Supporting Files of 3D Flow and Transport Sensitivity Analyses. Submittal date: 04/29/2003.

173235 LB0304SMDCREV2.001. Seepage Modeling for Performance Assessment, Including Drift Collapse: Input/Output Files. Submittal date: 04/11/2003.

169733 LB0306DRSCLTHM.001. Drift Scale THM Model Predictions: Simulations. Submittal date: 06/26/2003.

174490 LB0306DRSCLTHM.002. Drift Scale THM Model Predictions: Summary Plots. Submittal date: 06/26/2003.

165541 LB0307DSTTHCR2.002. Drift-Scale Coupled Processes (DST Seepage) Model: Data Summary. Submittal date: 07/24/2003.

171567 LB0308DRSCLTHM.001. Drift Scale THM Model Predictions for Poor Quality Rock in Tptpll: Simulations. Submittal date: 08/29/2003.

174489 LB0310MR0060R1.010. Supplemental Radionuclide Transport Simulations: Input/Output Files. Submittal date: 10/23/2003.

170718 LB0310MTSCLTHM.002. Mountain Scale THM Predictions: Summary Plots. Submittal date: 10/21/2003.

166714 LB0311ABSTHCR2.001. Drift Scale Coupled Process Abstraction Model (for Intact-Drift Case). Submittal date: 11/07/2003.

173280 LB0407AMRU0120.001. Supporting Calculations and Analysis for Seepage Abstraction and Summary of Abstraction Results. Submittal date: 07/29/2004.

171706 LB0408CMATUZFT.004. Leaching of Altered Cementitious Materials - EQ3/6 Simulations for Cementitious Material Transport. Submittal date: 08/31/2004.

171595 LB0408U0170FEP.001. Sensitivity Study of Fracture Width Influence on UZ Flow and Transport: Simulations. Submittal date: 09/01/2004.

171596 LB0408U0170FEP.002. Sensitivity Study of Fracture Width Influence on UZ Flow and Transport: Summaries. Submittal date: 09/01/2004.

179180 LB0610UZDSCP30.001. Drift-Scale Calibrated Property Set for the 30-Percentile Infiltration Map. Submittal date: 11/02/2006.

178586 LB0611MTSCHP10.001. Mountain Scale Calibrated Property Set for the 10-Percentile Infiltration Map. Submittal date: 11/28/2006.

180293 LB0611MTSCHP30.001. Mountain Scale Calibrated Property Set for the 30-Percentile Infiltration Map. Submittal date: 11/28/2006.

178587 LB06123DPDUZFF.001. 3-D UZ Flow Fields for Present-Day Climate of 10th-, 30th-, 50th- and 90th -Percentile Infiltration Maps. Submittal date: 12/19/2006.

180294 LB0612MTSCHP50.001. Mountain Scale Calibrated Property Set for the 50-Percentile Infiltration Map. Submittal date: 12/19/2006.

180295 LB0612MTSCHP90.001. Mountain Scale Calibrated Property Set for the 90-Percentile Infiltration Map. Submittal date: 12/20/2006.

180296 LB0612MTSCHPFT.001. Calibrated UZ Fault Property Sets. Submittal date: 12/07/2006.

179296 LB0612PDFEHMFF.001. Flow-Field Conversions from TOUGH2 to FEHM Format for Present Day 10-, 30-, 50-, and 90-Percentile Infiltration Maps. Submittal date: 12/19/2006.

179150 LB0612PDPTNTSW.001. Vertical Flux at PTN/TSW Interface for Present-Day Climate of 10th, 30th, 50th, and 90-Percentile Infiltration Maps. Submittal date: 12/19/2006.

179066 LB07013DGTUZFF.001. 3-D UZ Flow Fields for Glacial Transition Climate of 10th-, 30th-, 50th-, and 90th-Percentile Infiltration Maps. Submittal date: 01/03/2007.

179064 LB07013DMOUZFF.001. 3-D UZ Flow Fields for Monsoon Climate of 10th-, 30th-, 50th-, and 90th-Percentile Infiltration Maps. Submittal date: 01/03/2007.

179160 LB0701GTFEHMFF.001. Flow-Field Conversions from TOUGH2 to FEHM Format for Glacial Transition Climate 10th-, 30th-, 50th-, and 90th-Percentile Infiltration Maps. Submittal date: 01/05/2007.

179153 LB0701GTPTNTSW.001. Vertical Flux at PTN/TSW Interface for Glacial Transition Climate of 10th, 30th, 50th, and 90th-Percentile Infiltration Maps. Submittal date: 01/03/2007.

179297 LB0701MOFEHMFF.001. Flow-Field Conversions from TOUGH2 to FEHM Format for Monsoon Climate 10th-, 30th-, 50th-, and 90th-Percentile Infiltration Maps. Submittal date: 01/05/2007.

179156 LB0701MOPTNTSW.001. Vertical Flux at PTN/TSW Interface for Monsoon Climate of 10th, 30th, 50th and 90th-Percentile Infiltration Maps. Submittal date: 01/03/2007.

179283 LB0701PAWFINFM.001. Weighting Factors for Infiltration Maps. Submittal date: 01/25/2007.

179507 LB0702PAFEM10K.002. Flow Field Conversions to FEHM Format for Post 10,000 Year Peak Dose Fluxes in the Unsaturated Zone for Four Selected Infiltration Rates. Submittal date: 02/15/2007.

179511 LB0702PASEEP01.001. New Extended-Range Seepage Look-Up Tables for Intact and Collapsed Drifts Plus Supporting Files. Submittal date: 02/20/2007.

181635 LB0702PASEEP02.001. Seepage Abstraction for Degraded Drifts. Submittal date: 06/29/2007.

180776 LB0702PAUZMTDF.001. Unsaturated Zone Matrix Diffusion Coefficients. Submittal date: 05/10/2007.

179324 LB0702UZP10KFF.002. 3-D UZ Flow Fields for Post-10,000 Climate Infiltration Maps. Submittal date: 02/15/2007.

179332 LB0702UZPTN10K.002. Vertical Flux at PTN/TSW Interface for Post-10K-Year Climate Infiltration Maps. Submittal date: 02/15/2007.

181217 LB0705DSTHC001.001. Drift-Scale THC Simulation Results with Water HDPERM3 (W0). Submittal date: 05/02/2007.

180854 LB0705DSTHC001.002. Input and Output Files of Drift-Scale THC Simulations with Water HDPERM3 (W0). Submittal date: 05/02/2007.

181300 LB0705TRAVTIME.001. Simulated Breakthrough Curves and Travel Times. Submittal date: 05/18/2007.

181445 LB0706UZSEEP05.001. Mathcad 11 Spreadsheets for Probabilistic Seepage Evaluation. Submittal date: 06/05/2007.

106785 LB990701233129.001. 3-D UZ Model Grids for Calculation of Flow Fields for PA for AMR U0000, "Development of Numerical Grids for UZ Flow and Transport Modeling". Submittal date: 09/24/1999.

122757 LB990801233129.003. TSPA Grid Flow Simulations for AMR U0050, "UZ Flow Models and Submodels" (Flow Field #3). Submittal date: 11/29/1999.

118717 LB990801233129.009. TSPA Grid Flow Simulations for AMR U0050, "UZ Flow Models and Submodels" (Flow Field #9). Submittal date: 11/29/1999.

147115 LB9908T1233129.001. Transport Simulations for the Low, Mean, and Upper Infiltration Scenarios of the Present-Day, Monsoon, and Glacial Transition Climates for AMR U0050, "UZ Flow Models and Submodels." Submittal date: 03/11/2000.

146894 LB991201233129.001. The Mountain-Scale Thermal-Hydrologic Model Simulations for AMR U0105, "Mountain-Scale Coupled Processes (TH) Models". Submittal date: 12/03/1999.

142973 LL000122051021.116. Summary of Analyses of Glass Dissolution Filtrates. Submittal date: 01/27/2000.

172021 LL030211523125.006. EQ3/6 Modeling of Grout-Reacted Liquid Carbonation Experiments. Submittal date: 07/01/2003.

162949 LL030408023121.027. Cl Abundance and Cl Ratios of Leachates from ESF Core Samples. Submittal date: 04/17/2003.

169583 LL030410012251.056. LTCTF Corrosion Rate Calculations for 2 1/2 - Year Exposed Titanium Alloy GR7 Specimens Cleaned Under TIP-CM-51. Submittal date: 07/16/2003.

170502 LL031001023121.035. Conversion of Corrosion Testing Solutions from Molar to Molal Concentration Units (II). Submittal date: 04/23/2004.

171476 LL040801512251.115. Bacterial Growth Dynamics, Limiting Factors, and Community Diversity in a Proposed Geological Nuclear Waste Repository Environment. Submittal date: 08/18/2004.

171362 LL040803112251.117. Target Compositions of Aqueous Solutions Used for Corrosion Testing. Submittal date: 08/14/2004.

178283 LL060904312251.186. Modeling of Pitzer pH for Selected ECORR Test Solutions. Submittal date: 11/02/2006.

180553 LL0702PA013MST.068. Input and Output Files for the SMT, SDT and DDT Submodels and MSTHAC Extract Output Files Used in ANL-EBS-MD-000049 Multiscale Thermohydrologic Model. Submittal date: 04/27/2007.

183159 LL070800612251.197. Electrochemical Testing of Titanium Grade 7 and Titanium Grade 29 Alloys in Dust-Like Electrolytes - Developed. Submittal date: 08/28/2007.

185101 LL960905751021.019. Ten Year Results from Unsaturated Drip Tests with UO2 at 90C: Implications for the Geologic Disposal of Spent Nuclear Fuel. Submittal date: 09/25/1996.

152926 MO0003RIB00073.000. Physical and Chemical Characteristics of Ti Grades 7 and 16. Submittal date: 03/13/2000.

152554 MO0004QGFMPICK.000. Lithostratigraphic Contacts from MO9811MWDGFM03.000 to be Qualified Under the Data Qualification Plan, TDP-NBS-GS-000001. Submittal date: 04/04/2000.

149806 MO0004YMP98132.004. Flood Inundation Areas in the Vicinity of Yucca Mountain. Submittal date: 03/31/2000.

155959 MO0010CPORGLOG.003. Calculated Porosity Values at Depth Derived from Qualified Geophysical Log Data from Modern Boreholes. Submittal date: 10/16/2000.

171565 MO0011YMP00114.000. Potential Repository Site. Submittal date: 11/21/2000.

153777 MO0012MWDGFM02.002. Geologic Framework Model (GFM2000). Submittal date: 12/18/2000.

154733 MO0102DQRBTEMP.001. Temperature Data Collected from Boreholes Near Yucca Mountain in Early 1980's. Submittal date: 02/21/2001.

169995 MO0107TC239938.000. Hastelloy Alloy C-22, the Most Versatile Nickel-Chromium-Molybdenum Alloy Available Today with Improved Resistance to Both Uniform and Localized Corrosion as Well as a Variety of Mixed Industrial Chemicals. Submittal date: 07/23/2001.

161845 MO0209EBSPMFSD.029. Probable Maximum Flood Study Data. Submittal date: 09/18/2002.

161496 MO0301SEPFEPS1.000. LA FEP List. Submittal date: 01/21/2003.

162385 MO0302PNLDUFTD.000. Flowthrough Dissolution Data. Submittal date: 02/28/2003.

163441 MO0304PNLLPHDD.000. Low PH Dissolution Data. Submittal date: 04/09/2003.

185014 MO0401MWDRPSHA.000. Results of the Yucca Mountain Probabilistic Seismic Hazard Analysis (PSHA). Submittal date: 02/20/2008.

173078 MO0408EG831811.008. Magma Cooling and Solidification. Submittal date: 09/13/2004.

171483 MO0408MWDDDMIO.002. Drift Degradation Model Inputs and Outputs. Submittal date: 08/31/2004.

172682 MO0501BPVELEMP.001. Bounded Horizontal Peak Ground Velocity Hazard at the Repository Waste Emplacement Level. Submittal date: 01/11/2005.

172601 MO0501SEPFEPLA.001. LA FEP List and Screening. Submittal date: 01/17/2005.

172830 MO0502ANLGAMR1.016. HLW Glass Degradation Model. Submittal date: 02/08/2005.

174811 MO0506MWDTLVAC.000. TSPA-LA Validation and Analysis Cases. Submittal date: 06/30/2005.

175064 MO0508SEPFEPLA.002. LA FEP List and Screening. Submittal date: 08/22/2005.

177371 MO0602SPAMODAR.000. Model Archives from USGS Special Investigations Report 2004-5205, Death Valley Regional Ground-Water Flow System, Nevada and California-Hydrogeologic Framework and Transient Ground-Water Flow Model. Submittal date: 02/10/2006.

176868 MO0604SPAPHR25.001. PHREEQC Data 0 Thermodynamic Database for 25 Degrees C - File: PHREEQCDATA025.DAT. Submittal date: 04/10/2006.

179988 MO0609SPASRPBM.004. Soil Related Parameters for the Biosphere Model. Submittal date: 03/28/2007.

179352 MO0610MWDHFM06.002. Hydrogeologic Framework Model (HFM2006) Stratigraphic Horizon Grids. Submittal date: 11/01/2006.

182035 MO0612WPOUTERB.000. Output from General and Localized Corrosion of Waste Package Outer Barrier Report. Submittal date: 07/18/2007.

179310 MO0701PAGROUND.000. Groundwater Colloid Concentration Parameters. Submittal date: 01/18/2007.

180392 MO0701PAKDSUNP.000. Colloidal KDS for U, NP, RA and SN. Submittal date: 04/17/2007.

180508 MO0701PASHIELD.000. Waste Package/Drip Shield Early Failure Probabilities. Submittal date: 04/24/2007.

180391 MO0701PASORPTN.000. Colloidal Sorption Coefficients for PU, AM, TH, CS, and PA. Submittal date: 04/17/2007.

179925 MO0702PASTREAM.001. Waste Stream Composition and Thermal Decay Histories for LA. Submittal date: 02/15/2007.

180514 MO0702PASTRESS.002. Output DTN of Model Report, "Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials," ANL-EBS-MD-000005. Submittal date: 04/24/2007.

181990 MO0703PAEVSIIC.000. Evaluation of Stage II Condensation. Submittal date: 07/16/2007.

182029 MO0703PAGENCOR.001. Output from General Corrosion and Localized Corrosion of Waste Package Outer Barrier 2007 Second Version. Submittal date: 07/18/2007.

183148 MO0703PASDSTAT.001. Statistical Analyses for Seismic Damage Abstractions. Submittal date: 09/21/2007.

183156 MO0703PASEISDA.002. Seismic Damage Abstractions for TSPA Compliance Case. Submittal date: 09/21/2007.

APPENDIX A

REPOSITORY DESIGN USE IN PERFORMANCE ASSESSMENT

The use of the repository design in performance assessment can be demonstrated by identification of representative FEPs that have been either excluded or included based on that design. The design elements are represented as parameters that define the physical dimensions, characteristics, and long-term behavior of the waste form, waste packages, emplacement drift, drip shields, and other components of the repository system. A mapping of these parameters to representative FEPs relying on those parameters is contained in Table A-1.

These control parameters, as well as the resulting design based on these control parameters, have been used as the basis to exclude or include repository design-related FEPs. Table A-1 depicts how the repository design has been included in the performance assessment. It is relevant to note that in some cases the repository design supports the basis to exclude FEPs while in other cases the repository design has been used to support the spatial domain of concern, boundary conditions, or initial conditions used in models and analyses that are abstracted in the TSPA model. Representative FEPs are selected based on either the control parameter being explicitly identified in the FEP Screening Justification or TSPA Disposition in Section 6, or by inference when a FEP Screening Justification or TSPA Disposition is based on additional detailed modeling and analysis. Representative FEPs selected based on inference are noted with an asterisk (*) in the table. Note that Table A-1 is not intended to be all inclusive.

Table A-1. Repository Design Use in Performance Assessment

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
01-01 Repository Geographic and Geologic Location	• FEP 0.1.03.00.0A – Spatial Domain of Concern* • FEP 1.1.01.01.0A – Open Site Investigation Boreholes (Excluded) • FEP 1.1.07.00.0A – Repository Design • FEP 2.1.06.01.0A – Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS (Excluded) • FEP 2.1.07.04.0A – Hydrostatic Pressure on Waste Package (Excluded) • FEP 2.1.07.04.0B – Hydrostatic Pressure on Drip Shield (Excluded) • FEP 2.1.08.09.0A – Saturated Flow in the EBS (Excluded) • FEP 2.2.08.03.0B – Geochemical Interactions and Evolution in the UZ (Excluded) • FEP 2.2.08.12.0A – Chemistry of Water Flowing into the Drift	Supports spatial domain of concern and boundary conditions for various mountain-scale, repository-scale, and drift-scale models Supports basis for FEP exclusion
01-02 Repository Layout	• FEP 1.1.07.00.0A – Repository Design • FEP 1.2.04.03.0A – Igneous Intrusion into Repository* • FEP 2.1.05.01.0A – Flow Through Seals (Access Ramps and Ventilation Shafts) (Excluded) • FEP 2.1.08.04.0A – Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps) • FEP 2.1.08.04.0B – Condensation Forms at Repository Edges (Repository-Scale Cold Traps) • FEP 2.1.08.09.0A – Saturated Flow in the EBS (Excluded) • FEP 2.1.11.03.0A – Exothermic Reactions in the EBS (Excluded) • FEP 2.1.13.02.0A – Radiation Damage in EBS (Excluded)	Supports spatial domain of concern and boundary conditions for various mountain-scale, repository-scale, and drift-scale models Supports basis for FEPs exclusion
01-03 Repository Geologic Location	• FEP 1.1.01.01.0A – Open Site Investigation Boreholes • FEP 1.2.03.02.0B – Seismic Induced Rockfall Damages EBS Components (Excluded) • FEP 1.2.03.02.0C – Seismic-Induced Drift Collapse Damages EBS Components • FEP 2.2.01.02.0A – Thermally-Induced Stress Changes in the Near-Field (Excluded) • FEP 2.2.01.03.0A – Changes in Fluid Saturations in the Excavation Disturbed Zone (Excluded) • FEP 2.2.03.01.0A – Stratigraphy • FEP 2.2.08.12.0A – Chemistry of Water Flowing into the Drift • FEP 2.1.03.10.0B – Advection of Liquids and Solids Through Cracks in the Drip Shield (Excluded)	Supports spatial domain of concern and boundary conditions for various mountain-scale, repository-scale, and drift-scale models Supports basis for FEPs exclusion
01-04 Repository Elevation – Standoff from Water Table	• FEP 2.1.08.12.0A – Induced Hydrologic Changes in Invert (Excluded) • FEP 2.2.10.04.0A – Thermal-Mechanical Stresses Alter Characteristics of Fractures Near Repository (Excluded)* • FEP 2.2.11.01.0A – Gas Effects in the SZ (Excluded)*	Supports basis for FEPs exclusion

Table A-1. Repository Design Use in Performance Assessment (Continued)

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
01-05 Repository Standoff from Quaternary Fault	• FEP 1.2.02.03.0A – Fault Displacement Damages EBS Components • FEP 2.2.07.05.0A – Flow in the UZ from Episodic Infiltration (Excluded)*	Supports spatial domain of concern and boundary conditions for various mountain-scale, repository-scale, and drift-scale models Supports basis for FEP exclusion
01-06 Repository Elevation – Overburden Thickness	• FEP 1.2.02.03.0A – Fault Displacement Damages EBS Components • FEP 1.2.07.01.0A – Erosion/Denudation (Excluded) • FEP 1.4.03.00.0A – Unintrusive Site Investigation (Excluded) • FEP 1.4.11.00.0A – Explosions and Crashes (Human Activities) (Excluded) • FEP 1.5.01.01.0A – Meteorite Impact (Excluded) • FEP 1.5.01.02.0A – Extraterrestrial Events (Excluded) • FEP 2.3.09.01.0A – Animal Burrowing/Intrusion (Excluded)	Supports spatial domain of concern and boundary conditions for various mountain-scale, repository-scale, and drift-scale models Supports basis for FEP exclusion
01-07 Repository Standoff from Perched Water	• FEP 2.2.06.03.0A – Seismic Activity Alters Perched Water Zones (Excluded)*	Supports basis for FEP exclusion
01-08 Orientation of Emplacement Drifts	• FEP 2.1.07.01.0A – Rockfall (Excluded)* • FEP 2.1.07.02.0A – Drift Collapse (Excluded)*	Supports basis for FEP exclusion
01-09 Excavation Methods	• FEP 1.1.02.00.0A – Chemical Effects of Excavation and Construction in EBS (Excluded) • FEP 1.1.02.00.0B – Mechanical Effects of Excavation and Construction in EBS (Excluded) • FEP 2.1.07.01.0A – Rockfall (Excluded) • FEP 2.2.01.01.0A – Mechanical Effects of Excavation and Construction in the Near Field*	Supports the basis for performance assessment initial conditions Supports basis for FEP exclusion
01-10 Emplacement Drift Configuration	• FEP 1.1.02.00.0B – Mechanical Effects of Excavation and Construction in EBS (Excluded) • FEP 1.1.07.00.0A – Repository Design • FEP 2.1.07.01.0A – Rockfall (Excluded) • FEP 2.1.07.06.0A – Floor Buckling (Excluded) • FEP 2.1.11.10.0A – Thermal Effects on Transport in EBS (Excluded) • FEP 2.2.06.04.0A – Effects of Subsidence (Excluded) • FEP 2.2.07.20.0A – Flow Diversion Around Repository Drifts	Supports spatial domain of concern and boundary conditions for various repository-scale and drift-scale models Supports basis for FEP exclusion

Table A-1. Repository Design Use in Performance Assessment (Continued)

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
01-11 Emplacement Drift Gradient	• FEP 2.1.08.12.0A – Induced Hydrologic Changes in Invert (Excluded)	Supports basis for FEP exclusion
01-12 Non-Emplacement Opening Gradient	• FEP 2.1.08.12.0A – Induced Hydrologic Changes in Invert (Excluded)*	Supports basis for FEP exclusion
01-13 Emplacement Drift Spacing	• FEP 2.1.08.11.0A – Repository Resaturation Due to Waste Cooling • FEP 2.2.06.04.0A – Effects of Subsidence (Excluded) • FEP 2.2.07.10.0A – Condensation Zone Forms Around Drifts • FEP 2.2.07.20.0A – Flow Diversion Around Repository Drifts • FEP 2.2.10.01.0A – Repository-Induced Thermal Effects on Flow in the UZ (Excluded)*	Supports spatial domain of concern and boundary conditions for various repository-scale and drift-scale models Supports basis for FEP exclusion
01-14 Verification of Design Rock Properties	• FEP 2.1.07.01.0A – Rockfall (Excluded)* • FEP 2.1.07.02.0A – Drift Collapse (Excluded)*	Supports basis for FEP exclusion
01-15 Design of Ground Support System	• FEP 1.1.01.01.0B – Influx Through Holes Drilled in Drift Wall or Crown (Excluded) • FEP 2.1.06.01.0A – Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS (Excluded) • FEP 2.1.06.02.0A – Mechanical Effects of Rock Reinforcement Materials in EBS (Excluded) • FEP 2.1.06.04.0A – Flow Through Rock Reinforcement Materials in EBS (Excluded) • FEP 2.1.07.01.0A – Rockfall (Excluded) • FEP 2.1.07.02.0A – Drift Collapse (Excluded) • FEP 2.1.09.09.0A – Electrochemical Effects in EBS (Excluded) • FEP 2.1.09.17.0A – Formation of Pseudo-Colloids (Corrosion Product) in EBS* • FEP 2.2.01.01.0B – Chemical Effects of Excavation and Construction in the Near-Field (Excluded) • FEP 2.2.08.03.0B – Geotechnical Interactions and Evolution in the UZ (Excluded)	Supports the basis for performance assessment initial conditions Supports basis for FEP exclusion
01-16 Air Circulation through Ground Support	• FEP 1.1.01.01.0B – Influx Through Holes Drilled in Drift Wall or Crown (Excluded) • FEP 2.1.06.04.0A – Flow Through Rock Reinforcement Materials in EBS (Excluded) • FEP 2.1.07.01.0A – Rockfall (Excluded)	Supports basis for FEP exclusion
01-17 Emplacement Drift Ground Support	• FEP 2.1.06.02.0A – Mechanical Effects of Rock Reinforcement Materials in EBS (Excluded) • FEP 2.1.07.01.0A – Rockfall (Excluded) • FEP 2.1.07.02.0A – Drift Collapse (Excluded)	Supports basis for FEP exclusion

Table A-1. Repository Design Use in Performance Assessment (Continued)

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
01-18 Unheated Drift Length	• FEP 2.1.06.01.0A – Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS (Excluded) • FEP 2.1.08.04.0A – Condensation Forms on Roofs of Drifts (Drift-Scale Cold Traps) • FEP 2.1.08.04.0B – Condensation Forms at Repository Edges (Repository-Scale Cold Traps)	Supports the basis for performance assessment initial and boundary conditions Supports basis for FEP exclusion
01-19 Flood Protection	• FEP 1.1.02.01.0A – Site Flooding (During Construction and Operation) (Excluded) • FEP 2.1.05.01.0A – Flow Through Seals (Access Ramps and Ventilation Shafts) (Excluded)	Supports basis for FEP exclusion
01-20 Repository Standoff from Paintbrush Nonwelded Hydrogeologic Unit	• FEP 2.2.10.05.0A – Thermo-Mechanical Stresses Alter Characteristics of Rocks above and below the Repository (Excluded)* • FEP 2.2.10.06.0A – Thermo-Chemical Alteration in the UZ (Solubility, Speciation, Phase Changes, Precipitation/Dissolution) (Excluded)*	Supports basis for FEP exclusion
01-21 Minimum Thickness of the Paintbrush Nonwelded Hydrogeologic Unit above the Repository	• FEP 2.2.07.05.0A – Flow in the UZ from Episodic Infiltration (Excluded)*	Supports basis for FEP exclusion
01-22 Repository Standoff from Calico Hills Nonwelded Hydrogeologic Unit	• FEP 2.2.10.07.0A – Thermo-Chemical Alteration of the Calico Hills Unit (Excluded)* • FEP 2.2.10.14.0A – Mineralogic Dehydration Reactions (Excluded)*	Supports basis for FEP exclusion
02-01 As-Emplaced Waste Configuration	• FEP 1.1.09.00.0A – Schedule and Planning* • FEP 1.2.03.02.0A – Seismic-Induced Rockfall Damages EBS Components* • FEP 2.1.06.05.0B – Mechanical Degradation of Emplacement Pallet (Excluded)* • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.09.09.0A – Electrochemical Effects in EBS (Excluded)*	Supports the basis for performance assessment initial conditions Supports basis for FEP exclusion

Table A-1. Repository Design Use in Performance Assessment (Continued)

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
02-02 As-Emplaced Waste Package-Drip Shield Configuration	• FEP 1.2.03.02.0A – Seismic Ground Motion Damages EBS Components* • FEP 1.2.03.02.0B – Seismic-Induced Rockfall Damages EBS Components (Excluded)* • FEP 2.1.03.07.0B – Mechanical Impact on Drip Shield (Excluded)* • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.07.01.0A – Rockfall (Excluded)* • FEP 2.1.09.09.0A – Electrochemical Effects in EBS (Excluded)*	Supports the basis for performance assessment initial and boundary conditions Supports basis for FEP exclusion
02-03 Committed Materials	• FEP 1.1.02.00.0A – Chemical Effects of Excavation and Construction in EBS (Excluded) • FEP 1.1.02.03.0A – Undesirable Materials Left (Excluded) • FEP 1.1.08.00.0A – Inadequate Quality Control and Deviations from Design (Excluded) • FEP 2.1.05.01.0A – Flow Through Seals (Access Ramps and Ventilation Shafts) (Excluded) • FEP 2.1.06.01.0A – Chemical Effects of Rock Reinforcement and Cementitious Materials in EBS (Excluded) • FEP 2.1.06.02.0A – Mechanical Effects of Rock Reinforcement Materials in EBS (Excluded) • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.09.01.0A – Chemical Characteristics of Water in Drifts • FEP 2.1.09.02.0A – Chemical Interaction with Corrosion Products • FEP 2.1.09.17.0A – Formation of Pseudo-Colloids (Corrosion Product) in EBS • FEP 2.1.09.28.0A – Localized Corrosion on Waste Package Outer Surface Due to Deliquescence (Excluded)* • FEP 2.1.12.04.0A – Gas Generation (CO_2, CH_4, H_2S) from Microbial Degradation (Excluded) • FEP 2.2.01.01.0B – Chemical Effects of Excavation and Construction in the Near-Field (Excluded)	Supports the basis for performance assessment initial and boundary conditions Supports basis for FEP exclusion
02-04 Invert and EBS Components in Situ Stress and Thermal Response	• FEP 2.1.06.05.0B – Mechanical Degradation of Invert (Excluded) • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.11.07.0A – Thermal Expansion/Stress of In-Drift EBS Components (Excluded)*	Supports basis for FEP exclusion
02-05 EBS In-Drift Materials Interactions	• FEP 2.1.03.04.0A – Hydride Cracking of Waste Packages (Excluded)* • FEP 2.1.03.04.0B – Hydride Cracking of Drip Shields (Excluded)* • FEP 2.1.06.07.0A – Chemical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded) • FEP 2.1.09.02.0A – Chemical Interaction with Corrosion Products • FEP 2.1.09.09.0A – Electrochemical Effects in EBS (Excluded)	Supports the basis for performance assessment initial conditions Supports basis for FEP exclusion

Table A-1. Repository Design Use in Performance Assessment (Continued)

Control Parameter	Representative FEPs Relying on Design/Control Parameter	Control Parameter Use in Performance Assessment
02-06 EBS Material Interactions – Copper	• FEP 2.1.03.09.0A – Copper Corrosion in EBS (Excluded) • FEP 2.1.09.02.0A – Chemical Interaction with Corrosion Products	Supports the basis for performance assessment initial conditions Supports basis for FEP exclusion
02-07 Emplacement Drift Invert Function	• FEP 2.1.06.05.0B – Mechanical Degradation of Invert (Excluded) • FEP 2.1.06.07.0B – Mechanical Effects at EBS Component Interfaces (Excluded)	Supports basis for FEP exclusion

APPENDIX B

ANALYSIS OF ROCKFALL AND ITS IMPACT TO DRIP SHIELD DENTING

B.1 INTRODUCTION

This appendix provides an analysis of data on rockfalls capable of denting a drip shield. The results from this analysis support the screening justification for excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield). The potential for SCC in the drip shield resulting from the damage areas associated with denting is addressed in the FEP screening justification and in Appendix C. The tearing or rupture of drip shield plates from large block impacts is excluded from the TSPA model because of low consequence as discussed in excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components).

The response of the rock mass surrounding a repository emplacement drift to a seismic event is a function of the structural characteristics of the rock. In the repository, lithophysal units (including the upper lithophysal zone (Tptpul) and lower lithophysal zone (Tptpll)) are characterized by lithophysal voids interconnected by intense fracturing (BSC 2004 [DIRS 166107], Section 6.4.1.1). The strength of the lithophysal rock ranges from approximately 10 to 40 MPa (BSC 2004 [DIRS 166107], Table E-9). Postclosure ground motion in lithophysal rock results in rock failure, with fragmented rock particle sizes on the order of centimeters to decimeters (BSC 2004 [DIRS 166107], Section 8.1). The individual fragments are too small to damage the drip shield; the drip shields in the lithophysal rock zone are damaged from the static loading due to rubble accumulation and seismic-induced dynamic loading (SNL 2007 [DIRS 176828], Section 6.10.1). Approximately 85% of the repository emplacement area will be in lithophysal rock (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). Therefore, approximately 85% of the drip shields will not be subject to denting from rockfall.

The nonlithophysal units (including the middle nonlithophysal zone (Tptpmn) and the lower nonlithophysal zone (Tptpln)) are composed of strong, intact blocks of welded tuff that are separated by fracture planes (BSC 2004 [DIRS 166107], Section 6.4.1.1). The strength of the nonlithophysal rock ranges from approximately 40 to 360 MPa (BSC 2004 [DIRS 166107], Table E-8). Postclosure ground motion in nonlithophysal rock results in a varying extent of drift damage due to rockfall (BSC 2004 [DIRS 166107], Section 8.1), with the rockfall results described in *Drift Degradation Analysis* (BSC 2004 [DIRS 166107], Section 6.3.1.2). Some of the rock blocks ejected from the walls or back of the emplacement drifts will impact the drip shield and could result in mechanically stressed areas. If the stress is sufficiently high, the damaged area may be susceptible to stress corrosion cracking (SNL 2007 [DIRS 181953], Section 6.2.2). This appendix provides a reasonable estimate of the potential for damage (i.e., denting and cracking) to occur to the drip shield relative to its performance as a barrier to seepage contacting the waste packages. This analysis is designed to estimate the rockfall events that could result in such dents or cracking as a function of seismic event probabilities.

B.2 PROBABILITY ANALYSIS FOR EBS FEP JUSTIFICATION RELATED TO DRIP SHIELD DENTING

The probability that seismic-induced rockfall causes a significant dent on the drip shield can be evaluated from structural response calculations for large rock blocks impacting the drip shield and from the bounded hazard curve for horizontal peak ground velocity (PGV) at the

emplacement drifts. A dent is considered significant if it has a concave shape that can retain a significant amount of standing liquid (seepage) in the dent.

The rockfall and denting probability analysis is based on three types of information:

- Analysis of rockfall induced by vibratory ground motions in the nonlithophysal zones
- Structural response of the drip shield to individual rock block impacts
- The bounded hazard curve for PGV.

The occurrence of multiple rockfalls impacting the drip shield at the same location is addressed in excluded FEP 2.1.07.01.0A (Rockfall). The probability analysis is reasonable and conservative because of the issues discussed in Section B.2.4.

B.2.1 Analysis of Rockfall Data in Nonlithophysal Zones

Rockfall calculations for the nonlithophysal zones have been performed (BSC 2004 [DIRS 166107], Section 6.3) using vibratory ground motions at the 1.05, 2.44, and 5.35 m/s PGV levels (BSC 2004 [DIRS 170027], Tables 6.3-14, 6.3-16, and 6.3-18). A total of 50 realizations were performed at the 1.05 and 2.44 m/s PGV levels and 44 realizations were performed at the 5.35 m/s PGV level. Each realization analyzes the response of a 21.74-m-long section of drift (Figure B-1) with a randomly sampled fracture pattern. The output from each realization includes the impact parameters (location, relative velocity, block kinetic energy, block momentum, etc.) of the individual rock blocks on the top and sides of the drip shield. The shape of the drip shield, depicted in Figure B-2, in the rockfall calculations has been simplified to a rectangular cross-section as depicted in Figure B-3, ignoring the curvature of the top of the drip shield. This geometric simplification is not significant for the probability analysis that follows, since the simplified drip shield is only used as a marker for collecting rockfall data (i.e., locations and relative velocities of the rockfall impacts) (BSC 2004 [DIRS 166107], Section 6.3.1.1).

The impact data for the rock blocks at the 1.05, 2.44, and 5.35 m/s PGV levels have been filtered to retain only the blocks that contact the top of the drip shield, including the top corners of the rectangular cross-section (Table B-1). Table B-1 contains a truncated list of blocks (sorted by impact energy) beginning with the rock block with the highest impact energy. A review of these data indicates that the blocks with the greatest impact energies impact the shoulders (i.e., the top corners of the rectangular cross-section) of the drip shield. The list of blocks in Table B-1 has been truncated at a point coincident to the block with the highest impact energy that impacts the center third of the drip shield. For example:

- At the 1.05 m/s PGV level, the two blocks with the greatest impact energies of 87 and 84 kJ are shoulder impacts; the block with the third highest impact energy, 32 kJ, contacts the top of the drip shield, toward the center.

- At the 2.44 m/s PGV level, the blocks with the seven greatest impact energies, ranging from 153 to 45 kJ, are shoulder impacts. The block with the eighth greatest impact energy, 44 kJ, contacts the top of the drip shield, toward the center.

- At the 5.35 m/s PGV level, the blocks with the twenty-four greatest impact energies, ranging from 707 to 48 kJ, are shoulder impacts. The block with the twenty-fifth greatest impact energy, 48 kJ, contacts the top of the drip shield, toward the center.

Blocks that impact the shoulders of the drip shield are likely to form a crease where the slope of the drip shield is large. The creases are expected to allow seepage to run down the side of the drip shield, rather than retaining a "pool" of liquid in the dent. The blocks impacting the center third of the drip shield (Figure B-2) could form dents that can pool water (since the slope of the drip shield increases away from the crown).

NOTES: To download data from the source DTN: (1) Select "Download files." (2) Copy the segmented zip file (10 files total) into a folder with approximately 140 GB of available space (the download requires 45 GB on one drive and the extraction requires 95 GB on that drive or another drive. If sufficient disk space is not available, contact the Model Warehouse Data Administrator using the link provided within the DTN). (3) Select file: *MO0408MWDDDMIO_002RPC1.zip*, to extract the data from the DTN (note that WinZip version 9.0 or higher must be used to extract the compressed files; select "Use folder names" from the WinZip "Extract" dialog box). Source data are provided by the following Excel spreadsheets within the extracted data from the source DTN (the files are located in folder: Calculation Files\3DEC rockfall results):

- *nonlith rockfall characteristics in emplacement drifts with 1e-4 gm.xls*
- *nonlith rockfall characteristics in emplacement drifts with 1e-5 gm.xls*
- *nonlith rockfall characteristics in emplacement drifts with 1e-6 gm.xls*
- *nonlith rockfall characteristics in emplacement drifts with 1e-7 gm.xls.*

The data in this table are provided in the worksheet "Impact Information," located within each of the Excel spreadsheets listed above. This table contains a truncated list of blocks (sorted by impact energy) beginning with the rock block with the highest impact energy. The list of blocks has been truncated to show the block with the highest impact energy that impacts center 1/3 of the drip shield. Note that the drip shield has been represented by a simplified, rectangular geometry. Only those rockfalls impacting the top of the simplified rectangular drip shield have been included. The coordinate system and impact angle are illustrated in Figure B-3. Based on the local coordinate system used (see Figure B-3), the rock blocks impacting the crown of the drip shield will have a y-coordinate (column "y-imp" in the Excel file) of 1.44 m. The center one-third of the crown is in the range of z-coordinate (column "z-imp" in the Excel file) of −0.426 to 0.426. Note that the total simulated drift length is calculated knowing the number of simulations as provided by the source DTN (i.e., either 50 or 44 simulations) and the length of drift per simulation (i.e., 21.74 m, Figure B-1).

B.2.2 Structural Response of the Drip Shield to Individual Rock Blocks

The structural response of the drip shield to impacts by individual rock blocks has already been calculated using a three-dimensional representation of the drip shield as discussed in *Drip Shield Structural Response to Rock Fall Supplemental Calculation* (BSC 2005 [DIRS 174052]). The individual rock blocks are idealized as cubic in shape with two possible orientations: an edge-on impact to the crown of the drip shield and a corner-on impact to the crown of the drip shield. The edge-on impact has the edge perpendicular to the longitudinal axis of the drip shield. The corner-on impact has the corner impacting between the longitudinal stiffeners that support the crown of the drip shield. In either case, the center of mass is located directly over the impact point.

The impact energy of the individual rock blocks has been selected to span the range of impact energies that are expected to result in a significant dent on the crown of the drip shield. The six individual cases are described as follows (BSC 2005 [DIRS 174052], Section 3.2.2):

- 880 Joule/0.28 metric ton block that corresponds to the 50th percentile of impact energy for the 2.44 m/s PGV level (unbounded ground motion with 10^{-6} annual exceedance frequency)
- 2,569 Joule/0.69 metric ton block that corresponds to the 75th percentile of impact energy for the 2.44 m/s PGV level (unbounded ground motion with 10^{-6} annual exceedance frequency)
- 12,894 Joule/0.96 metric ton block that corresponds to the 95th percentile of impact energy for the 2.44 m/s PGV level (unbounded ground motion with 10^{-6} annual exceedance frequency)
- 86,559 Joule/7.49 metric ton block that corresponds to the maximum impact energy for the 1.05 m/s PGV level (unbounded ground motion with 10^{-5} annual exceedance frequency)
- 152,775 Joule/11.87 metric ton block that corresponds to the maximum impact energy for the 2.44 m/s PGV level (unbounded ground motion with 10^{-6} annual exceedance frequency)
- 706,914 Joule/28.29 metric ton block that corresponds to the maximum impact energy for the 5.35 m/s PGV level (unbounded ground motion with 10^{-7} annual exceedance frequency).

The computational results for the edge-on impacts are summarized in Table B-2. Based on the results in Table B-2, the 152,775-Joule impact corresponds to the maximum rock block impact energy at the 2.44 m/s PGV level. This did not result in a dent that would retain water. It follows then that only edge-on impacts with energies greater than 152,775 Joules could result in a dent that could catch or retain seepage. The computational results for the corner-on impacts are presented in *Drip Shield Structural Response to Rock Fall Supplemental Calculation* (BSC 2005 [DIRS 174052], Figures 7-21 to 7-25).

A corner-on impact, between the longitudinal stiffeners, results in significant denting to the drip shield plates at lower impact energies than for the edge-on impacts in Table B-2. However, this corner-on geometry is considered unlikely, particularly for blocks that are 1 metric ton or larger. As represented in the drip shield structural response calculation (BSC 2005 [DIRS 174052], Section 6.3), those blocks with corner impacts are assumed to have a resultant centroid velocity vector that is directly in line with the impacting block corner (Figure B-2). In other words, all of the force of the accelerated block is assumed to be concentrated directly through the block corner. This assumption is highly improbable as the model predictions of rockfall (BSC 2004 [DIRS 166107], Section 6.3) show that blocks have complex, irregular geometries (BSC 2004 [DIRS 166107], Appendix I), and that the applied complex earthquake vibratory motion results in blocks that rotate as they fall (BSC 2004 [DIRS 166107], Figure 6-38). The blocks then

impact the curving drip shield crown with glancing impacts that have not only normal, but also tangential force components. Thus, the assumed corner impacts are considered to be an extreme case. Additionally, contacts of a rock block corner to the stiff drip shield structure will result in shearing or fragmentation and disintegration of the contact point, which will consume some of the block kinetic energy. This fragmentation potential was not accounted for in the analysis of denting (BSC 2005 [DIRS 174052], Section 6.5). The result of fragmentation is that, in reality, contact forces and energies would be far smaller than represented in the corner impact analyses. The results for the corner-on impacts are excluded from further consideration.

Table B-2. Results for Edge-On Impacts

Impact Energy (Block Mass)	Location in Source	Structural Response
880 Joule (0.28 MT)	Figure 7-14	No measurable dent—seepage will run off.
2,569 Joule (0.69 MT)	Figure 7-15	No significant deformation—seepage will run off.
12,894 Joule (0.96 MT)	Figure 7-16	Small deformation, but the slope within the dent allows seepage to run off.
86,559 Joule (7.49 MT)	Figure 7-17	Significant dent, but the remaining slope within the dent allows seepage to run off.
152,775 Joule (11.87 MT)	Figure 7-18	Significant dent, with a small flat at the top of the crown but no depression. Droplets of seepage may remain on the flat, but should runoff before forming a "pool" with significant depth.
706,914 Joule (28.29 MT)	Figure 7-19	Significant denting, with a small depression between the longitudinal stiffeners. Seepage can pool in this dent. The dent is 63.5 mm long in the axial direction. The volume of the small depression is about 5.35×10^{-5} m^3 or 1.8 ounces.

B.2.3 Bounded Hazard Curve for Peak Ground Velocity

There are no blocks from the simulations at the 1.05 m/s and 2.44 m/s PGV levels that cause a significant dent to form on the drip shield. The probability that seismic events with PGV levels greater than 2.44 m/s will occur can be calculated from the hazard curve for PGV. A hazard curve defines the annual frequency of seismic events that exceed a given intensity level. Intensity is often measured in peak ground acceleration or peak ground velocity. Intensity is measured by horizontal PGV. The bounded hazard curve for PGV indicates that the annual exceedance frequency for all seismic events with PGV greater than 2.44 m/s is 4.52×10^{-7} per year (DTN: MO0501BPVELEMP.001 [DIRS 172682]).

This exceedance frequency includes very unlikely seismic events, including those with exceedance frequencies less than 10^{-8} per year, and this corresponds to the 5.35 PGV level with the 706,914-Joule impact energy by a 28.29 metric ton block. However, the performance assessment for the repository must consider only those events with probabilities greater than 1 in 10,000 over a 10,000-year period (10 CFR 63.114 [DIRS 180319]), corresponding to events with an annual probability[1] greater than 10^{-8}. It follows that the very unlikely seismic events can be

[1] The exceedance frequency from the hazard curve and the exceedance probability are essentially equal for very low frequency events. The probability of one or more events for a random (Poisson) process with annual rate λ over duration T is given by $(1 - e^{-\lambda T})$. When λ is small enough, the probability that one or more events occur in an interval T becomes $(1 - e^{-\lambda T}) = 1 - (1 - \lambda T + (\lambda T)^2 - \ldots) \approx \lambda T$ (Taylor series expansion for an exponential, Bolz and Tuve 1973 [DIRS 148520], Table 9-47, exponential series, p. 892). The annual probability for one or more events is then given by $(\lambda T)/T = \lambda$, the annual frequency of events.

excluded from this probability analysis. These very unlikely events can be eliminated from consideration by subtracting the exceedance frequency for the very unlikely events from that for all the events with PGV greater than 2.44 m/s:

$$\textit{Final Frequency} = 4.52 \times 10^{-7}\ \textit{per year} - 10^{-8}\ \textit{per year} = 4.42 \times 10^{-7}\ \textit{per year} \qquad \text{(Eq. B-1)}$$

The annual probability of seismic events that can cause a significant dent to form in the drip shield is then 4.42×10^{-7} per year, and the corresponding probability over 10,000 years[2] is given by:

$$\textit{Probability Over 10,000 Years} = (4.42 \times 10^{-7}\ \textit{per year})(10{,}000\ \textit{years}) = 4.42 \times 10^{-3} \sim 0.004 \qquad \text{(Eq. B-2)}$$

This probability (alone) cannot be used to screen denting of the drip shield out of TSPA because it exceeds 1 chance in 10,000. However, the reasonable conservatisms in the probability calculation are considered next.

B.2.4 Conservatisms in Probability Analysis

The probability analysis for denting from rockfall induced by seismic events has the following reasonable conservative assumptions:

- A large rock block is a partly fractured structure that is likely to crumble or partly shatter on impact with the drip shield. However, the potential for block failure is not included in the structural response calculations.

- The orientation and shape of rock blocks are chosen to increase damage by locating the center of mass directly above the impact point. Blocks have a cubic shape for the calculations, with the center of mass directly above an edge that contacts the crown of the drip shield. Based on the rockfall calculations, impacts by the highest energy blocks are likely to be mitigated by the tendency toward shoulder impacts rather than crown impacts and by the irregular block shape, wherein the center of mass is not directly over the impact point.

It should be noted that the ratio of the damaged area on the drip shield to the total drip shield area within the repository is very small. The largest dent capable of pooling water is 63.5 mm long (Table B-2) in the axial direction. Given the 21.74-m rockfall model domain (Section B.2.1), there is 0.0635-m dent length per 21.74 m of drip shield. Furthermore, 85% of the drip shields in the repository will not be subject to denting from rockfall since they will be located in lithophysal rocks (Section B.1).

A typical criterion for the accuracy of this expansion is that $\lambda T \leq 0.1$. This criterion is satisfied for this analysis because $\lambda = 4.4 \times 10^{-7}$ per year and $T = 10{,}000$ years, so that $\lambda T = 4.4 \times 10^{-3}$.

[2] FEP screening justifications are based on the initial 10,000 years after closure.

APPENDIX C

BOUNDING ANALYSIS OF WATER FLOW THROUGH SCC CRACKS IN DRIP SHIELD AND WASTE PACKAGE UNDER SHEET FLOW AND IMPINGING SEEPAGE CONDITIONS

C.1 INTRODUCTION

This appendix provides bounding analysis to evaluate the potential for water flow through seismically induced SCC-damaged drip shields and waste packages, for sheet flow (static) and impinging drip (dynamic) conditions. The analysis is conducted for the following two cases:

- Effect of sheet flow (static) water over through-wall cracks in SCC-damaged drip shields and waste packages. This condition represents the flow of water in sheets, or equivalently, rivulets, and also from "pooling" of seepage in the vicinity of the cracks.

- Effect of impinging drips (falling drops) directly on through-wall cracks in SCC-damaged drip shields and waste packages.

The analysis does not consider microscopic "film flow" along solid surfaces (as investigated by Hu et al. 2001 [DIRS 161623]) because it involves small liquid flow rates and is considered to have negligible effect on drip shield performance, by comparison to the advective water flow rate thresholds that are important to the repository performance:

- TSPA considers "no seepage" for the locations with less than a threshold seepage rate of 0.1 kg/yr per waste package location (SNL 2007 [DIRS 181244], Section 6.4[a]). Such small seepage rates are rare in the seepage abstraction and mainly a result of the interpolation procedure.

- A liquid influx rate into a breached waste package less than 100 mL/yr is negligible, compared to vapor influx, for ionic strength and pH changes of the in-package water (SNL 2007 [DIRS 180506], Section 6.10.9.1[a]).

These flow rate thresholds are also used to evaluate the significance of estimated water flow rates through cracks in the drip shield. The results from this analysis support the screening justification for excluded FEP 2.1.03.10.0A (Advection of Liquids and Solids Through Cracks in the Waste Package) and excluded FEP 2.1.03.10.0B (Advection of Liquids and Solids Through Cracks in the Drip Shield).

C.2 BOUNDING ANALYSIS FOR THROUGH-WALL SCC CRACKS IN DRIP SHIELD AND WASTE PACKAGE OUTERBARRIER

This section provides bounding analysis for: (1) the geometry of a through-wall SCC cracks in drip shield and WPOB, and (2) reasonable upper-bound numbers of through-wall SCC cracks in the drip shield and WPOB damaged by seismic-induced events (e.g., ground motion, rockfall, and rock rubble loading).

C.2.1 Width and Opening Area of a Through-Wall SCC Crack

Stress corrosion cracks in the drip shield and WPOB can be treated as semi-elliptical (SNL 2007 [DIRS 181953], Sections 6.6.2 and 6.8.5.2). Figure C-1 presents the simplified geometry of through-wall cracks. The opening displacement of a crack in an infinite sheet for a plane stress condition can be calculated using the equation given by Tada et al. (2000 [DIRS 167756], p. 125):

$$b = \frac{2(2c)\sigma}{E} \quad \text{(Eq. C-1)}$$

where b = crack width (mm), $2c$ = crack length (mm), σ = residual tensile stress (Pa), and E = the modulus of elasticity (Pa). The opening area, A_{SCC}, for an elliptical crack can be estimated by:

$$A_{SCC} = \pi\left(\frac{b}{2}\right)\left(\frac{2c}{2}\right) = \frac{(2\pi c^2)\sigma}{E} \quad \text{(Eq. C-2)}$$

When Equations C-1 and C-2 are used to estimate the width and opening area of a through-wall crack, σ is the maximum tensile stress across the wall thickness of the dominant stress plane (SNL 2007 [DIRS 181953], Section 6.6.2).

An initially semi-elliptical crack becomes a semi-circular crack as it grows to a through-wall crack (Figure C-1) (SNL 2007 [DIRS 181953], Section 6.6.2). Therefore, the expected maximum length ($2c$) of the cracks is at least two times the wall thickness (SNL 2007 [DIRS 181953], Sections 6.6.2 and 6.8.5.2). The crack width and opening area are assumed to be the same through the wall thickness. For an actual SCC crack propagating through the wall thickness, the crack width and opening area are likely to decrease along the wall thickness because of the residual stress redistribution and relaxation at the crack tip as the crack grows through the wall thickness. For the drip shield and waste package that are damaged by seismic-induced events, the residual tensile stress tends to decrease from the outer surface (where the seismic impact occurs) to the inner surface of the drip shield or WPOB. The likely shape of the through-wall cracks that result from seismic damage would be one with a larger opening in the outer surface side and a much smaller opening size at the penetration point in the inner wall surface. Those effects can be amplified when neighboring cracks propagate in parallel through the wall thickness (SNL 2007 [DIRS 181953], Sections 6.7.1.2 and 6.7.1.3).

For this analysis, the room-temperature yield strength (σ_{YS}) of Titanium Grade 7 or Alloy 22 is used for the residual stress, σ, in Equations C-1 and C-2. Values for σ_{YS} and E for the titanium alloy and Alloy 22 at room temperature are found in DTN: MO0702PASTRESS.002 [DIRS 180514] (file: *Model Output DTN.doc*) and listed in Table C-1. The use of room-temperature values is justified because SCC is a corrosion process that requires the presence of water inside and around the crack mouth to support associated corrosion reactions and is therefore operative below the water boiling temperature at the repository. In addition, using the property values from DTN: MO0702PASTRESS.002 [DIRS 180514] (file: *Model Output DTN.doc*, Table 8-1), the σ_{YS}/E ratios in Equations C-1 and C-2 for Alloy 22 and Titanium Grade 7 are larger for the room temperature values than the values at 93°C for Alloy 22 and those at 149°C for Titanium Grade 7; the use of the room temperature values results in a larger crack opening size and therefore is reasonable and conservative.

If SCC breach of the drip shield occurs during the first 10,000 years after repository closure when the drip shields maintain most of the design wall thickness of 15 mm (i.e., $2c$ = 30 mm), the maximum width of a through-wall crack in the drip shield is calculated to be approximately

155 μm (Equation C-1), and the maximum crack mouth area is approximately 3.65 mm^2 (Equation C-2).

For the waste packages, if SCC breach occurs during the first 10,000 years after repository closure when the WPOB maintains most of the design wall thickness of 25 mm (i.e., $2c = 50$ mm), the maximum width of a through-wall crack in the WPOB is calculated to be approximately 195 μm (Equation C-1), and the maximum crack mouth area is approximately 7.68 mm^2 (Equation C-2).

Table C-1. Yield Strength and Modulus of Elasticity of Titanium Grade 7 and Alloy 22 Used in This Analysis

Materials	Yield Strength (MPa) at Room Temperature	Modulus of Elasticity (GPa) at Room Temperature
Titanium Grade 7	276	107
Alloy 22	403	206

C.2.2 Drip Shield SCC Damage Induced by Seismic Events

Seismic-induced SCC of the drip shield plate can occur when the resultant residual tensile stress is greater than 80% of the yield strength of Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 8.1.5). The seismic consequence abstraction analysis provides the areas on the drip shields damaged by seismic loading and rockfall (DTN: MO0703PASDSTAT.001 [DIRS 183148], files: *DS Damaged Areas with Rubble.xls* and *Nonlith Damage Abstraction for DS.xls*), and the summary of the analysis results is found in DTN: MO0703PASEISDA.002 [DIRS 183156]. The seismic-induced damaged area on the drip shield is defined as the residual tensile stress exceeding 80% of the at-temperature yield strength of Titanium Grade 7 (SNL 2007 [DIRS 181953], Section 8.1.5). This analysis assumes that the damage to drip shields due to seismic ground motion is distributed randomly over the surface of the drip shield.

Considering two bounding arrangements for the through-wall cracks in the drip shields (SNL 2007 [DIRS 181953], Section 6.8.5.2), the crack opening area density (crack opening area per unit seismically damaged area) (ρ_{SCCA}) is calculated as follows:

$$\rho_{SCCA} = C \times \frac{\pi \sigma_{YS}}{\sqrt{3}\, E} \qquad \text{(Eq. C-3)}$$

$$C = uniform(1, 4) \qquad \text{(Eq. C-4)}$$

where C is an epistemic uncertainty factor given by a uniform distribution between 1 and 4. Details of this bounding crack arrangement and geometry are given in *Stress Corrosion Cracking of Waste Package Outer Barrier and Drip Shield Materials* (SNL 2007 [DIRS 181953], Section 6.8.5.2). The total through-wall SCC crack opening area per drip shield (A_{DS_SCC}) that results from the seismic damage is calculated as:

$$A_{DS\_SCC} = C \frac{\pi \sigma_{YS\_DS}}{\sqrt{3}\, E_{DS}} \cdot A_{SD\_DS} \qquad \text{(Eq. C-5)}$$

where A_{SD_DS} is the seismically damaged area on the drip shield (similar to SNL 2007 [DIRS 181953], Equation 32 in Section 6.7.2), and is provided by the seismic consequence abstraction analysis (DTN: MO0703PASDSTAT.001 [DIRS 183148], files: *DS Damaged Areas with Rubble.xls* and *Nonlith Damage Abstraction for DS.xls*; DTN: MO0703PASEISDA.002 [DIRS 183156]). Regions of seismic damage are assumed to be distributed randomly over the drip shield surface.

C.2.2.1 Seismic-induced damage area of drip shield

Damage to a drip shield could occur in either the lithophysal or nonlithophysal host rock. The nonlithophysal zone comprises approximately 15% of the repository area (SNL 2007 [DIRS 179466], Table 4-1, Parameter Number 01-03). To evaluate drift degradation and rockfall impact damage on drip shields, from seismic ground motion in the first 10,000 years, a peak ground velocity (PGV) of 1.05 m/s was selected as a representative seismic ground motion. This corresponds to a mean annual exceedance frequency of approximately 10^{-5}/yr (DTN: MO0501BPVELEMP.001 [DIRS 172682]), which roughly equates to 1 chance in 10 of occurring in the first 10,000 years. The full plate thickness for drip shields was selected as appropriate for the first 10,000 years because the extent of general corrosion of Titanium Grade 7 during this time will be very small, and will not markedly alter structural performance.

For drift degradation in the lithophysal zone at the 1.05 m/s PGV level, the resulting degraded drift volume, on a per meter basis (also the volume of rock needed to fill the drift) is quantified as a uniform distribution between 30 and 120 m^3 (DTN: MO0703PASEISDA.002 [DIRS 183156], Section 1.1, step 5.e.). For this evaluation, the median value (75 m^3 per meter of drift length) was selected for a nominal collapsed drift volume. An estimate of how much rock volume is produced during such an event is quantified in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Figure 6-57) and, at the 1.05 m/s PGV, has a mean value of 7.47 m^3

and a standard deviation of 8.37 m^3, which are both per meter of drift length (SNL 2007 [DIRS 176828], Table 6-30).

The total rubble accumulation on the drip shield for the time up to the point of the evaluation was estimated by selecting the 99th percentile value of the analysis for the selected PGV level. This is calculated to be 38.7 m^3 per meter of drift length (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *Lith Rubble Abstraction.xls*, worksheet: "Gamma Abstraction," cell: AE11), and is also shown in Figure 6-57 of *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]).

Combining the estimate of rock rubble volume accumulation with the volume needed to fill a degraded drift, an estimate of the percentage fill of the drift is found by dividing 38.7 m^3 by 75 m^3, or approximately 52%. At this drift fill volume, no damage to the drip shield with the 15-mm plate thickness is estimated, as shown in DTN: MO0703PASDSTAT.001 [DIRS 183148] (file: *DS Damaged Area with Rubble.xls*, worksheet: "1.05 ms PGV - Case 2 BCs," cells: M57 to M68, and worksheet: "1.05 ms PGV - Case 1 BCs," cells: M54 to M65).

In the nonlithophysal zone, the impact damage to a drip shield due to the six largest rock blocks ejected during a 1.05 m/s PGV event was evaluated as indicated in *Mechanical Assessment of Degraded Waste Packages and Drip Shields Subject to Vibratory Ground Motion* (SNL 2007 [DIRS 178851], Table 6-153). The largest rock block considered for this analysis was at the 99.9th percentile for all blocks ejected for the 1.05 m/s PGV event (SNL 2007 [DIRS 178851], Table 6-154), and the impact by the block was estimated to result in a damage area of 0.0159 m^2 for the 15-mm drip shield plate thickness (SNL 2007 [DIRS 178851], Table 6-157). Because the estimated damage area is for one-quarter of the drip shield, the damage area for the entire drip shield is obtained by multiplying the estimate by 4, for a total damage area of 0.064 m^2.

The upper-bound damage area in the drip shield with 15-mm plate thickness that could result from seismic ground motion at the 1.05 m/s PGV level in the first 10,000 years in the repository is estimated to be 0.064 m^2, which corresponds to 0.48% of the total topside surface area of the drip shield (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*). A reasonable upper-bound total number of through-wall SCC cracks per damaged drip shield is estimated to be 326 cracks, and the corresponding upper-bound total crack-mouth opening area of through-wall SCC cracks per damaged drip shield is approximately 1,190 mm^2 (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*).

C.2.3 Waste Package SCC Damage Induced by Seismic Events

The seismic consequence abstraction analysis provides the areas on the waste packages damaged by the seismic ground motion (DTN: MO0703PASEISDA.002 [DIRS 183156]). The seismic-induced damaged area on the waste package is defined as the residual tensile stress exceeding 90% to 105% of at-temperature yield strength of Alloy 22 (SNL 2007 [DIRS 181953], Section 8.1.1).

Considering two bounding arrangements for the through-wall cracks in the waste packages (SNL 2007 [DIRS 181953], Section 6.7.3), the crack opening area density (crack opening area

per unit seismically damaged area) (ρ_{SCCA}) is calculated using Equations C-3 and C-4 and using the yield strength and elastic modulus of Alloy 22. As for the drip shield, C in Equation C-6 is an epistemic uncertainty factor given by a uniform distribution between 1 and 4 (as defined in Equation C-4). The total through-wall SCC crack opening area per waste package (A_{WP_SCC}) that results from the seismic damage is calculated as follows:

$$A_{WP\_SCC} = C \frac{\pi \sigma_{YS\_WP}}{\sqrt{3}\, E_{WP}} \times A_{SD\_WP} \qquad \text{(Eq. C-6)}$$

Where, A_{SD_WP} is the seismically damaged area on the waste package, and is provided by the seismic consequence abstraction analysis (DTN: MO0703PASEISDA.002 [DIRS 183156]). This analysis assumes that regions of damage to the WPOB due to seismic ground motion are distributed randomly over the surface of the waste package.

C.2.3.1 Seismic-Induced Damage Area of Waste Package

As for the drip shield, seismic ground motion at a PGV of 1.05 m/s was selected as a representative condition for evaluating seismic-induced damage to waste packages in the first 10,000 years in the repository. This PGV level corresponds to a mean annual exceedance frequency of approximately 10^{-5} (DTN: MO0501BPVELEMP.001 [DIRS 172682]), which roughly equates to 1 chance in 10 of occurring in the first 10,000 years.

As recommended by *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.5.1.2) the WPOB thickness of 23-mm, with intact internals, was selected as appropriate for the first 10,000 years of the repository. Degradation or thinning of the WPOB by general corrosion will be insignificant during this time period, and will not markedly alter structural performance. A reasonably conservative estimate of the general corrosion penetration depth for the first 10,000 years is only 0.3 mm using the 50th percentile general corrosion rate (30.8 nm/yr) at 100°C for the expected case (the medium uncertainty level for R_o and the mean apparent activation energy of 40.78 kJ/mol) (DTN: MO0612WPOUTERB.000 [DIRS 182035], file: *BaseCase GC CDFs2.xls*).

Seismic Consequence Abstraction (SNL 2007 [DIRS 176828], example in Section 6.8.3.1) provides the seismic damage analysis for two states of the waste package internals: intact and degraded state. The degraded state requires breach of the waste package and subsequent corrosion of the internals. An intact state of the internals was selected as appropriate for the first 10,000 years of the repository because earthquakes of sufficient magnitude to cause significant damage to the WPOB occur relatively infrequently during this time period, and the internals will not undergo substantial degradation by corrosion until a package experiences an extensive breach. Because they are the most abundant waste package types in the repository, the TAD-bearing waste package and the 5-DHLW/DOE SNF codisposal waste package are considered in this analysis.

Analyses have shown that the TAD-bearing waste packages of 23-mm-thick WPOB with intact internals are not subject to SCC damage from the 1.05 m/s PGV level ground motions (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *Kinematic Damage Abstraction 23-mm*

Intact.xls, worksheet: "WP Total"), and the results are also discussed in *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 6.5.1.2, Table 6-4). Therefore, no TAD-bearing waste packages are considered for this analysis.

The codisposal waste packages can be subject to SCC-damage from the same PGV level ground motions, and the 95th percentile value (0.377 m^2) was selected as a reasonably conservative upper-bound value for the damage area of the waste package (DTN: MO0703PASDSTAT.001 [DIRS 183148], file: *CDSP Kinematic Damage Abstraction 23-mm Intact.xls*, worksheet: "Gamma for 90%_i23"), and the analysis results are also shown in Figure 6-33 of *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828]). This codisposal waste package damage area is used as a representative value for the waste package in the analysis.

The selected damage area corresponds to 0.95% of the total surface area of the codisposal waste package (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*). A reasonably conservative upper-bound total number of through-wall SCC cracks per damaged waste package is estimated to be 697 cracks, and the corresponding upper-bound total crack-mouth opening area of through-wall SCC cracks per damaged waste package is approximately 5,351 mm^2 (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*).

C.3 BOUNDING ANALYSIS FOR WATER FLOW RATE IN SCC THROUGH-WALL CRACKS IN SHEET FLOW

This analysis evaluates the water flow rate in through-wall SCC cracks in the drip shield and waste package for sheet flow. This condition represents those such as a slowly moving water layer, or equivalently, rivulet flow, or limited "pooling" of seepage drips in the vicinity of a crack, but not impinging drips directly onto the cracks. The analysis assumes full liquid saturation for the tight, compact porous medium filling the cracks that are in the path of sheet flow. The initial transient unsaturated condition for the porous medium filling cracks is not included. The SCC cracks that are not affected by sheet flow are expected not to be fully saturated with water, and are permeable to gases and water vapor in the drift.

The SCC process will result in accumulation of corrosion products from associated corrosion reactions and mineral precipitates from evaporation of the water filling the crack. As discussed later, propagation of SCC cracks through the thickness of drip shield plates or the WPOB could take hundreds to thousands of years to occur for repository-relevant conditions. As SCC cracks grow through the wall, intermittent wetting and drying cycles (e.g., from episodic drips) will promote precipitation, and accumulation of corrosion products and mineral particles inside the crack. In particular, episodic drips on the drip shield surface are enhanced by spatial and temporal movements of seeps in the drift. It is further enhanced by gas pressure fluctuations and moisture redistribution in the host rock in response to barometric changes (BSC 2004 [DIRS 169734], Sections 7.3.2 and 7.4.1).

The expected SCC crack propagation rate for Titanium Grade 7 under repository conditions is approximately 10^{-10} mm/s (SNL 2007 [DIRS 181953], Section 8.1.5), and at this rate, it will take approximately 4,700 years to penetrate the 15-mm thick drip shield, assuming conservatively a constant crack growth rate as it propagates through the wall thickness. The upper-bound crack

propagation rate is approximately 10^{-8} mm/s (SNL 2007 [DIRS 181953], Section 8.1.5), and it still takes approximately 50 years for through-wall penetration. For Alloy 22 the maximum measured SCC crack growth rate in an aggressive corrosion condition relevant to the repository environments is 4.23×10^{-9} mm/s (DTN: MO0705CREEPSCC.000 [DIRS 183681], file: *SDFRvData.xls*, worksheet: "Graphs1;" SNL 2007 [DIRS 181953], Table 7-4), and at this rate, it will take approximately 190 years to penetrate the 25-mm-thick WPOB, assuming conservatively a constant crack growth rate as it propagates through the wall thickness. The model-predicted mean crack propagation rate at a reasonably bounding stress intensity factor of 40 MPa√m is 1.00×10^{-9} mm/s (DTN: MO0705CREEPSCC.000 [DIRS 183681], file: *SDFRvData.xls*, worksheet: "Graphs1"), and it will take approximately 800 years for through-wall penetration at this rate, assuming a constant crack growth rate through the wall thickness.

A detailed study using high-resolution analytical electron microscopy showed accumulation of corrosion products and presence of water from the external environment deep inside very fine SCC cracks in stainless steels and nickel-based alloys (Bruemmer and Thomas 2001 [DIRS 183685]). The corrosion product oxides tend to cement and agglomerate, especially in the presence of other minerals such as silica (Milnes and Fitzpatrick 1995 [DIRS 105911], pp. 1,180 to 1,183). SCC cracks for corrosion resistant materials like Alloy 22 and Titanium Grade 7 are typically tight and tortuous, and require only small amounts of corrosion products or mineral precipitates to become filled. In addition, because of the larger molar volumes for corrosion products compared with the base metal (e.g., titanium oxide from corrosion of Titanium Grade 7, and nickel and chromium oxides from Alloy 22), the corrosion products and mineral precipitates will be compacted inside the crack as more corrosion products form from general corrosion of the crack walls. This analysis considers that the SCC cracks in the drip shield and waste package are continuously filled with compact cemented corrosion products and mineral precipitates as the cracks grow through the wall thickness.

The saturated hydraulic conductivity of the compact, cemented porous material filling the cracks is estimated using the Kozeny-Carman equation (Bear 1972 [DIRS 156269], pp. 165 to 167) for the permeability, and using the relationship between the permeability and hydraulic conductivity (Domenico and Schwartz 1990 [DIRS 100569], pp. 61 to 63):

$$K = \left(\frac{\rho_w g}{\mu_w} \right) k = \frac{1}{5M^2} \left(\frac{\rho_w g}{\mu_w} \right) \frac{\phi^3}{(1-\phi)^2} \qquad \text{(Eq. C-7)}$$

where

K = Saturated hydraulic conductivity (cm/s)

k = permeability (cm^2)

M = Specific surface area of porous medium (surface area of solid per unit volume of solid, cm^2/cm^3)

ϕ = Porosity of medium

ρ_w = Density of water (g/cm^3)

μ_w = Absolute viscosity of water (Poise, g/cm-s)

g = Gravitational constant (981 cm/s^2).

The Kozeny-Carman equation is a widely used predictive equation for permeability, and its dependence on particle size (Bear 1972 [DIRS 156269], p. 165). The equation is based on a theory that treats a porous medium as a bundle of capillary tubes of equal length (Bear 1972 [DIRS 156269], p. 166), and this simplifying assumption gives rise to uncertainty in the estimation of permeability for real porous media. The specific surface area (M) for the porous medium filling the cracks is estimated by multiplying the density of the medium (g solid porous medium/cm^3 solid porous medium) by another type of specific surface area (cm^2 solid porous medium/g solid porous medium). The latter is measured typically by the gas absorption method. The porosity (0.4) of unconsolidated corrosion products (DTN: SN0703PAEBSRTA.001 [DIRS 183217], file: *SN0703PAEBSRTA.001 - RTA Input Tables.doc*, Table 8.2-6) is used as a reasonable conservative upper-bound in the analysis. Porosity of consolidated, compact corrosion products (and mineral precipitates) inside cracks would likely be less, and result in a lower saturated hydraulic conductivity value in Equation C-7. The density of pure water (0.965 g/cm^3) and the viscosity of pure water (0.00315 g/(cm s)) at 90°C (Lide 2000 [DIRS 131202], p. 6-9) are used in the analysis, and the effect of dissolved solutes on these properties is not considered.

Assuming unit static head gradient in the crack, the volumetric water flow rate (Q, cm^3/s) through the through-wall cracks is calculated as follows:

$$Q = K\, n_{SCC}\, A_{SCC} \qquad \text{(Eq. C-8)}$$

where

n_{SCC} = Number of through-wall cracks in the path of sheet flow that potentially flow water

A_{SCC} = Crack mouth opening area of a single through-wall crack from Equation C-2.

Parameter n_{SCC} is estimated using laboratory drip test results, which indicate that only through-wall cracks in the top part of the drip shield or waste package, where the surface is within 10 to 20 degrees of horizontal, can potentially flow in response to sheet flow conditions (DTN: SN0506F4104405.003 [DIRS 174472], file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*, table: "Sheet Flow Block Tests"). This corresponds to 2.8% to 5.6% of the total number of through-wall cracks in the drip shield and WPOB, approximating their surface area to an equivalent circular geometry and assuming the seismic-damage areas are randomly distributed over the drip shield and waste package surface.

C.3.1 Water Flow Rate in SCC Through-Wall Cracks in Sheet Flow Condition in Drip Shield

For estimating the saturated hydraulic conductivity of the porous medium inside cracks in the drip shield using the Kozeny-Carman equation (Equation C-7), a simplifying assumption is made that the porous medium consists primarily of titanium oxide (TiO_2), a corrosion product of Titanium Grade 7. The titanium oxide particles are expected to be a few tens of nanometers in size as shown from electron microscopy studies of corrosion products formed on Titanium Grade 7 samples (He et al. 2007 [DIRS 183687], p. 789 and Figure 14-b). As described previously, the titanium corrosion products inside the cracks are expected to form cemented agglomerates of poorly crystalline or polycrystalline precipitated particles. Specific surface area of 6 to 50 m^2/g for commercial grade crystalline rutile and anatase (Siriwardane and Wightman 1983 [DIRS 183688]) are used for the titanium oxide corrosion products. The specific surface area used is conservative because, as discussed previously, the surface areas of titanium oxide corrosion product particles are expected to be much higher. The density of natural rutile (4.26 g/cm^3; Lide 2000 [DIRS 131202], p. 4-108) is used for titanium oxide.

A previous study considered calcite as the crack filling material (BSC 2001 [DIRS 156807]). The specific surface area of calcium carbonate precipitates or weathered calcium carbonates in soil environments is equivalent to, or greater than, the values used for titanium corrosion products in this analysis. The specific surface area for calcium carbonate in soil environments was reported to range from a few tens to a few hundreds of m^2/g (Holford and Mattingly 1975 [DIRS 183686]). Typical commercial reagent-grade crystalline calcium carbonate powders have a specific surface area that ranges from 0.4 to 13 m^2/g (Amer et al. 1985 [DIRS 183684], Table 1). The density (2.71 g/cm^3) of natural calcite (Lide 2000 [DIRS 131202], p. 4-47) is a factor of two less than that of rutile used for the titanium corrosion products, but this makes only a minor difference in the saturated hydraulic conductivity estimates using Equation C-7. Therefore, use of calcium carbonate precipitates or weathered calcium carbonate as the crack filling materials will not make much difference in the hydraulic conductivity estimates.

With the values for the parameters of the Kozeny-Carman equation described previously, the saturated hydraulic conductivity of the titanium oxide filling inside cracks is estimated to range from 7.44×10^{-4} m/yr (or 2.36×10^{-11} m/s for the lower bound of the specific surface area) to 5.17×10^{-2} m/yr (or 1.64×10^{-9} m/s for the upper bound of the specific surface area) (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cells: B29 and D29). The estimated hydraulic conductivity values fall in the range for clay, from 1.0×10^{-11} to 4.7×10^{-9} m/s (Domenico and Schwartz 1990 [DIRS 100569], Table 3-2). Considering the high specific surface area of the corrosion products, the good match with the values for clays shows that the estimated range for the hydraulic conductivity is reasonable. Clays are characterized as having very fine particle sizes, rugged platy surface morphology, and high specific surface area. Clay-rich media have very low permeability when wet, even when settled or compacted.

Using the upper-bound value of 18 for n_{SCC} in Equation C-8, the volumetric flow rate of water through the SCC through-wall cracks in the drip shield is estimated to be in the range 0.05 to 3.42 cm^3/yr (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow DS flow rate," cells: B31 and D31). The

estimated flow rates through damaged drip shields for sheet flow conditions are small enough that this flow need not be considered as a potential source of flow through SCC cracks in the underlying waste package outer barrier. These estimated flow rates are much less than the threshold seepage rate of 100 mL/yr per waste package that is important to the repository performance as determined by TSPA (SNL 2007 [DIRS 181244], Section 6.4[a]; SNL 2007 [DIRS 180506], Section 6.10.9.1[a]).

C.3.2 Water Flow Rate in SCC Through-Wall Cracks in the WPOB for Sheet Flow Conditions, under Completely Failed Drip Shields

A similar bounding analysis is conducted for a SCC-damaged waste package with completely failed drip shield that does not perform the seepage diversion function. The affected waste package is assumed to be exposed directly to the drift seepage. This is not an expected condition for the drip shield in the first 10,000 years of the repository because it requires a mechanism such as drip shield early failure (SNL 2007 [DIRS 178765], Section 7).

As detailed in Section C.2.3.1, the upper-bound total number of through-wall SCC cracks per damaged waste package from the seismic ground motions at the 1.05 m/s PGV level is estimated to be 697 cracks, and the upper-bound total crack-mouth opening area of through-wall SCC cracks per damaged waste package is approximately 5,351 mm^2 (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*). Approximating the waste package surface to a circular geometry and assuming the seismic-damage areas are randomly distributed over the waste package surface, the upper-bound number of through-wall cracks that potentially flow water in sheet flow condition is 39 cracks (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow WP flow rate," cell: B19).

For estimation of the permeability (and hydraulic conductivity) of the crack filling medium using the Kozeny-Carman equation (Equation C-7), a simplifying assumption is made that nickel oxide (NiO) is the representative corrosion product of Alloy 22 that fills the cracks. Calcium carbonate precipitates or weathered calcium carbonate in soil environment can also be considered as an alternative crack filling material, but this does not make much difference in the hydraulic conductivity estimate for the reasons discussed previously. The parameter values that are specific to this analysis are:

- Density of nickel oxide, 6.72 g/cm^3 (DTN: SN0703PAEBSRTA.001 [DIRS 183217], file: *SN0703PAEBSRTA.001 - RTA Input Tables.doc*, Table 8.2-6).

- Specific surface area of nickel oxide, 1 to 30 m^2/g (DTN: SN0703PAEBSRTA.001 [DIRS 183217], file: *SN0703PAEBSRTA.001 - RTA Input Tables.doc*, Table 8.2-4).

- Porosity of crack filling medium, 0.4 (DTN: SN0703PAEBSRTA.001 [DIRS 183217], file: *SN0703PAEBSRTA.001 - RTA Input Tables.doc*, Table 8.2-6). The porosity value used in the analysis is for unconsolidated corrosion products and considered as a reasonably conservative upper bound in the analysis. Porosity of consolidated, compact corrosion products (and mineral precipitates) inside crack would be lower and result in a lower saturated hydraulic conductivity estimate.

Using the density and viscosity of pure water at 90°C, the saturated hydraulic conductivity of the nickel oxide filling inside cracks is estimated to range from 8.30×10^{-4} m/yr (or 2.63×10^{-11} m/s for the upper bound of the specific surface area) to 7.47×10^{-1} m/yr (or 2.37×10^{-8} m/s for the lower bound of the specific surface area) (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow WP flow rate," cells: D29 and B29, respectively).

Using the upper-bound value of 39 for n_{SCC} in Equation C-8, the volumetric flow rate for liquid water in SCC through-wall cracks in the WPOB for sheet flow conditions, exposed directly to drift seepage (i.e., no seepage protection by the drip shield) is estimated to be in a range of 0.25 to 222.18 cm^3/yr (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Sheet flow WP flow rate," cells: B31 and D31). As discussed earlier, these estimated flow rates are for conditions that are unexpected for the first 10,000 years of the repository. Much of the estimated flow rate range is less than the threshold seepage rate of 100 mL/yr per waste package location as determined for TSPA (SNL 2007 [DIRS 181244], Section 6.4[a]; SNL 2007 [DIRS 180506], Section 6.10.9.1[a]). Note also that advection of water into the inner canister of the waste package will be further hindered by the presence of the 50-mm Stainless Steel Type 316 inner vessel, and the 25-mm TAD canister.

C.4 WATER FLOW RATES THROUGH SCC CRACKS IN DRIP SHIELD BY IMPINGING DRIPS

The laboratory drip tests (DTN: SN0506F4104405.003 [DIRS 174472], files: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc*, and *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*, table: "Dynamic Drop Block Tests") showed that dripping onto a through-wall crack can cause water to flow through the crack. This analysis evaluates the water flow rate through a drip shield damaged by through-wall cracks, with seepage drips impinging onto the cracks. The analysis considers that drip shields are damaged from seismic-induced rockfall and ground motion at the 1.05 m/s PGV level for the first 10,000 years of the repository, and that regions of SCC crack damage are distributed uniformly over the drip shield surface. This analysis uses the same characterization of seismic-induced SCC damage as detailed in Section C.2.2.1. The SCC cracks that are not affected by drips and resulting sheet flow are expected not to be fully saturated with water, and will be permeable to gases and water vapor in the drift.

The amount of the drift seepage that potentially impinges on the through-wall cracks in a drip shield is estimated as follows:

$$F_{DS\_impinging\_drips} = F_{drift\_seepage} \times f_{DS\_drip\_angle} \times f_{DS\_crack\_area} \quad \text{(Eq. C-9)}$$

where

$F_{DS\_impinging\_drips}$ = Amount of the drift seepage flux that impinges on to through-wall cracks in drip shield

$F_{drift\_seepage}$ = Drift seepage flux

$f_{DS\_drip\_angle}$ = Fraction of the drip shield area that is potentially subject to flow through cracks under impinging drips

$f_{DS\_crack\_area}$ = Fraction of the drip shield area that corresponds to the total opening area of through-wall cracks from seismic damage, calculated by dividing the total crack opening areas in the drip shield (Equation C-5) by the total drip shield surface area.

Parameter $f_{DS\_drip\_angle}$ corresponds to the top 40- to 90-degree angle of the drip shield (DTN: SN0506F4104405 [DIRS 174472], file: *Dynamic_Drop_Test_ Summary_SCC_4-15-05.doc*, tables: "Summary of Dynamic Sample Block Test Results" and "Summary of SCC Dynamic Drop Test Results;" file: *SCC_PhaseII_Test_ Preliminary_Summary_9-21-05.doc*, table: "Dynamic Drop Block Tests"). Approximating the drip shield surface area to an equivalent circular geometry, the area associated with the top 40- to 90-degree angle corresponds to 0.11 to 0.25 of the total drip shield outer surface area. The range is characterized as an epistemic uncertainty with a uniform distribution between the bounds (0.11 and 0.25).

The flow rate through the cracks in the drip shield ($F_{DS\_seepage}$) is estimated by multiplying the impinging drift seepage flux ($F_{impinging\_drips}$) with a crack seepage scaling factor (f_{crack_seeps}), which is the fraction of the total amount of drips that flows through the cracks. The factor is based on the data from the dynamic drip tests on Stainless Steel Type 316 and Titanium Grade 7 test samples with varying shapes and aperture sizes of cracks, including actual SCC cracks in a large stainless steel plate (DTN: SN0506F4104405.003 [DIRS 174472], files: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc* and *SCC_PhaseII_Test_Preliminary_ Summary_9-21-05.doc*).

$$F_{DS\_seepage} = f_{crack\_seeps} \times F_{DS\_impinging\_drips} \quad \text{(Eq. C-10)}$$

The largest aperture size of the cracks in one location of the stainless steel plate is approximately 381 µm, and the largest aperture size in other location is approximately 127 µm (Walton 2005 [DIRS 175407], pp. 110 and 145). The crack seepage scaling factor ranges from 0.0 to 0.04, and is characterized as an epistemic uncertainty with a uniform distribution between the bounds (0.0 and 0.04).

Using the bounding values for the parameters of this analysis, and for the drip shield SCC-damage from seismic-induced rockfall and ground motion at the 1.05 m/s PGV level (Section C.2.2.1), the damaged drip shield can still reduce the drift seepage flux by more than six orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell: B25). For example, if the damaged drip shield were subject to a reasonable-bound drift seepage flux of 500 L/yr (DTN: MO0705TSPASEEP.000 [DIRS 183008], file: *v5.005_Seismic-FD_1Myr_CDSP_ SeepRate_Bin5_stats.txt*; based on the mean drift seepage rate of approximately 460 L/yr from percolation subregion 5 (highest percolation rate subregion) at 10,000 years) the maximum volumetric flow rate through the damaged drip shield is estimated to be only 0.4 mL/yr, which is negligibly small (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow*

through SCC cracks.xls, worksheet: "Impinging drip flow rate," cell: B24). The estimated upper-bound flow rate is much less than the threshold seepage rate of 100 mL/yr per waste package that is important to repository performance as determined by TSPA (SNL 2007 [DIRS 181244], Section 6.4[a]; SNL 2007 [DIRS 180506], Section 6.10.9.1[a]).

C.5 WATER FLOW RATES THROUGH SCC CRACKS IN WASTE PACKAGE BY IMPINGING DRIPS

This analysis evaluates the water flow rate in through-wall SCC cracks in the WPOB, for impinging-drip conditions, underneath SCC-damaged drip shields. The analysis assumes that waste packages are damaged from seismic-induced ground motion at the 1.05 m/s PGV level in the first 10,000 years of the repository, and that the resulting through-wall SCC cracks are distributed uniformly over the waste package surface. This analysis uses the same characterization of seismic-induced SCC damage as detailed in Section C.2.3.1. The SCC cracks that are not affected by drips or resulting sheet flow are expected not to be fully saturated with water, and will remain permeable to gases and water vapor in the drift.

The amount of the seepage from an SCC-damaged drip shield that potentially impinges on through-wall cracks in the underlying waste package is estimated as follows:

$$F_{WP\_impinging\_drips} = F_{DS\_seepage} \times f_{WP\_drip\_angle} \times f_{WP\_crack\_area} \quad \text{(Eq. C-11)}$$

where

$F_{WP\_impinging\_drips}$ = Amount of the seepage flux from an SCC-damaged drip shield that impinges on through-wall cracks in the underlying waste package

$F_{DS\_seepage}$ = Seepage flux from SCC-damaged drip shield (see analysis in Sections C.4 and C.3.1)

$f_{WP\_drip\_angle}$ = Fraction of the waste package area that is potentially subject to flow through cracks under impinging drips

$f_{WP\_crack\_area}$ = Fraction of the waste package area that corresponds to the total opening area of through-wall cracks from seismic damage, calculated by dividing the total crack opening areas in the waste package (Equation C-6) by the total waste package surface area.

As in the analysis for the drip shield (Section C-4), $f_{WP\_drip\_angle}$ corresponds to the top 40- to 90-degree angle of the waste package (DTN: SN0506F4104405.003 [DIRS 174472], file: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc*, tables: "Summary of Dynamic Sample Block Test Results and Summary of SCC Dynamic Drop Test Results;" file: *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*, table: "Dynamic Drop Block Tests"). The area associated with the top 40- to 90-degree angle corresponds to 0.11 to 0.25 of the total waste package surface area. The range is characterized as an epistemic uncertainty with a uniform distribution between the bounds (0.11 and 0.25).

The flow rate through the cracks ($F_{WP\_seepage}$) is estimated by multiplying the impinging drift seepage flux ($F_{WP\_impinging\_drips}$) with a crack seepage scaling factor (f_{crack_seeps}) that is based on the data from the dynamic drip tests on Stainless Steel Type 316 and Titanium Grade 7 test blocks with varying shapes and aperture sizes of cracks, including actual SCC cracks in a large stainless steel plate (DTN: SN0506F4104405.003 [DIRS 174472], files: *Dynamic_Drop_Test_Summary_SCC_4-15-05.doc* and *SCC_PhaseII_Test_Preliminary_Summary_9-21-05.doc*).

$$F_{WP\_seepage} = f_{crack\_seeps} \times F_{WP\_impinging\_drips} \quad \text{(Eq. C-12)}$$

The crack seepage factor ranges from 0.0 to 0.04, and is characterized as epistemic uncertainty with a uniform distribution between the bounds (0.0 and 0.04).

Using the bounding values for the parameters of this analysis, and the waste package damage from ground motion at the 1.05 m/s PGV level (Section C.2.3.1), the damaged waste package reduces the seepage flux from the SCC-damaged drip shield by more than five orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell: H25). Combined, the SCC-damaged drip shield and waste package can reduce the drift seepage flux on to the drip shield by at least ten orders of magnitude (output DTN: SN0705WFLOWSCC.001, file: *Bounding calc for water flow through SCC cracks.xls*, worksheet: "Impinging drip flow rate," cell: H27). This means that advective flow of seepage through seismic-induced SCC damage in the drip shield and the underlying waste package, is much less than the amount of water that is retained in the corrosion reactions in a breached waste package (SNL 2007 [DIRS 177404], Figure 6.5-8), and is therefore negligible.

APPENDIX D

SCIENTIFIC ANALYSES DISCUSSION AND SUPPORTING DOCUMENTATION FOR METEORITE IMPACT AND CRATERING PROBABILITY AND CONSEQUENCES

This appendix is referenced in FEP 1.5.01.01.0A (Meteorite Impact). It provides a detailed calculation and discussion regarding meteorite impact and provides the technical basis for exclusion based on probability for meteorite crater diameters larger than the threshold diameter associated with a frequency of one per 10,000 per 10,000 years.

Possible effects of a large meteorite impact near the repository include penetration of the repository and exhumation of waste. A meteorite associated with an impact crater not deep enough to exhume waste could reactivate or form faults and fractures, change the rock stress, and the associated shock wave could possibly cause damage to drifts and waste packages, or initiate an earthquake. Of particular interest for smaller meteorite impacts is the possibility of increased water percolation in the unsaturated zone to the repository through damage to the geologic layers that limit percolation.

Analysis of a meteorite impact depends on the probability of occurrence of variously sized impact craters, the area and relative dimensions of the repository footprint, and the depth of the repository below the ground surface. The probability of an impact crater of a given size occurring directly over or adjacent to the repository is dependent on the total flux of meteorites to the earth surface and on the repository footprint area. The size of the craters of interest is determined by the depth from ground surface to the top of the repository and/or any intervening geologic layers of particular interest due to their physical or hydrologic properties, and the spatial relationship of crater diameter to exhumation depth and fracturing depth. Accordingly, this appendix specifically examines the waste emplacement drifts and the probability of crater diameters sufficient to exhume waste, to fracture overlying rock units down to the repository depth, and to fracture to a depth less than the repository depth but sufficient to impair performance. Two crater sizes of interest in the analysis are: (1) craters that are deep enough to exhume waste from the repository, and (2) craters that are deep enough to fracture or damage the Paintbrush non-welded tuff (PTn) layer above the repository. Potential fracturing or damage to the overlying Tiva Canyon units is not of concern because of the damping effect of the PTn (SNL 2007 [DIRS 184614], Section 6.9[a]).

Section D1 lists the assumptions used in the analysis. Sections D2 and D3 describe the repository target area and the depth to and thickness of the PTn unit, respectively, which are the key site characteristics that are of interest to this analysis. Section D4 presents the development of the probability of meteorite impact. The probability of meteorite impact is based on cratering frequency distributions (annualized number of events per km^2) from observed earth and lunar cratering data (Sections D4.2.1 through D4.2.3). These distributions are then adjusted based on meteoroid influx after considering atmospheric shielding effects (Section D4.2.4). The slope and power constant of the modified distributions are obtained after regression analyses for the upper and lower portions of the distribution and for two air entry velocities of 15 and 20 km/s, which bound the range of cratering rate distributions for the FEP screening analysis (Section D4). Using the slope and power constant obtained, the probability of meteorite impact is calculated by integrating the frequency distribution over the target area. The maximum-impact crater diameter is then identified from the probability curve for the threshold of occurrence of 1×10^{-8} per year over the target area. Using correlation relationships identified in Section D4.3.5 between the crater diameter and the exhumation depth or the fracturing depth, the threshold exhumation and fracturing depths are then estimated from the maximum-impact crater diameter. Finally, the threshold exhumation depth is compared to the overburden thickness above the repository, and

the threshold fracturing depth is compared to the depth to and thickness of the PTn unit within the repository area. Results of these comparisons provide the technical basis to screen out the FEP based on low probability (Section D5). Section D5 also presents consideration of other additional impacts before reaching the final screening decision. Direct inputs are listed in Table D-5 and indirect inputs in Table D-6. The qualification of previously unqualified data for its intended use in this appendix is documented in Section D6.

For clarity, the following terms are used in the discussions: *Meteoroid* refers generically to a non-anthropogenic space object prior to entry to earth's atmosphere, *meteor* refers to the object once it enters earth's atmosphere and prior to impact, and *meteorite* refers to the object (or fragments of the object) impacting on (or in the case of aerial explosion, occurring near) the earth's surface. The terms *bolide* and *fireball* are also used. A *bolide* is defined as a meteor that shows signs of explosion or fragmentation, and a *fireball* is defined as a bright meteor with luminosity that equals or exceeds that of the brightest planets (generally magnitude of −3 or brighter).

A summary of velocity information from the reviewed literature is provided in Table D-1, which lists point values or average values where distributions were given. Calculated impact velocities of known meteoroids and comets range from 12.9 km/sec for small Earth-crossing objects with diameters less than 50 m (Chyba 1993 [DIRS 135248], Table 1a) to over 70 km/sec for long-period comets (Marsden and Steel 1994 [DIRS 129308], Table VI). The entry velocity of meteoroids is typically about 20 km/s (Hills and Goda 1993 [DIRS 135281], Section 2.1). Note that the extremes given above are values from an ensemble. However, a velocity of 15 km/s, in addition to being conservative with respect to crater formation, is consistent with the average impact velocities (Table D-1, Column 4) of observed meteors with diameters of particular interest (i.e., producing craters with frequencies at or greater than the screening criterion) (Chyba 1993 [DIRS 135248], Table 1a; Ceplecha 1994 [DIRS 135243], Table 2). Table D-1 is provided for informational purposes as the crater impact analysis is based on crater diameter distributions.

D1 ASSUMPTIONS

The following assumption is used in the analysis. For the meteorite analysis (provided in this appendix), assumptions are made to ensure that the analysis is conservative in nature and that the range of uncertainty in values is covered. The justification for the assumption are explained in later sections.

D1.1 ZONE OF FRACTURING IS CYLINDRICAL WITH DEPTH, RATHER THAN PARABOLIC

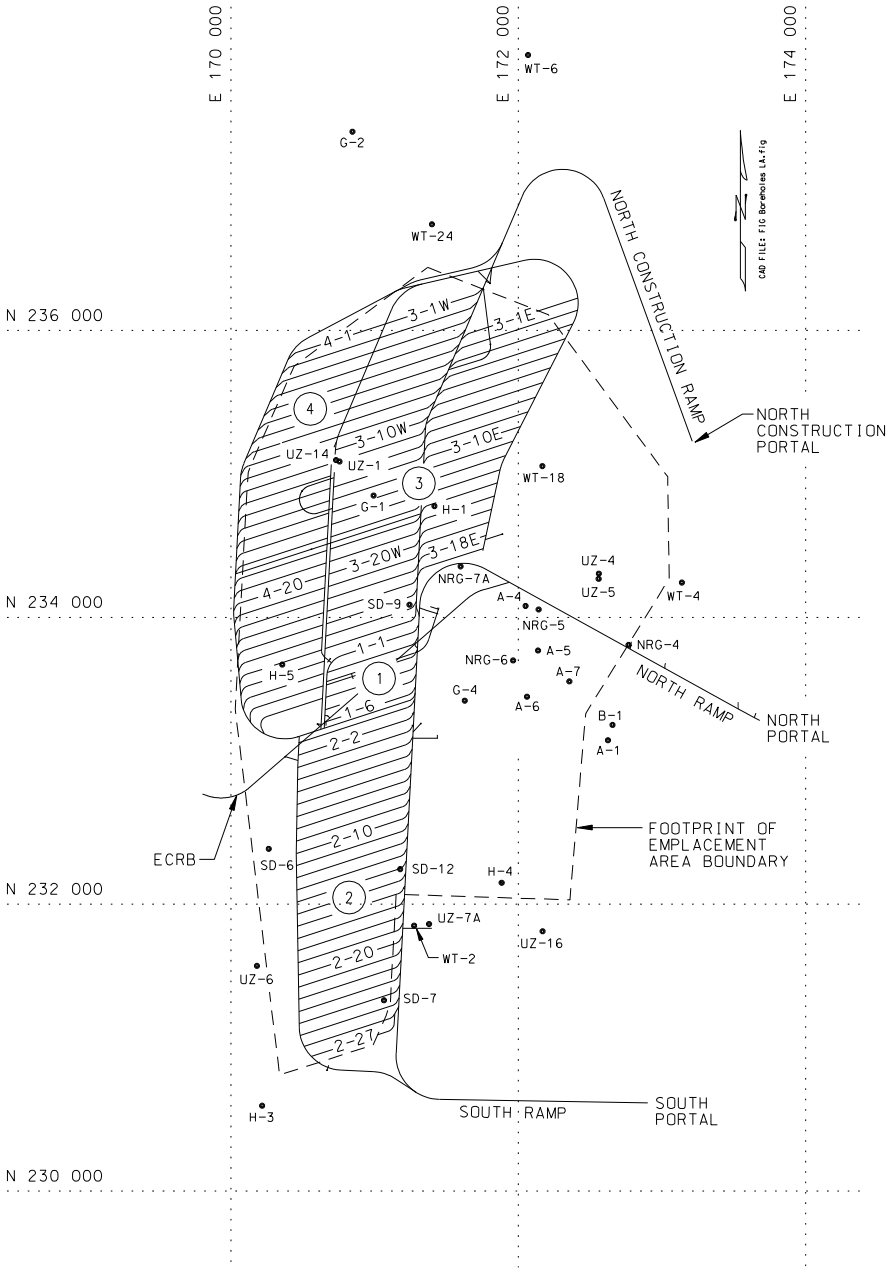
For analysis purposes, the vertical extent of effects (e.g., exhumation or fracturing) is represented as a cylinder.

The diameter of the cylinder is assumed to correspond to the crater diameter, and the depth corresponds to the depth of interest derived from the crater diameter. In reality, the effects are more likely parabolic in nature (inferred from Wuschke et al. 1995 [DIRS 129326], Figure 1). By assuming a cylindrical zone, the maximum depth of the effect (exhumation or fracturing) is applied throughout the area below the crater diameter and, thereby, conservatively considers a larger volume of the material overlying the repository.

D2 REPOSITORY FOOTPRINT AND TARGET AREA

The repository emplacement area is of primary interest to the analysis of meteorite impact. The target area to be used for this FEP screening includes the TSPA-LA emplacement drifts and surrounding areas. Figure D-1 shows the emplacement drifts and nearby boring locations.

Information of the repository layout for the TSPA-LA, including endpoint coordinates of emplacement drifts, can be found in subsurface facilities drawings (BSC 2007 [DIRS 183743], Tables 2 to 5). The maximum extent of the emplacement drifts is shown in Table D-2.



Sources: SNL 2007 [DIRS 179466], Table 4-1, Parameter 01-03; BSC 2007 [DIRS 182926], Figure 2.

Figure D-1. Waste Emplacement and Repository Target Area and Surrounding Boreholes

Table D-2. Emplacement Drift Endpoint Coordinates

Drift Number and Basis	Drift End Coordinate (m)
(3-1W) northernmost drift end	N236237
(2-27) southernmost drift end	N230944
(3-4E) easternmost drift end	E172309
(4-20) westernmost drift end	E170085

Source: BSC 2007 [DIRS 183743], Tables 2 to 5.

The total emplacement area is 6,004,074 m^2 (BSC 2003 [DIRS 165572], Table II-1) or ~6.0 km^2. For this analysis, a larger rectangular area containing the emplacement drifts is considered using original dimensions as follows.

North/South Length (L) (236237 m to 230944 m) = 5.3 km
East/West Width (W) (172309 m to 170085m) = 2.2 km
Approximate Area (A) 5.3 km × 2.2 km = 11.7 km^2

The measured distances are rounded upward to the nearest tenth of a kilometer, and the rounding is inconsequential because a rectangular repository area is used as a calculational simplification. Also, the repository length was extended by 0.1 km to account for the construction ramp location. Using the adjusted value of 5.4 km, the rectangular area is approximately 11.9 km^2. This is defined as the target area that represents the repository emplacement drifts and surrounding areas that could potentially be impacted by meteorites. Use of this rectangular target area with adjustments of lengths as simplifications to the repository footprint will result in a conservative overestimation of the repository emplacement area by a factor of about 2, which in turn will lead to a conservative overestimation of the meteorite impact probability.

D3 DEPTH AND THICKNESS OF THE PAINTBRUSH NONWELDED TUFF UNIT

The Paintbrush non-welded tuff (PTn) primarily consists of nonwelded to partially welded tuffs and extends from the base of the densely to moderately welded Tiva Canyon welded tuff (TCw) to the top of the Topopah Spring welded unit (TSw), which is densely welded (BSC 2004 [DIRS 170029], Table 6-2). It is stated in *UZ Flow Models and Submodels* (SNL 2007 [DIRS 184614], Section 6.2.2[a]) about the paintbrush (PTn) unit that:

> The PTn unit, as described by the current geological model, consists primarily of non- to partially welded tuffs. The dip of these layers is generally less than 10° to the east or southeast. The combined thickness of the PTn layers ranges from 150 m in the north of the model area to 30 m or less, even completely disappearing in several areas of the south. However, the PTn unit is present over the entire repository area, where the thickness of the PTn unit ranges from approximately 30 to 60 m, and it is even thicker to the north of the repository. The PTn unit as a whole exhibits very different hydrogeologic properties from the TCw and TSw units that bound it above and below. The TCw and TSw units have low porosity and intense fracturing typical of the densely welded tuffs at Yucca Mountain. In contrast, the PTn has high porosity and low fracture intensity, and its matrix

system has a large capacity for storing groundwater. It has been shown to effectively damp spatial and temporal variations in percolation flux.

The large storage capacity and low fracture frequency of the highly porous PTn unit may effectively dampen transient pulses of infiltration and more evenly distribute the downward flow of water. Geologic data indicate that the PTn ranges in thickness from greater than 125 m beneath northern Yucca Mountain to about 20 m in the south, with breaks in area coverage along the Solitario Canyon, Iron Ridge, and Dune Wash fault systems. The depth to the top of the PTn unit is shown in Figure D-2, the thickness of the PTn unit in Figure D-3, and the depth to the base of the PTn in Figure D-4. The repository underground layout incorporates a minimum PTn thickness of 10 m (BSC 2008 [DIRS 183627], Table 1, Parameter 01-21). Therefore, the meteorite impact on the PTn unit and thereby UZ flow and transport can be considered insignificant if one of the following conditions is met within the repository target area defined in Section D2:

(a) The overburden thickness above the PTn exceeds the exhumation or fracturing depth of the crater.

(b) The combined thickness of the PTn unit and the overburden above it exceeds the sum of the crater exhumation or fracturing depth plus 10 m that is required to maintain the effectiveness of the PTn unit in damping episodic infiltration pulses.

D4 CRATERING RATE DISTRIBUTIONS

D4.1 PROBABILITY OF IMPACT BASED ON INDIVIDUAL OBJECTS

Various authors have calculated the probability of entry of known individual interplanetary bodies into the earth's atmosphere. These probabilities are for any entry into the earth's atmosphere. However, the interest here concerns the cumulative probability of impact of all objects, not just for individual objects, so the following information is considered as corroborative-use only.

Chyba (1993 [DIRS 135248], Table 1a) addresses 12 objects with diameters of less than 55 m that have been observed to date. Excluding object 1991-VG (a suspected possible human artifact), the mean calculated probability of impact on the earth's atmosphere for the known bodies is 29 per gigayear, suggesting rates on the order of 3×10^{-8} per year, or on the order of 3×10^{-4} in 10,000 years (Chyba 1993 [DIRS 135248], p. 701) for the whole earth surface, and it is stated to be a factor of approximately seven greater than for other earth-crossing asteroids. Since impact is a spatially random process (Grieve 1987 [DIRS 135254], p. 257), dividing this value by the surface area of the earth (5.1×10^{8} km^2), and multiplying by the maximum area of the repository footprint (approximated by a 12 km^2 rectangular area; see Section D2), yields a probability of impact above the repository on the order of 10^{-15} per year, or approximately 10^{-11} in 10,000 years.

Marsden and Steel (1994 [DIRS 129308], p. 235, Figure 4) provide the calculated atmospheric entry probabilities, defined as crossing within 0.1 to 1 astronomical unit (AU) (1 AU = 149,598,000 km) of earth's orbit, for all observed long-period comets (i.e., orbit duration of greater than 200 years). The greatest calculated probability is 2.6×10^{-7} per orbit (Marsden and Steel 1994 [DIRS 129308], Figure 4) and the estimated mean impact probability is 2×10^{-9} to 3×10^{-9} per orbit (Marsden and Steel 1994 [DIRS 129308], Table V). Dividing by the minimum orbital period of 200 years (by definition of a long-period comet) yields a maximum probability of approximately 1.3×10^{-11} per year, or on the order of 10^{-7} in 10,000 years for the whole earth. If one neglects atmospheric shielding effects, the probability of impact above the repository can be estimated by dividing the probability by 5.1×10^{8} km^2, the approximate surface area of the earth, and multiplying by the maximum repository area (12 km^2). This yields a maximum probability of approximately 3.1×10^{-19} per year or about 3.1×10^{-15} in 10,000 years.

The probability of the impact of any individual known object is, therefore, at least ten or eleven orders of magnitude less than the regulatory threshold of an annualized event frequency of about 10^{-8} or, more specifically, a probability of 10^{-4} in 10,000 years. Thus, cratering from these objects is not considered in the crater impact analysis.

D4.2 CRATERING RATE DISTRIBUTIONS FROM EARTH AND LUNAR OBSERVATIONS

The FEP screening considers the cratering rate distributions derived from Grieve et al. (1995 [DIRS 135260]), which are based on world-wide cratering information (Section D4.2.1). It also considers the distribution from Wuschke et al. (1995 [DIRS 129326]), which is based on

cratering of the Canadian shield, and serves as a "realistic case" (Section D4.2.2). In addition, the analysis examines the distribution proposed by Neukum and Ivanov (1994 [DIRS 121510]), which is based on lunar cratering data (Section D4.2.3). Because the Neukum and Ivanov distribution was developed assuming an "atmosphereless earth," it serves as an upper bound for earth cratering. However, this distribution is only used for corroboration purposes, as it is unrealistic to expect that the atmosphere has no effect on the cratering distribution.

D4.2.1 Crater Diameter Frequency Distributions

Existing distributions in the literature are stated, generally, to apply to crater diameters on the scale of kilometers, rather than within the primary range of interest for this analysis (79 to 625 m as discussed in Section D4.3.2). Accordingly, this analysis develops a cratering distribution applicable to the smaller diameter range. This flux-derived distribution is developed based on meteoroid flux, meteoroid properties, and on meteoroid radius to crater diameter relationships (Section D4.2.4).

An applicable cumulative cratering rate (and one commonly used for these types of analyses) can be derived from a power law derived by Grieve and Robertson (1984 [DIRS 185030], Abstract), and Grieve (1987 [DIRS 135254], p. 257 and Figure 8). The cumulative number of impact craters, $F(D)$, larger than a crater of diameter D, (in units of km), produced per year per square km, can be represented by a power law proportional to the apparent crater diameter to the k power (Grieve 1987 [DIRS 135254], p. 257 and Figure 8):

$$F(D) = K \times D^k \qquad \text{(Eq. D-1)}$$

The value for K can be derived by fixing $F(D)$ at 5.5×10^{-15} per km^2 per year for D = 20 km (Grieve et al. 1995 [DIRS 135260], p. 196). Thus:

$$F(20) = K(20)^{-1.8} = 5.5 \times 10^{-15}\ (1/\text{km}^2\text{-yr}) \qquad \text{(Eq. D-2)}$$

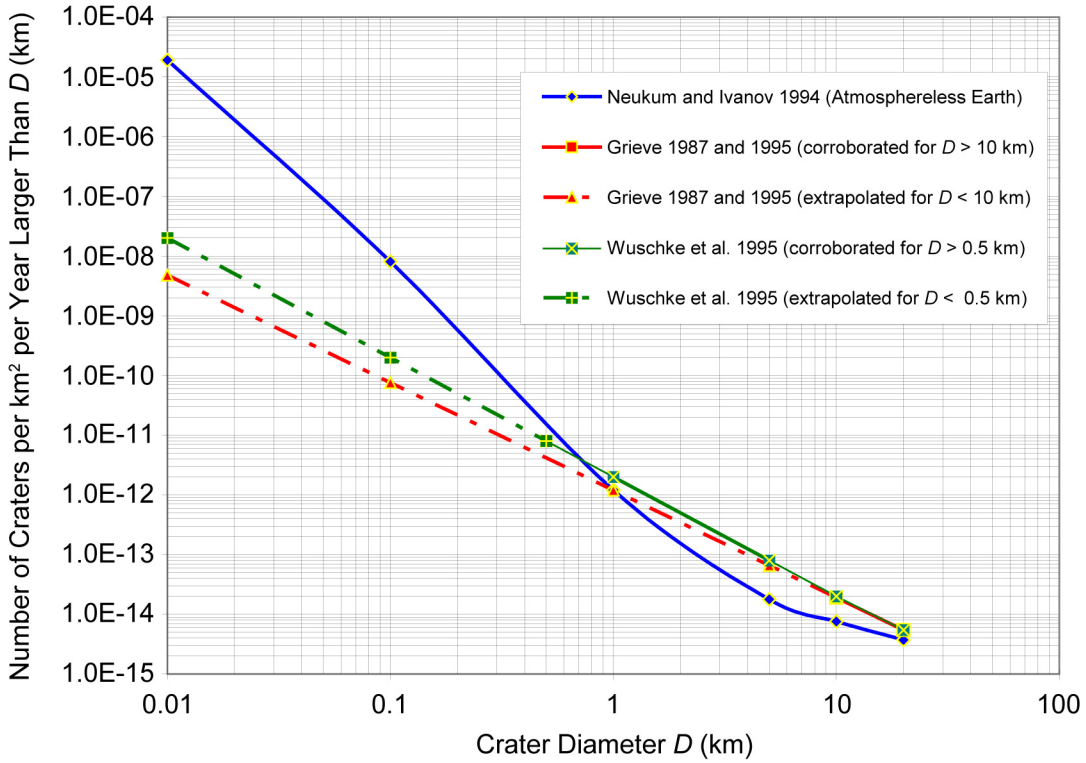
which gives a value of 1.2×10^{-12} for K, and giving the equation for the cumulative number of craters per year per km^2 with diameters larger than D as

$$F(D) = 1.2 \times 10^{-12} \times D^{-1.8} \qquad \text{(Eq. D-3)}$$

The given proportionality ($D^{-1.8}$) applies for earth crater diameters greater than 10 km, per analysis by Neukum and Ivanov (1994 [DIRS 121510], p. 404). The departure of the cumulative size-frequency distribution from the proportionality below diameters of 10 km is shown in Figure 8 of Grieve (1987 [DIRS 135254], p. 257). The slope change represents a decreased number of small crater observations, which indicates a shortage of known craters (Grieve 1987 [DIRS 135254], Figure 8) due to recognition and crater retention problems.

Using a repository emplacement area of no greater than 11.9 km^2, the cratering diameter of interest is that associated with a probability of $1 \times 10^{-8}/11.9 = 8.4 \times 10^{-10}$/km^2/yr (i.e., the regulatory threshold for consideration). From Equation D-3, this gives a crater diameter of no more than 30 m.

The respective distributions based on observed earth and lunar cratering are shown in Figure D-5 where Equation D-3 is extrapolated back to a crater diameter of 0.01 km. Given the distribution of crater diameters by Grieve (1998 [DIRS 163385], Figure 8), it is conservative (in relation to observed craters) to extend the distribution to smaller diameters, which overstates the number of craters used in this analysis compared to the actual number observed to date.



Source: Neukum and Ivanov 1994 [DIRS 121510]; Grieve 1987 [DIRS 135254]; Grieve et al. 1995 [DIRS 135260]; and Wuschke et al. 1995 [DIRS 129326].

Figure D-5. Cratering Rate Distribution from Four Sources

D4.2.2 Wuschke et al. (1995)

A particular example of the use of Grieve's distribution and the consideration of exhumation and fracturing depths is presented by Wuschke et al. (1995 [DIRS 129326]). The analyses presented in this study was for a hypothetical depository deep in plutonic rock of the Canadian shield, located at least 500 m below ground surface with a total area of 4 km^2. The curve from Wuschke et al. (1995 [DIRS 129326]), if comparable to the information used by Hughes (1998 [DIRS 162562], p. 34), may only be valid down to diameters of 1 km. For Wuschke et al. (1995 [DIRS 129326], p. 4), the distribution is derived from subsets of the observed earth cratering distribution used by Grieve (1987 [DIRS 135254]), and is given as:

$$F(D) = 2.0 \times 10^{-12} D^{-2} \quad \text{(Eq. D-4)}$$

where D is km, and $F(D)$ in $1/km^2/yr$. This denotes a slightly steeper slope compared to Grieve (2.0×10^{-12} compared to 1.2×10^{-12}). Wuschke's approach results in a slightly decreased annual frequency for a 20-km diameter crater (5.0×10^{-15} per km^2 compared to the values from Grieve of 5.5×10^{-15} km^2). This difference is reflected in the plot in Figure D-5.

The findings of this study are presented in Table 1 of Wuschke et al. (1995 [DIRS 129326], p. 26) and provide the annual probability and cumulative probability for 10,000 years for meteorite impact events. The results indicate that the annualized probability of impact for the Canadian repository design sufficient to cause damage by exhumation and fracturing is approximately 7.6×10^{-12} to 6.5×10^{-11} per year, respectively. This is associated with crater diameters of 7.6 to 0.66 km for exhumation and fracturing, respectively. Given the parameters used for the hypothetical Canadian repository (area of 4 km^2 and depth of 500 m), the reported probabilities should be less than the probability of impact for the Yucca Mountain repository (depths greater than 200 m below the surface and total area not to exceed 11.9 km^2 (SNL 2007 [DIRS 179466], Table 4-1, Parameters 01-02 and 01-06)) for the same effects of exhumation and fracturing. For exhumation of the Yucca Mountain repository, the least frequent and maximum crater diameter that could cause such an event is a crater diameter of 2 km (i.e., 200 m/0.10), and the most frequent would be a crater diameter of 625 m (200 m/0.32). Based on Figure D-6, and using a siting area of 11.9 km^2, such events occur with annual frequencies on the order of 10^{-10}, or about an order of magnitude more frequently than for the hypothetical Canadian design. For fracturing to repository depth, the crater diameter of interest is 263 m (i.e., 200 m/0.76). This occurs, based on Figure D-6, with an annual frequency of on the order of 10^{-9}, and again this is more frequent than predicted for the Canadian repository as expected.

D4.2.3 Neukum and Ivanov (1994)

The plot of the Neukum and Ivanov (1994 [DIRS 121510]) information represents a true upper bound (i.e., an "atmosphereless" earth which neglects effects of ablation and fragmentation). Because it is unrealistic due to an "atmosphereless" earth, it is discussed for corroborative purposes only, but it also provides a true upper bound.

Neukum and Ivanov (1994 [DIRS 121510], Table IV) provide a tabulation of impact accumulation rates and mean time intervals between impacts for earth, based on lunar craters and adjusted for gravity differences. This table includes the mean interval between events with energies equal to or greater than that required to form a crater of a given diameter. The cumulative cratering rate (or frequency) of such events can be derived from the calculated mean intervals by using the inverse of the mean interval. The frequency per square kilometer of the earth's surface can be derived by dividing the frequency by the area of earth's surface. This curve represents an extreme upper bound for the cratering rate on earth in the range of crater diameters of interest as it accounts for gravity differences between the lunar and earth surfaces and includes data for small-diameter craters. It does not take into account atmospheric shielding effects, which are known to exist and are significant in reducing crater frequency and size. The data used in plotting Figure D-5 is given in Table D-3.

Given that the footprint area is no greater than 11.9 km^2 as previously mentioned, the cratering diameter of interest is that associated with an annualized probability of $8.4 \times 10^{-10}/km^2$ (i.e., $8.4 \times 10^{-10}/km^2$ multiplied by an area of 11.9 km^2 equates to an annualized probability of 1×10^{-8}).

Based on Figure D-5, this equates to a crater diameter of less than 200 m. Using the exhumation depth relationship mentioned above, such a crater diameter could result in exhumation depths greater than 20 m and less than 64 m, which are insufficient to exhume waste at the depth of the proposed repository (i.e., greater than 200 m below ground surface (SNL 2006 [DIRS 179466], Table 4-1, Parameter 01-06)) or to exhume significant portions of the Paintbrush hydrogeologic unit. With regard to fracturing, the depth could be as little as 70 m to as great as 150 m. These depths are insufficient to reach to the proposed repository depth, although the values may represent depths that are sufficient to fracture the Paintbrush nonwelded unit in certain portions of the repository area, depending on the choice of factors (0.3 or 0.76). However, it must be kept in mind that the stated values represent the "worst-case" model proposed in the literature for exhumation and fracturing, coupled with the "upper bound" for crater diameter distribution. They are not realistic in that they are based on an "atmosphereless" earth.

D4.3 PROBABILITY OF A CRATER DIAMETER OF INTEREST OCCURRING WITHIN THE REPOSITORY TARGET AREA

Figure D-5 represents the range of possible frequencies of impacts resulting in a given or larger crater diameter per km^2. All frequency curves fall below the Neukum and Ivanov curve. This is to be expected since the curve derived from Neukum and Ivanov (1994 [DIRS 121510], Table IV) is based on the lunar cratering rate and neglects any atmospheric shielding effects. The relationship of the Neukum and Ivanov curve to the other curves shows that the Neukum and Ivanov curve is an upper bound within the range of interest. As discussed below, the bounding nature is used to divide the mass flux curves and to define the related coefficients and integration limits for those curves. The Neukum and Ivanov curve is not further used in the probability calculations, since it would unrealistically overestimate the frequency of occurrence.

D4.3.1 Simple and Complex Cratering

The amount of meteor kinetic energy acting in combination with the impacted rock properties determines the features, shape, size, and depth of any crater and any related cratering effects such as fracturing. The potential consequences are divided at the first level based on two types of observed cratering. Simple craters consist of an elevated rim and central depression. Complex cratering involves the uplift and significant vertical displacement of the central portion of the crater. Complex cratering can be initiated with crater diameters of 2 km in sedimentary rocks; however, terrestrial simple craters may also exhibit crater diameters up to 4 km, which is the threshold for simple-to-complex cratering in crystalline rocks based on the direct inputs justified for use in Section D6 (Grieve 1987 [DIRS 135254], p. 249; Grieve et al. 1995 [DIRS 135260], p. 194; Wuschke et al. 1995 [DIRS 129326], p. 3). The threshold for FEP screening based on probability is stated as an annualized equivalence of 10^{-8} events per year for the repository area (Section D1). Based on the cratering rate distributions given in Figure D-6, a 2-km crater diameter occurs at a frequency of approximately 10^{-10} or less per year, which is two orders of magnitude less frequent than the threshold for consideration. Consequently, complex cratering features, which can onset at a crater diameter of 2 km, do not occur with sufficient frequency to be of concern for FEP screening. Because such large diameter craters are very unlikely events, complex cratering is not further considered in the FEP analysis.

D4.3.2 Derivation of Cratering Distributions Adjusted for Target Area

The target area is initially assumed rectangular in shape, with the dimensions described in Section D2. However, if a meteorite were to impact exterior to the repository boundary, but within one-half of the crater diameter from the boundary, the repository could still potentially be affected. This affects the boundaries on each side of the repository. Assuming fracturing and exhumation effects are cylindrical below the entire crater, the target area can be expressed as:

$$\text{Area (A)} = (L + (2 \times D/2))(W + (2 \times D/2)) = (L+D)(W+D) \qquad \text{(Eq. D-5)}$$

Equation D-5 further simplifies to:

$$\text{Area (A)} = LW + (L+W)D + D^2 \qquad \text{(Eq. D-5a)}$$

where:

L	=	length of target area (km)
W	=	width of target area (km)
D	=	diameter of crater (km)

Starting with Equation D-1, the overall annual probability of meteorite impacts that could disrupt or fracture the repository is given by the product of the frequency of impact and the target area integrated over the range of possible crater diameters:

$$P(D) = \int F(D)\, A\, dD \qquad \text{(Eq. D-6)}$$

From Equations D-2 and D-5a and with k equaling the power of the distribution for a given meteorite crater distribution:

$$P(D) = \int (-k\, K\, D^{k-1})\, (LW + (L+W)\, D + D^2)\, dD \qquad \text{(Eq. D-7)}$$

By removing the constants k and K and using the additive properties of integrals and exponents, the resulting integral is in the form of $\int u^n\, du$

$$P(D) = -k\, K \int (LWD^{k-1} + (L+W)D^k + D^{k+1})\, dD \qquad \text{(Eq. D-7a)}$$

Equation D-7a simplifies to:

$$Pf(D) = -kK\left(\frac{LWD^k}{k} + \frac{(L+W)D^{k+1}}{k+1} + \frac{D^{k+2}}{k+2}\right)\Bigg|_{D\,\min}^{D\,\max} \qquad \text{(Eq. D-7b)}$$

where:

P(D)	=	frequency of meteorite impacts per year capable of creating crater of diameter D
K	=	the proportionality constant
k	=	power of the distribution
L	=	length of the repository (km)
W	=	width of the repository (km)
D	=	diameter of the crater (km).

The lower limit (D_{min}) to the integral is assumed to be 0.001 km (1 m), based on the need to capture very small crater diameters. The choice is arbitrary based on the possible scale of interest, and larger or smaller values could have been chosen. The upper limit (D_{max}) was set at 100 km, which is on the order of the largest recognized crater diameter on the earth's surface. The choice for an upper limit value only affects the shape and magnitude of frequency curves for the largest values of the crater diameters.

D4.3.3 Calculation of Cratering Distribution for the Repository Target Area

Equation D-7b is applied below to calculate the cratering probability distribution for the target area for the Grieve (1987 [DIRS 135254]) distribution (Section D4.2.1) and the Wuschke et al. (1995 [DIRS 129326]) distribution (Section D4.2.2). For the Grieve (1987 [DIRS 135254]) distribution, the value for *k* is –1.8 and the value for K is 1.2×10^{-12}, as shown in Equation D-2. Table D-3 provides the annual probability calculations for cratering above the repository for the repository target area. The results are shown in Figure D-6, which indicates that for a threshold probability of 10^{-8} events per year, the diameter of the largest crater is estimated to be conservatively less than 60 m.

D4.3.4 Exhumation Depth within the Target Area

D4.3.4.1 Relationship Exhumation Depth and Crater Diameter

A range of exhumation depth-to-crater diameter ratios of 0.10 to 0.33 is assumed in this appendix, and a value of 0.32 based on Wuschke et al. (1995 [DIRS 129326], Figure 1) and 0.28 from Grieve (1998 [DIRS 163385], p. 113).

D4.3.4.2 Estimation of Exhumation Depth within the Target Area

For a maximum crater diameter of 60 m that corresponds to a cratering probability of 10^{-8} within the target area (Section D4.3.3), the exhumation depth ranges from 6 to 20 m, given an exhumation depth-to-crater diameter ratio of 0.10 to 0.33 as described above. Because the overburden thickness above the repository within the target area is at least 200 m as discussed in Section D2 (see also SNL 2007 [DIRS 179466], Table 4-1, Parameter 01-06), the probability of waste exhumation from cratering is less than 10^{-8} within the target area.

D4.3.5 Estimation of Fracturing Depth within the Target Area

D4.3.5.1 Relationship Fracturing Depth and Crater Diameter

The fracturing depth-to-crater diameter ratios assumed in this appendix ranges from 0.33 to 0.76 based on values of 0.75-0.76 (Wuschke et al. 1995 [DIRS 129326], Section 2.2 and Figure 1). Because the intended use is for the FEP screening, the conservative value of increased fracturing depth to 0.76 of the crater diameter, as indicated by Wuschke et al. (1995 [DIRS 129326]), is used to ensure that the range of uncertainty in this relationship is covered.

The use of this value based on effects in plutonic rock is somewhat contrary to the observation made by Grieve (1998 [DIRS 163385], p. 113) that depths in sedimentary rocks tend to be shallower than in plutonic rock. However, the use of these values is consistent with use of cratering rate and crater diameter distributions from these same sources.

D4.3.5.2 Estimation of Fracturing Depth within the Target Area

For a maximum crater diameter of 60 m that corresponds to a cratering probability of 10^{-8} per year within the target area (Section D4.3.3), the fracturing depth ranges from about 20 to 45 m, given a fracturing depth–to–crater diameter ratio of 0.33 to 0.76 as described in Section D4.3.5.1. Because the distance overburden thickness above the repository within the target area is at least 200 m as given in *Total System Performance Assessment Data Input Package for Requirements Analysis for Subsurface Facilities* (SNL 2007 [DIRS 179466], Table 4-1, Parameter 01-06), the probability of waste exhumation from cratering is less than 10^{-8} within the target area. Fracturing depths of less than 45 m would not affect infiltration into the repository because they are too shallow to reach the top of the PTn over most of the repository area. Figure D-2 shows that with the exception of the northwestern- and northern-most tip of the repository where the PTn outcrops, the distance to the top of the PTn is at least 60 m. In these northern areas with a lesser distance between the ground surface and the PTn, the PTn itself is more than 90 m thick (Figure D-3). Therefore, the PTn unit would maintain its original thickness (Figure D-4) even after the impact of a maximum-penetration cratering event that corresponds to the 10^{-8} annualized exceedance probability, and will continue to meet the 10-m thickness requirement set forth in the selection of the repository layout (BSC 2008 [DIRS 183627], Table 1, Parameter 01-21) that ensures that the unit will remain effective in damping the episodic infiltration transients (see excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). The fracturing of the PTn can, therefore, be excluded based on low probability because the probability of fracturing the PTn to less than 10 m thick is less than 10^{-8} per year.

Table D-3. Annual Frequency of Cratering above Repository for TSPA-LA Emplacement Area

Figure D-6. Annualized Frequency of Cratering above the Repository for the Target Area

D5. CONCLUSIONS

The probability of the occurrence of crater diameters of interest (i.e., the diameters that define whether the repository is affected by direct exhumation, fracturing to repository depth, or fracturing of other overlying units of interest) is compared to the FEP screening threshold diameter of one chance in 10,000 of occurring in 10,000 years (or an annualized occurrence of 10^{-8}). If the probability of occurrence is less than this threshold, the effect can be excluded from further consideration in TSPA.

The above analysis shows that at an annualized probability of 10^{-8} (the FEP screening probability threshold), the corresponding crater diameter resulting from impact of the largest meteor fragment is less than 60 m (Figure D-6).

As discussed in Section D4.3, the probability of the formation of such craters within the repository target area sufficient to result in exhumation to the depth of the repository falls below the regulatory criterion of 10^{-8} per year. Likewise, maximum fracturing induced by a threshold cratering event will not be sufficient to reduce the thickness of the PTn unit to less than 10 m, which is the requirement set forth in the selection of the repository layout (BSC 2008 [DIRS 183627], Table 1, Parameter 01-21) to ensure that the unit is effective in damping the episodic infiltration transients (see excluded FEP 2.2.07.05.0A (Flow in the UZ from Episodic Infiltration)). Significant fracturing of the PTn can, therefore, be excluded based on low probability because the probability of reducing the PTn to a thickness of less than 10 m is less than 10^{-8} per year.

Smaller crater diameters occur more frequently, but these are of insufficient size to result in direct exhumation or fracturing to the depth of the repository and are excluded based on low consequence. Larger crater diameters occur less frequently and are less probable than the exceedance probability, and are therefore excluded from the TSPA as low probability events. Effects on infiltration due to changes in ecological factors due to small meteor craters or the effects of a near-surface explosion associated with a meteorite are also excluded based on low consequence because such events would likely have only transient effects or have no means of affecting the subsurface postclosure repository (see also excluded FEPs 1.4.03.00.0A (Unintrusive Site Investigation) and 1.5.01.02.0A (Extraterrestrial Events)). A modern example of a site in which the ecology has recovered is the Tunguska site in Siberia.

Meteors that result in crater diameters of 60 m (corresponding to the threshold annual probability of 10^{-8}) could trigger earthquakes with Richter magnitudes ranging from Magnitude 5 to slightly less than Magnitude 7 (Hills and Goda 1993 [DIRS 135281], Figure 18). Existing seismic analyses cover this range of magnitude (CRWMS M&O 1998 [DIRS 103731], Section 4). Therefore, an earthquake caused by meteorite impact is excluded based on low consequence because it would not provide a significant contribution to the overall earthquake hazard. Earthquake hazards are already included and probabilistically weighted in the TSPA. The effects of changes in rock stress, such as those caused by seismic activity, are addressed in multiple FEPs such as excluded FEPs 2.2.06.01.0A (Seismic Activity Changes Porosity and Permeability of Rock), 2.2.06.02.0A (Seismic Activity Changes Porosity and Permeability of Faults), and 2.2.06.02.0B (Seismic Activity Changes Porosity and Permeability of Fractures).

Because percolation is not significantly affected and no fracturing occurs down to the repository depth, with no associated waste exhumation, there is no mechanism for a meteorite impact at the threshold annual probability or greater to affect groundwater flux through the repository horizon. Therefore, the dose and release of radionuclides are not significantly changed.

Based on the preceding discussion, meteorite impact is excluded from the performance assessment conducted to demonstrate compliance with proposed 10 CFR 63.311 and 10 CFR 63.321 (70 FR 53313 [DIRS 178394]), and with 10 CFR 63.331 [DIRS 180319], on the basis of low probability for exhumation and fracturing to repository depth and to the PTn unit within the repository target area.

D6 DATA QUALIFICATION

This section provides the data qualification for unqualified external sources used as direct input only for the screening analysis of FEP 1.5.01.01.0A (Meteorite Impact) in this appendix. Data qualifications are performed in accordance with SCI-PRO-005, *Scientific Analyses and Calculations*.

D6.1 DATA FOR QUALIFICATION

There are six external sources of data used as direct input for this screening analysis listed in Table D-4.

D6.1.1 Qualification Method

The data to be evaluated have been extracted from non-YMP-specific sources and will be qualified for intended use. The method for qualification of the six external sources of data is the technical assessment method (SCI-PRO-001, Attachment 3, Method 5. The rationale for using this method is that it is the most suitable considering the methodology, data acquisition or development results, and use in similar applications are applicable. Qualification process attributes used in the technical assessment of each external source are selected from the list provided in Attachment 4 of SCI-PRO-001. Attributes specifically applicable as data qualification attributes in this appendix are:

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical)

Table D-4. Data Sets for Use within this Technical Product

Item	Source	Description of Direct Input	Summary of Source
1	Grieve and Robertson 1984 [DIRS 185030]	Power law for distribution for terrestrial craters Abstract, p. 231	Introduction of a size-frequency power law relationship for analyzing terrestrial and lunar crater diameters. This power law was further improved and used in later publications concerning crater impacts.
2	Grieve 1987 [DIRS 135254]	Use of a power law for cratering rate distribution based on observed earth cratering and threshold size for onset of complex cratering. pp. 248 and 257, Figure 8	This is a seminal work in the area of impact cratering and lists observed craters, crater characteristics, and cratering rates. The paper provides relationships of crater diameter to crater depth and provides a cratering rate estimate for large-diameter craters that are generally used in hazard estimates. This paper was taken from a peer-reviewed journal. The documentation is somewhat limited, but is generally accepted as reliable.
3	Grieve et al. 1995 [DIRS 135260]	Crater rate distribution based on observed earth cratering. pp. 194 to 196	This is an update to the 1987 paper by the primary author. It provides updated cratering information, defines the constants, and addresses the limits for simple and complex cratering. This paper was taken from a technical journal. Acknowledgments are given to peer-reviewers on an earlier version of the document. This paper provides a listing of observed cratering impact structures and their diameters and ages, allowing independent confirmation of the developed distribution. A thorough reference list is also provided.
4	Grieve 1998 [DIRS 163385]	Crater diameter to depth of effect relationships. Depth of exhumation is approximately 0.28 times the crater diameter. p. 113, Figure 8	This is an update and summary of previous papers and summarizes the results of studies to date, and provides a distinction of the cratering effect data based on craters in sedimentary and crystalline materials. This paper is focused on updating the “state of knowledge” regarding the number of craters, cratering mechanics, shock metamorphism, and effect of impacts on biological evolution. This paper was taken from a compendium addressing flux with time and impact effects. An extensive reference list is provided.
5	Hills and Goda 1993 [DIRS 135281]	Earthquake magnitudes due to a meteoroid impact range from magnitude 5 to slightly less than magnitude 7 on the Richter scale. Figure 18	This paper focuses on evaluating effects of small asteroids impacting the Earth. The paper provides a relationship between crater diameters and earthquake energy. This paper was taken from a peer-reviewed journal. Los Alamos National Laboratory prepared the work, and the development of the models is well documented and supporting equations are provided. No information is provided on quality control or development procedures
6	Wuschke et al. 1995 [DIRS 129326]	Spatial relationships of crater diameter to extents and depth of fracturing and exhumation. p. 3 Spatial extent of fracturing is assumed to be spherical. Figure 1 Cratering rate data for the Canadian shield and application to a hypothetical Canadian repository. pp. 4 and 26	This paper is directly applicable as it presents a well-documented evaluation equivalent to the evaluation needed for the YMP. The paper provides a detailed analysis of the hazard and risk associated with meteorite impact above an underground repository. Assumptions, spatial relationships, mathematical formulations, and uncertainty analysis are all documented within the report. This paper was prepared by AECL Research to evaluate risk from meteorite impact on a hypothetical underground repository. The paper reports results of a specific technical analysis. Citations are provided for all sources and uncertainty analyses are provided.

D6.1.2 Technical Assessment of External Data from Grieve 1987

The action taken to qualify the meteoroid impact data from "Terrestrial Impact Structures" (Grieve 1987 [DIRS 135254]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

> Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from "Terrestrial Impact Structures" (Grieve 1987 [DIRS 135254]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from "Terrestrial Impact Structures" (Grieve 1987 [DIRS 135254]):

> R.A.F. Grieve has been on the faculty for the Department of Geological Sciences at Brown University and a member of the Geophysics Division for the Geological Survey of Canada. These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Grieve for their intended use in this appendix.
>
> The report is a seminal work in the area of impact cratering and lists observed craters, crater characteristics, and cratering rates. The paper builds on earlier relationships of crater diameter to crater depth and provides a cratering rate estimate for large-diameter craters that are generally used in hazard estimates. This paper was taken from a peer-reviewed journal. The documentation is somewhat limited, but is generally accepted as reliable and has been updated on a periodic basis.

Based on the assessment made above, data from "Terrestrial Impact Structures" (Grieve 1987 [DIRS 135254]) are qualified for use as direct input for this appendix.

D6.1.3 Technical Assessment of External Data from Grieve and Robertson 1984

The action taken to qualify the meteoroid impact data from "The Potential for the Disturbance of a Buried Nuclear Waste Vault by a Large-Scale Meteorite Impact" (Grieve and Robertson 1984 [DIRS 185030]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from "The Potential for the Disturbance of a Buried Nuclear Waste Vault by a Large-Scale Meteorite Impact" (Grieve and Robertson 1984 [DIRS 185030]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from "The Potential for the Disturbance of a Buried Nuclear Waste Vault by a Large-Scale Meteorite Impact" (Grieve and Robertson 1984 [DIRS 185030]):

R.A.F. Grieve has been on the faculty for the Department of Geological Sciences at Brown University and a member of the Geophysics Division for the Geological Survey of Canada. P. B. Robertson has been a member of the Earth Sciences Branch of The Department of Energy, Mines and Resources for Ontario Canada. These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Grieve and Robertson for their intended use in this appendix.

The report introduces the size-frequency power law relationship for analyzing terrestrial and lunar crater diameters used in this appendix. This power law was further improved and used in later publications concerning crater impacts.

Based on the assessment made above, data from "The Potential for the Disturbance of a Buried Nuclear Waste Vault by a Large-Scale Meteorite Impact" (Grieve and Robertson 1984 [DIRS 185030]) are qualified for use as direct input for this appendix.

D6.1.4 Technical Assessment of External Data from Grieve 1998

The action taken to qualify the meteoroid impact data from "Extraterrestrial Impacts on Earth: The Evidence and the Consequences" (Grieve 1998 [DIRS 163385]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were

conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from "Extraterrestrial Impacts on Earth: The Evidence and the Consequences" (Grieve 1998 [DIRS 163385]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from "Extraterrestrial Impacts on Earth: The Evidence and the Consequences" (Grieve 1998 [DIRS 163385]):

R.A.F. Grieve has been on the faculty for the Department of Geological Sciences at Brown University and a member of the Geophysics Division for the Geological Survey of Canada. These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Grieve for their intended use in this appendix.

This report is an update and summary of previous papers and summarizes the results of studies to date, and provides a distinction of the cratering effect data based on craters in sedimentary and crystalline materials. This paper is focused on updating the "state of knowledge" regarding the number of craters, cratering mechanics, shock metamorphism, and effect of impacts on biological evolution.

Based on the assessment made above, data from "Extraterrestrial Impacts on Earth: The Evidence and the Consequences" (Grieve 1998 [DIRS 163385]) are qualified for use as direct input for this appendix.

D6.1.5 Technical Assessment of External Data from Hills and Goda 1993

The action taken to qualify the meteoroid impact data from "Fragmentation of Small Asteroids in the Atmosphere" (Hills and Goda 1993 [DIRS 135281]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from "Fragmentation of Small Asteroids in the Atmosphere" (Hills and Goda 1993 [DIRS 135281]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from "Fragmentation of Small Asteroids in the Atmosphere" (Hills and Goda 1993 [DIRS 135281]):

> J. G. Hills and M.P. Goda have been members of the Theoretical Astrophysics Group at Los Alamos National Laboratory. These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Hills and Gods for their intended use in this appendix.
>
> The report relates the earthquake energy level from a meteoroid impact as determined from the Richter scale to the impact crater diameter, thus providing a link to the repository seismic analyses.

Based on the assessment made above, data from "Fragmentation of Small Asteroids in the Atmosphere" (Hills and Goda 1993 [DIRS 135281]) are qualified for use as direct input for this appendix and FEP 1.5.01.01.0A (Meteorite Impact).

D6.1.6 Technical Assessment of External Data from Grieve et al. 1995

The action taken to qualify the meteoroid impact data from "The Record of Terrestrial Impact Cratering" (Grieve et al. 1995 [DIRS 135260]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

> Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from "The Record of Terrestrial Impact Cratering" (Grieve et al.1995 [DIRS 135260]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from "The Record of Terrestrial Impact Cratering" (Grieve et al.1995 [DIRS 135260]):

> R.A.F. Grieve has been on the faculty for the Department of Geological Sciences at Brown University and a member of the Geophysics Division for the Geological Survey of Canada. These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Grieve for their intended use in this appendix.
>
> This report is an update and summary of previous papers and summarizes the results of studies to date, and provides a distinction of the cratering effect data based on craters in sedimentary and crystalline materials. This paper is focused on updating the "state of knowledge" regarding the number of craters, cratering mechanics, shock metamorphism, and effect of impacts on biological evolution.

Based on the assessment made above, data from "The Record of Terrestrial Impact Cratering" (Grieve et al. 1995 [DIRS 135260]) are qualified for use as direct input for this appendix and FEP 1.5.01.01.0A (Meteorite Impact).

D6.1.7 Technical Assessment of External Data from Wuschke et al. 1995

The action taken to qualify the meteoroid impact data from *Assessment of the Long-Term Risk of a Meteorite Impact on a Hypothetical Canadian Nuclear Fuel Waste Disposal Vault Deep in Plutonic Rock* (Wuschke et al. 1995 [DIRS 129326]) is from SCI-PRO-001, Attachment 3, Method 5(b) as follows:

> Determination that confidence in the data acquisition or developmental results is warranted. A discussion and justification that the data acquisition and/or subsequent data development (e.g., reduction or extrapolation) discussed in source documentation was appropriate for the type of data under consideration. This could include assurances that processes were conducted by qualified professionals; data were collected under proper environmental conditions; collected results and/or data development are appropriate, reasonable, and suitable for their intended use; etc.

The following criteria were used to assess the external data from *Assessment of the Long-Term Risk of a Meteorite Impact on a Hypothetical Canadian Nuclear Fuel Waste Disposal Vault Deep in Plutonic Rock* (Wuschke et al. 1995 [DIRS 129326]):

1. Qualifications of personnel or organizations generating the data are comparable to qualification requirements of personnel generating similar data under an approved program that supports the YMP license application process or postclosure science.

2. The extent to which the data demonstrate the properties of interest (e.g., physical, chemical, geologic, mechanical).

Justification for the appropriate use of data from *Assessment of the Long-Term Risk of a Meteorite Impact on a Hypothetical Canadian Nuclear Fuel Waste Disposal Vault Deep in Plutonic Rock* (Wuschke et al. 1995 [DIRS 129326]):

D.M. Wuschke, S.H. Whitaker, B.W. Goodwin, and L.R. Rasmussen have been staff members of Atomic Energy of Canada, Limited (AECL). These associations demonstrate an appropriate technical level of competence for qualification of publications authored by Hills and Gods for their intended use in this appendix.

This paper is directly applicable as it presents a well-documented evaluation equivalent to the evaluation needed for YMP. The paper provides a detailed analysis of the hazard and risk associated with meteorite impact above an underground repository. Assumptions, spatial relationships, mathematical formulations, and uncertainty analysis are all documented within the report.

Based on the assessment made above, data from *Assessment of the Long-Term Risk of a Meteorite Impact on a Hypothetical Canadian Nuclear Fuel Waste Disposal Vault Deep in Plutonic Rock* (Wuschke et al. 1995 [DIRS 129326]) are qualified for use as direct input for this appendix and FEP 1.5.01.01.0A (Meteorite Impact).

INTENTIONALLY LEFT BLANK

APPENDIX E

LOW CONSEQUENCE CALCULATION FOR RUPTURE OF DRIP SHIELD PLATES FROM SEISMIC-INDUCED ROCK BLOCK IMPACTS

E.1 PURPOSE

This calculation demonstrates that drip shield plate failures due to seismic-induced rock block impacts in the nonlithophysal units of the repository have low consequence for repository performance. This calculation supports the screening justification for excluded FEP 1.2.03.02.0B (Seismic-Induced Rockfall Damages EBS Components).

E.1.1 Scope

The scope of this calculation is limited to estimating the dose to the reasonably maximally exposed individual within the first 10,000 years after repository closure due to drip shield plate failures caused by seismic-induced rock block impacts in nonlithophysal units of the repository. This calculation does not address the performance of naval spent nuclear fuel during seismic events. This calculation also does not address the preclosure response of the drip shield to seismic-induced rockfall.

E.1.2 Limitation

The maximum dose from drip shield plate failures is estimated using the results from the drip shield early failure modeling case (SNL 2008 [DIRS 183478], Sections 6.4 and 6.4.1). The drip shield early failure modeling case assumes that a single drip shield and its associated waste package fail simultaneously. This approach overestimates the dose from drip shield plate failures from seismic-induced rock block impacts because it ignores the potential for a delay between the time that localized corrosion could occur and the time that the drip shield fails due to rock block impacts. As shown by the last term in Equation E-2, the dose estimate begins from t_{LC}, the earliest time that localized corrosion could occur. In actuality, no dose would be possible until after a seismic event occurs, which could be later than t_{LC} because both localized corrosion and a seismic event that causes the drip shield plates to fail are required for a release, as explained in Section E.6.1. The potential delay in releases for a seismic event that occurs after t_{LC} is not included in the dose estimate in Equation E-2.

E.2 QUALITY ASSURANCE

Calculations performed under the technical work plan (SNL 2007 [DIRS 184327], Section 4) are subject to the requirements of SCI-PRO-005, *Scientific Analyses and Calculations*.

E.3 USE OF SOFTWARE

No qualified software is used to perform this calculation.

As already indicated in Section 3, MathCad Version 13.1 (STN: 611161-13.1-00), running under the Microsoft Windows 2000 Professional operating system, has been used to perform the calculation documented in this appendix. The standard features of MathCad are sufficient for these calculations. No macros, codes, or software routines are required for or developed during this work. As used here, MathCad Version 13.1 is not required to be qualified or documented in accordance with IM-PRO-003, *Software Management*. The formulas, inputs to the formulas, and outputs from the formulas in the MathCad calculation are identified in this appendix and in the MathCad file.

All MathCad files that are relevant for the calculation are included in output DTN: MO0707NONLITHO.000.

E.4 INPUTS

E.4.1 Direct Input

Table E-1 presents the direct input information for this calculation. The numerical values in Table E-1 are presented with the same number of significant figures and in the same units as the data in the source, unless otherwise noted. The technical product inputs identified in Table E-1 are appropriate for the development of a scientific analysis for the dose related to failures of drip shield plates in the nonlithophysal units of the repository.

E.4.2 Criteria

No criteria are specific to the calculation in this appendix.

E.4.3 Codes, Standards, and Regulations

No additional codes, standards, or regulations apply to the calculation in this appendix.

Table E-1. Direct Inputs for Appendix E

Input Data or Information	Value	Source
Bounded hazard curve at the emplacement drifts	See Table 1-1 or parameter PGV in Table 1-15 in the DTN	DTN: MO0703PASEISDA.002 [DIRS 183156], file: *Seismic Damage Abstractions for TSPA Compliance Case.doc*
Maximum annual exceedance frequency on the bounded hazard curve	4.287×10^{-4} per year	DTN: MO0703PASEISDA.002 [DIRS 183156], Step 2 or parameter LAMBDA_MAX in Table 1-15 in file: *Seismic Damage Abstractions for TSPA Compliance Case.doc*
Minimum annual exceedance frequency on the bounded hazard curve	10^{-8} per year	DTN: MO0703PASEISDA.002 [DIRS 183156], Step 2 or parameter LAMBDA_MIN in Table 1-15 in file: *Seismic Damage Abstractions for TSPA Compliance Case.doc*
Probability of damage to the drip shield or failure of the drip shield plates from seismic-induced rock block impacts in the nonlithophysal units	Values are tabulated in the DTN	DTN: MO0703PASEISDA.002 [DIRS 183156], Table 1-10 or parameter PD_DSNL in Table 1-18 in file: *Seismic Damage Abstractions for TSPA Compliance Case.doc*
Probability of the number of drip shields with failed plates from seismic-induced rock block impacts in the nonlithophysal units. This probability is conditional on the occurrence of drip shield damage or drip shield plate failures.	Values are tabulated in the DTN	DTN: MO0703PASEISDA.002 [DIRS 183156], Table 1-11 or parameters: PD_DSNL-STATE1, PD_DSNL_STATE2, PD_DSNL_STATE3, PD_DSNL_STATE4, and PD_DSNL-STATE5 in Table 1-18 in file: *Seismic Damage Abstractions for TSPA Compliance Case.doc*
Mean corrosion rate for Titanium Grade 7 under aggressive conditions, which applies to the top side of the drip shield plates	46.1 nm/yr	DTN: SN0704PADSGCMT.001 [DIRS 182122], Section 2 in file: *TSPA Implementation_DS GC Model.pdf*

Table E-1. Direct Inputs for Appendix E (Continued)

Input Data or Information	Value	Source
Mean corrosion rate for Titanium Grade 7 under benign conditions, which applies to the bottom side of the drip shield plates	5.15 nm/yr	DTN: SN0704PADSGCMT.001 [DIRS 182122], Section 3 in file: *TSPA Implementation_DS GC Model.pdf*

Dose time histories for the drip shield early failure modeling case	See file in DTN for data	DTN: MO0709TSPAREGS [DIRS 182976], file: *LA_v5.000_ED_003000_007_Dose_Total.txt*

Table E-1. Direct Inputs for Appendix E (Continued)

Input Data or Information	Value	Source
Expected annual dose for the drip shield early failure modeling case for 1,000,000 years after repository closure	Dose gradually decreases during the 1,000,000-year period	SNL 2008 [DIRS 183478], Figure 8.2-3(b)[a]
Expected annual dose for the seismic ground motion modeling case for 10,000 years after repository closure	See Table E-3 for numerical values from Figure 8.2-11(a)[a]	SNL 2008 [DIRS 183478], Figure 8.2-11(a)[a]
Expected annual dose for the seismic ground motion modeling case for 1,000,000 years after repository closure	0.1 to 1 mrem	SNL 2008 [DIRS 183478], Figure 8.2-11(b)[a]
Maximum duration of localized corrosion	12,000 years	SNL 2008 [DIRS 183478], Section 6.3.5.2.3

E.5 ASSUMPTIONS

Several supporting documents identify assumptions that are relevant to this calculation:

- Assumption 5.2, Randomness of Seismic Events, from *Seismic Consequence Abstraction* (SNL 2007 [DIRS 176828], Section 5.2) is relevant to this calculation.

- Assumptions 5.1, 5.3, 5.4, and 5.5 from *General Corrosion and Localized Corrosion of Waste Package Outer Barrier* (SNL 2007 [DIRS 180778], Sections 5.1, 5.3, 5.4, and 5.5) are relevant to the initiation, duration, and rate of localized corrosion on the outer corrosion barrier of the waste package.

- Sections 6.4.1.2 and 6.4.1.3 of *Total System Performance Assessment Model/Analysis for the License Application* (SNL 2008 [DIRS 183478]) describe the assumptions that are relevant to the drip shield early failure modeling case, which forms the basis for this low consequence analysis.

There are no additional assumptions for this calculation.

E.6 DISCUSSION

The following discussions address the technical approach, mathematical formulation, and the computational results of this analysis. A list of references used as indirect inputs is provided in Table E-2.

Table E-2. Indirect Inputs for Appendix E

E.6.1 Technical Approach

The dose from drip shield plate failures is estimated using the results of the drip shield early failure modeling case (SNL 2008 [DIRS 183478], Section 6.4). The drip shield early failure modeling case computes the dose that results from manufacturing defects or emplacement damage to drip shields. This modeling case simulates the effects of an early failure by removing a single drip shield as an impediment to seepage. If seepage occurs in a location with an early failed drip shield, the associated waste package is conservatively assumed to also be failed. Hence, the drip shield early failure modeling case describes the dose that may result if a drip shield and its associated waste package fail simultaneously.

The estimate of dose from drip shield plate failure accounts for the frequency of occurrence of rock block impacts in the nonlithophysal units, and the extent of ruptured drip shields caused by these impacts. Although the impacts may rupture the drip shield, the associated waste package is not expected to be breached from rock block impacts (SNL 2008 [DIRS 183478], Section 6.4.7.3). However, failure of the drip shield plates allows seepage to contact the waste package, potentially failing the waste package if localized corrosion initiates on the waste package outer corrosion barrier. This estimate considers localized corrosion as the process that may compromise the waste package subsequent to rupture of the drip shield plates. Other processes that affect the waste package outer corrosion barrier, such as damage from seismic ground motion, are not relevant because they are not altered by the rupture of the drip shield plates by rock block impacts.

The dose histories from the drip shield early failure modeling case (DTN: MO0709TSPAREGS.000 [DIRS 182976], file: *LA_v5.000_ED_003000_007_Dose_Total.txt*) are a function of the epistemic uncertainty in the TSPA model, the type of waste package that fails, and the seepage bin with the failed waste package. Each realization of the TSPA model has a unique "vector" of sampled values for random variables with epistemic uncertainty. There are a total of 300 epistemic vectors, denoted as $\mathbf{e}_i$ for i = 1, 2, 3, ..., 300, in the drip shield early failure modeling case (SNL 2008 [DIRS 183478], Section 7.3.1.2). The total number of epistemic vectors was selected to produce a stable mean dose, based on computational testing with the drip shield early failure modeling case. Each epistemic vector generates a total of 10 dose histories because the TSPA model has five repository percolation subregions (i.e., seepage bins) (DTN: LA0702PANS02BR.001 [DIRS 180322], file: README, second bullet under the heading: Repository Node Lists) with two different waste package types (SNL 2008 [DIRS 183478], Section 6.3.7) in each bin, for a total of 10 combinations.

These dose histories provide a basis for estimating the dose from tearing of drip shield plates due to large rock block impacts. Since the drip shield early failure modeling case computes the dose resulting from a single simultaneous failure of drip shield and waste package, the estimated dose must account for: (1) the number of drip shields damaged by the rock block impacts during a seismic event, (2) the timing of the seismic event relative to the occurrence of localized corrosion, (3) the two waste package types, and (4) the five repository percolation subregions (i.e., seepage bins). The first two factors are important because releases can only occur if the drip shield plates fail and if the associated waste package fails from localized corrosion. Stated differently, a seismic event that fails the drip shield plates must occur before or simultaneously with localized corrosion in order to have a radionuclide release. The type of waste package is important because it determines the radionuclide source term and the waste package temperature, which influences the timing of localized corrosion. The seepage bin is important because it determines, in part, the flow rates for radionuclide transport as well as influencing the chemistry of the seepage water and the waste package temperature.

E.6.2 Mathematical Formulation

Let $\overline{\overline{D}}_{NL}(\tau)$ denote the mean dose at time τ resulting from radionuclides released due to nonlithophysal rockfall induced by a seismic event. The quantity $\overline{\overline{D}}_{NL}(\tau)$ is estimated by:

$$\overline{\overline{D}}_{NL}(\tau) = \frac{1}{N}\sum_{i=1}^{N} \overline{D}_{NL}(\tau \mid \mathbf{e}_i) \qquad \text{(Eq. E-1)}$$

where $\overline{D}_{NL}(\tau|\mathbf{e}_i)$ is the expected dose at time τ due to nonlithophysal rockfall, conditional on a vector of samples values, $\mathbf{e}_i$, for epistemic uncertain parameters. The quantity $\overline{D}_{NL}(\tau|\mathbf{e}_i)$ is termed an expected dose because it is averaged over the aleatory uncertainty in the seismic events as well as the spatial variability between waste packages. The vectors $\mathbf{e}_i$ are determined by a Latin hypercube sample of size *N*. The value of *N* is 300 for this analysis.

The quantity $\overline{D}_{NL}(\tau|\mathbf{e}_i)$ is defined, in turn, as:

$$\overline{D}_{NL}(\tau|\mathbf{e}_i) = \sum_{p=1}^{2}\sum_{b=1}^{5} E\left(n_{LC}(p,b,\mathbf{e}_i)\right) \times D_{ED}(\tau - t_{LC}|1,p,b,\mathbf{e}_i) \qquad \text{(Eq. E-2)}$$

where:

$E\left(n_{LC}(p,b,\mathbf{e}_i)\right)$ is the expected number of waste packages of type p in bin b that fail due to drip shield plate failure and localized corrosion for the epistemic vector $\mathbf{e}_i$. The drip shield plate failures are the result of seismic-induced rock block impacts in the nonlithophysal units. These failures are a function of the intensity of the seismic event, measured as a function of horizontal peak ground velocity. The occurrence and timing of

localized corrosion is a function of the seepage bin. There are two waste package types, and five seepage bins in the TSPA model, which define the limits of the summations in Equation E-2.

$D_{ED}\left(\tau \middle| 1, p, b, \mathbf{e}_i\right)$ is the dose at time τ conditional on a single failed drip shield colocated with a failed waste package of type p in seepage bin b for the epistemic vector $\mathbf{e}_i$. This dose history is based on the results for the epistemic vector, $\mathbf{e}_i$, from the drip shield early failure modeling case (DTN: MO0709TSPAREGS.000 [DIRS 182976], file: *LA_v5.000_ED_003000_007_Dose_Total.txt*).

$t_{LC} = t_{LC}\left(p, b, \mathbf{e}_i\right)$ is the earliest time that localized corrosion is possible on a waste package of type p in bin b for the epistemic vector $\mathbf{e}_i$, based on DTN: MO0709TSPALOCO.000 [DIRS 182994], files:
LC_Initiation_Analysis_v2_CSNF_Bin1.TXT
LC_Initiation_Analysis_v2_CSNF_Bin2.TXT
LC_Initiation_Analysis_v2_CSNF_Bin3.TXT
LC_Initiation_Analysis_v2_CSNF_Bin4.TXT
LC_Initiation_Analysis_v2_CDSP_Bin1.TXT
LC_Initiation_Analysis_v2_CDSP_Bin2.TXT
LC_Initiation_Analysis_v2_CDSP_Bin3.TXT
LC_Initiation_Analysis_v2_CDSP_Bin4.TXT.

The term t_{LC} is necessary because localized corrosion requires seepage to be present, which may not occur until some time after repository closure. The inclusion of t_{LC} in $D_{ED}\left(\tau - t_{LC} \middle| 1, p, b, \mathbf{e}_i\right)$ shifts the beginning of radionuclide transport to the earliest time that localized corrosion could result in waste package failure. The use of the earliest time that localized corrosion is possible provides a conservative bias to the estimated dose because the seismic event that causes drip shield plate failure may occur after t_{LC}.

The term $E\left(n_{LC}\left(p, b, \mathbf{e}_i\right)\right)$ is estimated by:

$$E(n_{LC}(p,b,\mathbf{e}_i)) = \lambda_F \times T_{LC}(p,b,\mathbf{e}_i) \times (f_p \times f_b \times N_{WP} \times f_{NL}(b)) \times f_{LC}(p,b,\mathbf{e}_i) \quad \text{(Eq. E-3)}$$

where

λ_F is the frequency of drip shield failure due to rock block impacts caused by seismic events. This frequency is a calculated parameter in the MathCad file, based on 100,000 realizations

$T_{LC}(p,b,\mathbf{e}_i)$ is the latest time that localized corrosion could occur on a waste package of type p in bin b for epistemic vector $\mathbf{e}_i$, based on data in DTN: MO0709TSPALOCO.000 [DIRS 182994], files:
LC_Initiation_Analysis_v2_CSNF_Bin1.TXT
LC_Initiation_Analysis_v2_CSNF_Bin2.TXT
LC_Initiation_Analysis_v2_CSNF_Bin3.TXT
LC_Initiation_Analysis_v2_CSNF_Bin4.TXT
LC_Initiation_Analysis_v2_CDSP_Bin1.TXT
LC_Initiation_Analysis_v2_CDSP_Bin2.TXT
LC_Initiation_Analysis_v2_CDSP_Bin3.TXT
LC_Initiation_Analysis_v2_CDSP_Bin4.TXT.

$(f_p \times f_b \times N_{WP})$ is the total number of waste packages of type p in seepage bin b

f_p is the fraction of waste packages of type p in the inventory for the TSPA model, based on DTN: MO0702PASTREAM.001 [DIRS 179925], file: *DTN-Inventory-Rev00.xlsI*, worksheet: "UNIT CELL," cells: "G49 and K49"

f_b is the fraction of waste packages in seepage bin b

$f_{NL}(b)$ is the fraction of seepage bin b that is in the nonlithophysal units (DTN: MO0709TSPALOCO.000 [DIRS 182994], TSPA parameter: NonLith_Frac_CSNF_out)

$\boldsymbol{N_{WP}}$ is the total number of waste packages in the repository, based on DTN: MO0702PASTREAM.001 [DIRS 179925], file: *DTN-Inventory-Rev00.xlsI*, worksheet: "UNIT CELL," cells: G49 and K49

$f_{LC}(p,b,\mathbf{e}_i)$ is the maximum fraction of waste packages of type p in bin b on which localized corrosion may occur for epistemic vector $\mathbf{e}_i$.

Equation E-3 assumes that $\lambda_F \times T_{LC}$ represents the expected number of seismic events that cause drip shield failure and that can occur during the time when localized corrosion can occur. This is a conservative formulation because it assumes that localized corrosion can begin at time zero, rather than after rewetting occurs in percolation subregion *b*.

The MathCad calculation for λ_F, the frequency of drip shield failure due to rock block impacts, is a function of the following parameters: (1) the bounded hazard curve at the emplacement drifts, (2) the maximum and minimum annual exceedance frequencies on the bounded hazard curve, (3) the probability of damage/failure of the drip shield plates from seismic-induced rock block impacts in the nonlithophysal units, and (4) the conditional probability for the number of drip shields with failed plates from seismic-induced rock block impacts in the nonlithophysal units. These quantities are defined by Table 1-1, Step 2, Table 1-10, and Table 1-11, respectively, in DTN: MO0703PASEISDA.002 [DIRS 183156]. λ_F is also a function of the thickness of the drip shield plates as a function of time, based on mean corrosion rates for Titanium Grade 7 under aggressive and benign conditions (DTN: SN0704PADSGCMT.001 [DIRS 182122], Sections 2 and 3 in file: *TSPA Implementation_DS GC Model.pdf*) and the initial thickness of the plates (SNL 2007 [DIRS 179354], Section 4.1.2, Table 4-2, Parameter 07-04A).

E.6.3 Computational Results

Table E-3 presents the mean annual dose due to nonlithophysal rockfall, $\bar{\bar{D}}_{NL}(\tau)$, at 1,000, 2,000, 5,000, and 10,000 years. Table E-3 also presents the corresponding values for the seismic ground motion modeling case. The seismic ground motion modeling case represents the dose from damage to EBS components caused by vibratory ground motion and caused by rockfall induced in the lithophysal zones by vibratory ground motion. The mean annual dose due to nonlithophysal rockfall would be included as a component of the seismic ground motion modeling case if it is included in TSPA. A comparison of the mean annual doses from nonlithophysal rockfall and from the seismic ground motion modeling case is therefore appropriate for demonstrating low consequence.

Table E-3. Comparison of Mean Annual Dose Due to Nonlithophysal Rockfall with the Dose from the Seismic Ground Motion Modeling Case

Time after Repository Closure (years)	Mean Annual Dose – Nonlithophysal Rockfall (mrem)	Mean Annual Dose – Seismic Ground Motion Modeling Case (mrem)	Ratio of Nonlithophysal Rockfall Dose to Seismic Ground Motion Modeling Case Dose (%)
1,000	0.00098	0.002	49
2,000	0.00096	0.03	3.2
5,000	0.00037	0.1	0.37
10,000	0.00031	0.2	0.16

Sources: Output DTN: MO0707NONLITHO.000, file: *LA_v5_ED_003000_007_NL_LC_Dose.txt* for the nonlithophysal rock. Numerical values estimated from Figure 8.2-11(a)[a] in SNL 2008 [DIRS 183478] for the seismic ground motion modeling case.

A comparison of the ratios in Table E-3 demonstrates that: (1) the mean annual dose from the seismic ground motion modeling case is always greater than the estimated dose due to nonlithophysal rockfall; (2) at 1,000 years, the mean annual dose due to nonlithophysal rockfall is about 50% of the dose from the seismic ground motion modeling case, although the magnitude of the nonlithophysal-related dose is very small compared to the individual protection standard of 15 mrem during the first 10,000 years after closure (proposed 10 CFR 63.311(a)(1) [DIRS 178394]); and (3) after 2,000 years, the mean annual dose due to nonlithophysal rockfall is about 3% or less of the dose from the seismic ground motion modeling case. These results

indicate that the effects of nonlithophysal rockfall can be screened out of the performance assessment on the basis of low consequence to the seismic ground motion modeling case and to TSPA for the first 10,000 years after repository closure.

This same conclusion is valid for the period of geologic stability after repository closure because of the timing of localized corrosion and because the long-term dose from early dip shield failures is approximately constant. The timing of localized corrosion is important because a pathway for advective release through the EBS is only formed when the drip shield plates fail from seismic-induced nonlithophysal rockfall before or during a period when localized corrosion is active. In other words, a seismic event that causes plate failures after the period when localized corrosion is active will have no impact on dose because the waste package's outer corrosion barrier remains intact and can deflect seepage away from the waste form. As localized corrosion only occurs within the first 12,000 years after repository closure (SNL 2008 [DIRS 183478], Section 6.3.5.2.3), seismic events after this time will not affect the dose due to nonlithophysal rockfall. In addition, the expected dose for the drip shield early failure modeling case decreases gradually during the first 1,000,000 years after repository closure (SNL 2008 [DIRS 183478], Figure 8.2-3(b)[a]). The lack of new advective pathways after 12,000 years, and the gradual decrease in the expected annual dose for the drip shield early failure modeling case, means that the mean annual dose throughout the period of geologic stability that results from nonlithophysal rockfall within the first 12,000 years will remain less than or equal to its early-time maximum value of 0.001466 mrem at 1,240 years (output DTN: MO0707NONLITHO.000, file: *LA_v5_ED_003000_007_NL_LC_Dose.txt*) throughout the period of geologic stability.

The mean annual dose from the seismic ground motion modeling case varies between 0.1 and 1 mrem between 10,000 years and 1,000,000 years after repository closure (SNL 2008 [DIRS 183478], Figure 8.2-11(b)[a]). It follows that the mean annual dose from nonlithophysal rockfall is about 1% of the seismic ground motion modeling case (0.001466 mrem/0.1 mrem = 0.015) for the period from 10,000 years to 1,000,000 years after repository closure. This result indicates that the effects of nonlithophysal rockfall can be excluded from performance assessment on the basis of low consequence to the seismic ground motion modeling case during the period of geologic stability.

E.7 CONCLUSION

The effects of nonlithophysal rockfall on the drip shield can be excluded from the performance assessment on the basis of low consequence because the maximum mean dose from drip shield plate failures and seismic-induced nonlithophysal rockfall is a small fraction of the mean annual dose from seismic ground motion during the period of geologic stability.

The computational files and output from this calculation are documented in output DTN: MO0707NONLITHO.000.

APPENDIX F

CROSS-REFERENCE OF YMP LA FEPS TO INTERNATIONAL AND OTHER FEP DATABASES

F1. INTRODUCTION

As described in *Development of the Total System Performance Assessment-License Application Features, Events, and Processes* (BSC 2005 [DIRS 173800]), one of the major sources of FEP information was the list of FEPs in the Organisation for Economic Co-operation and Development database (OECD 2000 [DIRS 152952], Appendix D). During the process of analyzing FEPs for the TSPA-LA, each FEP contained in the OECD database (OECD 2000 [DIRS 152952], Appendix D) or identified from other sources (Freeze et al. 2001 [DIRS 154365], Tables 3 through 6) collectively referred to as "Source FEPs" was reviewed to determine if it had any possible relevance to the Yucca Mountain disposal system and, if it did, to ensure that it was addressed by one or more FEPs in the TSPA-LA FEP list. Version 2.1 of the OECD database (NEA 2006 [DIRS 185174]) was reviewed. It was determined that the FEPs introduced by the two new projects noted in Version 2.1 presented no additional scope beyond FEPs already addressed in the TSPA-LA FEP list. Details of this evaluation can be found in the Potential FEP Log in output DTN: MO0706SPAFEPLA.001.

Those FEPs in the OECD database (OECD 2000 [DIRS 152952], Appendix D) that addressed specific geographic features not located in the Yucca Mountain region (for example, specific geographic features of the Rhine river), were not included. However, those FEPs that addressed properties of specific features that could be applicable to similar features in the Yucca Mountain region were retained for consideration. The cross-referencing of FEPs between the OECD database (OECD 2000 [DIRS 152952], Appendix D) and the FEPs presented in this analysis report does not imply that there is an exact one-to-one or one-to-many correspondence among those FEPs.

The cross-referencing from TSPA-LA FEPs to Source FEPs (Table F-2) indicates that the TSPA-LA FEP addresses issues contained within the Source FEP(s). The cross-referencing from Source FEPs to TSPA-LA FEPs (Table F-3) indicates that the aggregate of all TSPA-LA FEPs tied to that specific Source FEP addresses all the major issues raised by the Source FEP.

These tables are provided to assist in demonstrating that the TSPA-LA FEP list is, in fact, both complete and comprehensive with respect to the source FEPs.

F1.1 DATA SOURCE

The information presented in Tables F-2 and F-3 is taken from the FEP Database output DTN: MO0706SPAFEPLA.001, tables: "FEPS," "SourceFEPs," and "FEPMapping NEAtoLA." The table "SourceFEPs" was imported directly from *Features, Events, and Processes (FEPs) for Geologic Disposal of Radioactive Waste: An International Database* (OECD 2000 [DIRS 152952], Appendix D) and then updated with FEPs from various other sources such as the 1999 system workshops. These tables were imported directly without editing and, therefore, reproduce typographical errors that were in the source. The source of each FEP in the "Source FEPs" table can be determined from the FEP identifier and format. The explanation is presented in Table F-1.

TSPA-LA FEP Number	TSPA-LA FEP Name	Source FEP No.	Source FEP Name
2.2.10.06.0A	Thermo-chemical alteration in the UZ (solubility, speciation, phase changes, precipitation/dissolution) (continued)	YSCP77	Precipitates from dissolved constituents of tuff and repository materials form by evaporation
		YSCP80	Heat-induced chemical reactions plug small fractures; flow is preferentially redirect to large fractures
		YSCP81	Calcite precipitation in hot region produces fluids depleted in calcite which dissolve calcite below the repository
2.2.10.07.0A	Thermo-chemical alteration of the Calico Hills unit	A 3.021	Chemical precipitation
		YM77	Thermo-chemical alteration of the Calico Hills unit SZ—Repository Induced Thermal Effects
2.2.10.08.0A	Thermo-chemical alteration in the SZ (solubility, speciation, phase changes, precipitation/dissolution)	A 3.021	Chemical precipitation
		H 2.3.12	Far-field transport: Thermal effects on hydrochemistry
		H 2.3.4	Far-field transport: Solubility constraints
		I 143	Groundwater (redirection of)
		I 233	Source term & solubility limits
		S 001	Alteration/weathering of flow paths
		S 060	Precipitation/dissolution
		S 092	Temperature, near-field rock
		YM51	Thermo chemical alteration of the saturated zone SZ—Repository Induced Thermal Effects
		YSCP17	Precipitation of zeolites in the saturated zone plug pores
2.2.10.09.0A	Thermo-chemical alteration of the Topopah Spring basal vitrophyre	A 3.021	Chemical precipitation
		I 143	Groundwater (redirection of)
		S 001	Alteration/weathering of flow paths
		YM109	Sorption of actinides on altered Topopah Spring basal vitrophyre
		YM203	Alteration of the Topopah Spring basal vitrophyre
		YM73	Thermo-chemical alteration of the Topopah Spring basal vitrophyre
		YM74	Formation of perched water on the altered Topopah Spring basal vitrophyre
		YM75	Sorption of contaminants by the altered Topopah Spring basal vitrophyre
		YM76	Redirection of transport paths by the altered Topopah Spring basal vitrophyre
2.2.10.10.0A	Two-phase buoyant flow/heat pipes	H 1.6.2	Thermal effects: Hydrogeological changes
		H 2.3.11	Far-field transport: Gas induced groundwater transport
		YM40	Two-phase buoyant flow / heat pipes

Table F-2. Cross Reference of TSPA-LA FEPs to Source FEPs (Continued)

TSPA-LA FEP Number	TSPA-LA FEP Name	Source FEP No.	Source FEP Name
2.2.10.10.0A	Two-phase buoyant flow/heat pipes (continued)	YM60	Resaturation of dry-out zone is affected by vapor flow
		YM62	Alteration of rock properties because of 2-phase flow
		YM64a	Heat pipe formation, 2-phase system
		YM91	Heat pipe -evolving
		YM92	Heat pipe -continuing
2.2.10.11.0A	Natural air flow in the UZ	YM41	Natural air flow in unsaturated zone
2.2.10.12.0A	Geosphere dry-out due to waste heat	I 300	Termperature effects (on transport)
		YM93	Geosphere dry-out due to waste heat
2.2.10.13.0A	Repository-induced thermal effects on flow in the SZ	H 1.6.2	Thermal effects: Hydrogeological changes
		I 143	Groundwater (redirection of)
		I 300	Termperature effects (on transport)
		J 4.2.04	Thermal buoyancy
		J 4.2.05	Changes in Groundwater Flow
		J 6.13	Geothermally induced flow .
		K 5.12	Density-driven groundwater flow (thermal)
		S 091	Temperature, far-field
		W 2.029	Thermal effects on material properties
2.2.10.14.0A	Mineralogic dehydration reactions	N 3.1.4	Induced hydrological changes (fluid pressure, density convection, viscosity)
		NRC NFE-1	Mineralogic dehydration reactions
2.2.11.01.0A	Gas effects in the SZ	A 2.44	Methane
		A 3.007	Bacteria and microbes in soil
		H 2.1.9	Effects of natural gases.
		H 2.3.11	Far-field transport: Gas induced groundwater transport
		I 015	Gas generation (CH4, CO2, H2)
		J 5.43	Methane intrusion
		K 5.24	Geogas
		K 6.24	Geogas
		N 1.2.13	Natural gas intrusion
		S 042	Gas flow and transport, near-field rock/far-field
		S 043	Gas generation and gas sources, far-field
		W 1.032	Natural gas intrusion
		W 2.025	Disruption due to gas effects
2.2.11.02.0A	Gas effects in the UZ	A 2.27	Gases and gas transport
		A 3.007	Bacteria and microbes in soil
		H 2.1.9	Effects of natural gases.
		I 015	Gas generation (CH4, CO2, H2)
		I 317	Unsaturated transport
		K 5.17	Gas pressure effects
		K 6.17	Gas pressure effects
		N 1.2.13	Natural gas intrusion

2.2.11.03.0A	Gas transport in geosphere	A 2.27	Gases and gas transport
		H 2.3.10	Far-field transport: Transport of radioactive gases
		H 2.3.11	Far-field transport: Gas induced groundwater transport
		H 4.1.3	Gas discharge
		K 4.11	Gas transport/dissolution
		N 1.6.4	Gas mediated transport
		S 042	Gas flow and transport, near-field rock/far-field
		S 098	Transport and release of nuclides, near-field rock
		W 2.089	Transport of radioactive gases
2.2.12.00.0A	Undetected features in the UZ	A 2.55	Rock properties - undetected features
		H 2.1.7	Faulting/fracturing
		J 6.01	Undetected fracture zones
		J 6.12	Undetected discontinuities
		N 1.2.12	Undetected features
		N 2.1.1	Undetected past intrusions
		S 064	Properties of far-field rock
		S 065	Properties of near-field rock
		YSCP19	Perched water escapes detection and waste is put in it
		YSCP20	Undetected fault dips below the repository providing a highly permeable flow path
		YSCP21	Undetected fault beneath the repository acts as a flow barrier altering the flow system
		YSCP22	Undetected fault connects tuff aquifers to carbonate aquifers; providing a fast path
		YSCP23	Undetected dike beneath the repository passing thru the Calico Hills provides a highly permeable flow path
		YSCP39	Undiscovered mine shaft (an old prospect hole) in a wash acts as a source for increased local infiltration

Table F-2. Cross Reference of TSPA-LA FEPs to Source FEPs (Continued)

TSPA-LA FEP Number	TSPA-LA FEP Name	Source FEP No.	Source FEP Name
2.2.12.00.0B	Undetected features in the SZ	H 2.1.7	Faulting/fracturing
		S 064	Properties of far-field rock
		S 065	Properties of near-field rock
		YSCP19	Perched water escapes detection and waste is put in it
		YSCP20	Undetected fault dips below the repository providing a highly permeable flow path
		YSCP21	Undetected fault beneath the repository acts as a flow barrier altering the flow system
		YSCP22	Undetected fault connects tuff aquifers to carbonate aquifers; providing a fast path
		YSCP23	Undetected dike beneath the repository passing thru the Calico Hills provides a highly permeable flow path
		YSCP39	Undiscovered mine shaft (an old prospect hole) in a wash acts as a source for increased local infiltration
2.2.14.09.0A	Far-field criticality	FFC-1	Far-field criticality, precipitation in organic reducing zone in or near water table
		FFC-2	Far-field criticality, sorption on clay/zeolite in TSbv
		FFC-3	Far-field criticality, precipitation caused by hydrothermal upwell or redox front in the SZ
		FFC-4	Far-field criticality, precipitation in perched water above TSbv
		FFC-5	Far-field criticality, precipitation in fractures of TSw rock
		FFC-6	Far-field criticality, dryout produces fissile salt in a perched water basin
		H 1.3.2	Nuclear criticality
		J 1.1.01	Criticality
		J 4.1.06	Reconcentration
		K 0.4	Nuclear criticality

N 2.2.6	Accidents during operation	1.1.12.01.0A	Accidents and unplanned events during construction and operation
N 2.2.7	Sabotage	1.4.02.01.0A	Deliberate human intrusion
N 2.2.8	Repository flooding during operation	1.1.02.01.0A	Site flooding (during construction and operation)
N 2.2.9	Abandonment of unsealed repository	1.1.04.01.0A	Incomplete closure
N 2.3	POST-CLOSURE SUB-SURFACE ACTIVITIES (INTRUSION)	1.4.02.01.0A	Deliberate human intrusion
N 2.3.1	Recovery of repository materials	1.4.02.01.0A	Deliberate human intrusion
N 2.3.10	Injection of liquid wastes	1.4.04.00.0A	Drilling activities (human intrusion)
N 2.3.11	Groundwater abstraction	1.4.07.02.0A	Wells
N 2.3.12	Underground nuclear testing	1.4.11.00.0A	Explosions and crashes (human activities)
N 2.3.2	Malicious intrusion	1.4.02.01.0A	Deliberate human intrusion
N 2.3.3	Exploratory drilling	1.4.04.00.0A	Drilling activities (human intrusion)
N 2.3.4	Exploitation drilling	1.4.04.00.0A	Drilling activities (human intrusion)
N 2.3.5	Geothermal energy production	1.4.04.00.0A	Drilling activities (human intrusion)
N 2.3.6	Resource mining	1.4.05.00.0A	Mining and other underground activities (human intrusion)
N 2.3.7	Tunnelling	1.4.05.00.0A	Mining and other underground activities (human intrusion)
N 2.3.8	Underground construction	1.4.05.00.0A	Mining and other underground activities (human intrusion)
N 2.3.9	Archaeological investigation	1.4.02.01.0A	Deliberate human intrusion
N 2.4	POST-CLOSURE SURFACE ACTIVITIES	2.4.10.00.0A	Urban and industrial land and water use
